26 Level of Care

Before the 1960s in the United States, most psychiatric care for serious mental illnesses took place in hospitals. The rest was individual therapy with a psychiatrist or psychologist or other highly trained professionals; this treatment was reserved mainly for patients considered “neurotic” and having the means to pay for hourly sessions that would often occur several days a week.

Several forces changed this. The community mental health movement was motivated by social justice, occurring at a time defined by the civil rights movement. Experts argued that the housing of seriously mentally ill patients in a public hospital was unjust. The treatment there emphasized long-term custodial care rather than rehabilitation, and few patients improved. Visionaries such as Walter Barton, then medical director for the American Psychiatric Association, argued that the federal government must lead the way to develop alternatives to the current system of institutionalization. The result was The Mental Retardation Facilities and Community Mental Health Centers Construction Act of 1963, championed by President Kennedy, who proposed a “wholly new emphasis and approach to care for the mentally ill.”

The act and the amendments that followed it under President Johnson initiated the federal government’s role in mental health care, something previously left to the states. It established a grant program for states to establish local mental health centers, under the overview of the National Institutes of Health. The purpose was to build a robust network of mental health centers for community-based care as an alternative to long-term institutionalization.

Only about half of the proposed centers were built, and funding for these sites has been chronically inadequate. Thus, the movement was more

successful at deinstitutionalizing mental health care than it has been at offering quality alternatives. Part of the reason for this is another crucial force in the US health care system, the rise of managed care. Managed care emphasizes seeking the lowest level of care possible and the use of lower-cost professionals as a way of saving money.

The result is that we now have a myriad of treatment settings, services, and options. Most rely on grants and third-party payers, although some require considerable patient expenditures. The details and terminology differ by institution and region. However, they roughly fall into several categories. In this chapter, we briefly describe these options as well as the requirements and goals for each treatment. Our purpose is to help the reader navigate these options with an emphasis on choosing the treatment that is best for the patient. Although analogous services exist for children and adolescents, this chapter focuses on adult levels of care.

Table 26-1 summarizes the main levels of care that we should consider for most psychiatric patients.

INPATIENT ADMISSION

Inpatient admission units are usually specializing in intensive psychiatric care. The patients may voluntarily agree to hospitalization, or clinicians may hospitalize them against their will in a manner consistent with state law. The units are usually locked and equipped to restrain or seclude patients when required. Nurses and other staff are present around the clock. Physicians are present on the unit at least 5 days a week, and a covering physician is always available.

The hospitalization allows an intense treatment, with regular observation throughout a day and robust treatments, including medical adjustments, group, and individual psychotherapies, case management, and milieu treatments. Previously the most common form of psychiatric care, inpatient hospitalization is now reserved for patients who are unsafe in or unlikely to benefit from other treatments.

The patient’s risk of illness or severity is usually high. Many patients are hospitalized because they are at high risk of imminently harming themselves or others. Alternatively, their disorder may be so impairing that they cannot function adequately outside the hospital or attend to even basic activities of

daily living (ADLs).

Usually, the treatments required are ones that clinicians cannot safely or practically give in other settings. These include treatments that require daily observation for serious side effects. They may be given with such frequency, such as some intense psychotherapies, that other settings are not practical. In the latter case, the clinicians have often already tried other settings and have decided that the patient is likely to deteriorate should they continue the attempts to treat the patient in another setting.

In some cases, the practicality of alternative treatments arises from a patient's poor insight or inability to cooperate with treatment. Such patients may require involuntary hospitalization, and an inpatient unit is the only setting that would be appropriate to hold them against their will until the treatment allows them an ability to make their ordinary appropriate judgments. In the most severe cases, staff may have to restrain a violent or self-harming patient physically.

Except for some specialized care facilities, the goals of treatment are short term. Treatments aim to manage the crisis and stabilize the patient to the point that treatment can continue in a less restrictive setting for the patient. Crisis interventions, intense and frequent therapy, and medications are usual treatments. Longer-term treatments may begin in this setting, but usually to continue the treatments following the hospitalization.

The length of stay varies widely. A 2010 Centers for Disease Control and Prevention (CDC) survey reported the average length of stay for patients with schizophrenia as about 7.2 days, and for major depressive disorder, about 10.6 days. This number varies significantly by regional practice. Internationally, it varies by health care system, economic resources, and many other factors. Figure 26-1 gives some example comparisons of the average lengths of stay in 2010 for various countries.

The goal of treatment is to return the patient to a safe and functional state so that the team can then transition the patient to a lower level of care. This goal includes reducing the patient's threat to themselves or others, decreasing the symptoms of the disorder, and improving the patient's functional level.

Table 26-1
Main Levels of Care

	Inpatient Hospitalization	Partial Hospital	Intensive Outpatient Treatment	Outpatient	Residential Care
Risk	High: risk of imminent danger to self/others	Moderate but not imminent risk	No imminent risk	Low risk of harm	Moderate risk
Disease severity	Severe symptoms	Moderate	Moderate	Mild to moderate	Moderately severe
Functioning, activities of daily living (ADLs)	Poor, cannot attend to basic ADLs without assistance	Moderate dysfunction	Mild to moderate dysfunction	Adequate to attend to ADLs independently or with some assistance	Severe
Treatments	Require around-the-clock administration, regular observation for side effects or adjustment, or are given at a frequency making other settings impractical	Fully staffed unit offering a range of services similar to inpatient, however, limited to the working day and given daily, usually 5 days a week	May vary from several times a week to weekly or monthly, depending on the level of severity and treatment. Includes both psychotherapies and medications	May vary from several times a week to weekly or monthly, depending on the level of severity and treatment. Includes both psychotherapies and medications	Psychosocial treatments and medication management, although not necessarily at the level of an inpatient unit
Patient cooperation	Voluntary or involuntary	Voluntary	Voluntary	Voluntary	Voluntary or court-ordered
Need for restraints	May need restraining for safety purposes to prevent violence or injury	None	None	None	None
Goals of treatment	Reduce safety concern, reduce symptoms, restore functioning	Improvements in symptoms and functioning to transition the patient to a less restrictive treatment	Achieve and maintain the usual premorbid level of functioning	Achieve and maintain the usual premorbid level of functioning	Improvement in symptoms and functioning to a level where the patient can live in a less restrictive setting

Discharge planning usually begins on day one of the hospitalization. It helps to identify early on the likely next step in treatment, should it be back home, to a transitional setting or, less often, to long-term custodial care.

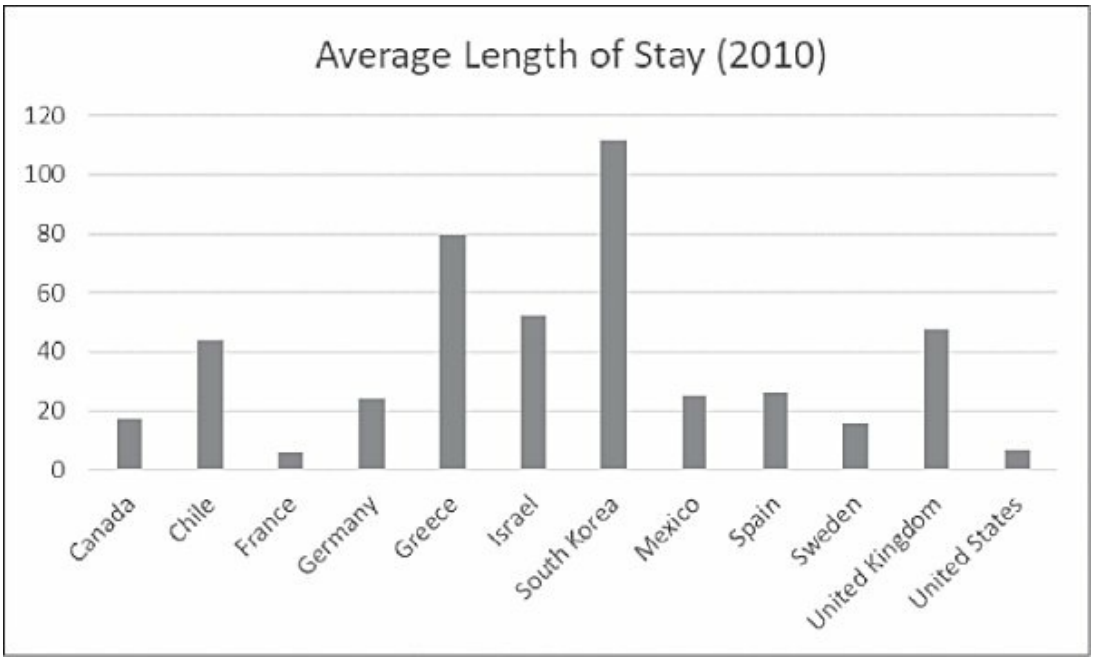

FIGURE 26-1

Average lengths of stay (LOS) for mental health disorders for selected countries in 2010. (Source: Organisation for Economic Co-Operation and Development [OECD.Stat].)

PARTIAL HOSPITAL TREATMENT

Partial hospitals are facilities that provide a near hospital level of care, the exception being that the care takes place for about 6 to 8 hours a day, after which the patients can go home. The service is fully staffed in a manner typical to a psychiatric hospital unit, however only during the day. The units usually offer a full range of treatment from various psychotherapies and psychosocial options to medication management. The patient usually attends daily, for 5 days a week.

Appropriate patients for a partial hospital program include patients who may be at significant risk for harm to themselves or others. However, the treatment team assesses that the patient is sufficiently stable such that the reinforcement of the intensive treatment is sufficient to prevent such harm. Thus, the patient is not an imminent risk or is not too impulsive to be trusted to be independent during the evening.

The patients are usually of moderate severity in symptoms. Similarly, they often have moderate dysfunction such that their self-care may be substandard. They often have ongoing trouble maintaining normal relationships.

The program usually offers a variety of psychotherapy treatments, often in a group setting. They have the benefit of milieu therapy in the unit environment. Case management is also available. Psychiatrists are present and help manage the patient's medication and overall treatment plan.

The average length of treatment is from 1 to a few weeks, although in some cases it may be longer. The treatment should continue until the patient is sufficiently stable for a less intensive mode of treatment.

INTENSIVE OUTPATIENT TREATMENT

Intensive outpatient treatment (IOP) is a treatment in the outpatient setting that involves 3 to 4 hours of psychosocial treatment for between 1 and 4 days of treatment, with an average of 6 to 12 hours of treatment per week.

This care is usually appropriate when the level of danger is sufficiently stable so as not to be at imminent risk of harming themselves or others.

Patients usually have moderate symptoms and mild to moderate functioning. For example, their self-care may be mildly below what we would expect for them. However, they should be sufficiently functional to be able to live independently or with assistance from a caregiver.

Although sufficiently stable to live independently, the psychiatrist should be sure that the patient's home environment is sufficiently safe and without illness triggers to allow for improvement with treatment.

The treatments emphasize a group format but often include some individual psychotherapy treatments or medication management. Psychotherapies may include cognitive behavioral therapy, interpersonal therapy, or other therapies in a group format.

The length of treatment varies widely and depends on the illness, but usually lasts 1 to several weeks. The goal is to address the patient's symptoms sufficiently that a less intensive model of care is feasible.

OUTPATIENT CARE

Outpatient care is pharmacologic or psychosocial management, provided by a health care professional, usually in an office setting.

This care is usually appropriate when the danger to the patient is considered reasonably low risk. Patients need not be free of all thoughts of harm to themselves or others; however, this risk should be low, and the clinician should have a reasonable belief that the patient can warn them should their situation worsen.

Also, the patient's disorder should be likely to improve with outpatient care. This situation, fortunately, includes most psychiatric disorders. The modes of treatment may include psychotherapy or medication or a combination of both.

Patients are voluntary and require some level of motivation for their treatment, sufficient so that they can show up regularly for their appointments. At times of symptomatic worsening, family members or other caretakers may assist with providing some external motivation until the patient can resume on their own.

The length of treatment varies widely depending on the disorder. The frequency of treatment also varies. In the case of an acute illness, such as an episode of major depressive disorder, a manic episode, or a worsening of

anxiety, the treatment may occur weekly or more frequently. Generally, the frequency of treatment will decrease as the patient improves, but as many disorders are chronic, patients often require ongoing medication or therapy to maintain remission. For patients who have been stable for an extended time, twice a year follow-ups may be reasonable. However, the clinician should work out with the patient a plan for increasing the follow-ups when necessary, as it less likely the clinician will catch a pending recurrence of the illness early.

RESIDENTIAL CARE

Residential care is a 24-hour facility that offers a level of treatment less intensive than traditional inpatient treatment. It generally does not have the level of security typical of an inpatient unit. Although medical and nursing staff are available, the units do not have the same level of staffing, and the treatments are not as frequent as an inpatient unit.

Patients may be at some risk of harming themselves or others, but not at imminent risk and thus not requiring the level of observation or restraint available in an inpatient unit. Their symptoms are moderately severe, as they can have severe functional limitations such that they cannot safely live independently. The patients are usually voluntary, although they may be court-ordered for treatment; however, in those cases, they are willfully participating. The units are usually not locked.

The facilities offer a variety of treatments, often in a group setting. The units differ from long-term rehabilitation units, such as nursing homes, in that the goals are improvement in symptoms and functioning and return to a lower level of care.

C Other Issues Relevant to Psychiatry

27 Ethics and Professionalism

Ethical guidelines and knowledge of ethical principles help psychiatrists avoid *ethical conflicts* (which are tensions between what one wants to do and what is ethically right to do) and think through *ethical dilemmas* (conflicts between ethical perspectives or values).

Ethics deal with the relations between people in different groups and often entail balancing rights. *Professional ethics* refers to the appropriate way to act when in a professional role. Professional ethics derive from a combination of morality, social norms, and the parameters of the relationship people have agreed to have.

PROFESSIONAL CODES

Most professional organizations and many business groups have codes of ethics that reflect a consensus about the general standards of appropriate professional conduct. The American Medical Association's (AMA's) *Principles of Medical Ethics* and the American Psychiatric Association's (APA's) *Principles of Medical Ethics with Annotations Especially Applicable to Psychiatry* articulate ideal standards of practice and professional virtues of practitioners. These codes include exhortations to use skillful and scientific techniques; to self-regulate misconduct within the profession; and to respect the rights and needs of patients, families, colleagues, and society.

BASIC ETHICAL PRINCIPLES

Four ethical principles that psychiatrists ought to weigh in their work are respect for autonomy, beneficence, nonmaleficence, and justice. At times, the principles conflict, and we must make decisions concerning how to balance

them.

Respect for Autonomy

Autonomy requires that a person act intentionally after being given sufficient information and time to understand the benefits, risks, and costs of all reasonable options. It may mean honoring an individual's right not to hear every detail and even choosing someone else (e.g., family or doctor) to decide the best course of treatment.

Psychiatrists need to provide patients with a rational understanding of their disorder and options for treatment. Patients need conceptual understanding; the psychiatrist should not merely state isolated facts. Patients also need time to think and to talk with friends and family about their decision. Finally, if a patient is not in a state of mind to make decisions for himself or herself, the psychiatrist should consider mechanisms for alternative decision-making, such as guardianship, conservators, and health care proxy.

A young adult experienced a schizophrenic episode in which his religious fervor turned into psychotic delusions. After being involuntarily hospitalized because he became suicidal, he insistently refused medication, claiming that his physicians were trying to poison him. His psychiatrist decided to respect his refusal of medication as long as he could control his suicidal tendencies. As his mental suffering became more intense, in 1 week, the patient changed his mind about medication and agreed to try it. The therapeutic relationship with his psychiatrist deepened, and the patient left the hospital willing to continue with both antipsychotic medication and psychotherapy. Although not all cases work out so well, this one illustrates the benefits of negotiation about treatment even when hospitalization is involuntary.

Beneficence

The requirement for psychiatrists to act with beneficence derives from their fiduciary relationship with patients and the profession's belief that they also have an obligation to the society. As a result of the role obligation of trust, psychiatrists must heed their patients' interests, even to the neglect of their

own.

The expression of the principle is called *paternalism*, the use of the psychiatrist's judgment about the best course of action for the patient or research subject. *Weak paternalism* is acting beneficently when the patient's impaired faculties prevent an autonomous choice. *Strong paternalism* is acting beneficently despite the patient's intact autonomy.

There are times when it is appropriate to permit beneficence to overrule patient autonomy. For example, when the patient faces substantial harm or risk of harm, we would choose the paternalistic act to ensure the optimal combination of maximal harm reduction, low added risk, and minimal necessary infringement on patient autonomy.

Nonmaleficence

To adhere to the principle of nonmaleficence (*primum non nocere* or *first, do no harm*), psychiatrists must be careful in their decisions and actions and must ensure that they have had adequate training for what they do. They also need to be open to seeking second opinions and consultations. They need to avoid creating risks for patients by an action or inaction.

Justice

The concept of justice concerns the issues of reward and punishment and the equitable distribution of social benefits. Relevant issues include whether resources should be distributed equally to those in greatest need, whether they should go to where they can have the most significant impact on the well-being of each individual served, or to where they will ultimately have the highest impact on society.

SPECIFIC ISSUES

From a practical point of view, several specific issues most frequently involve psychiatrists. These include (1) sexual boundary violations, (2) nonsexual boundary violations, (3) violations of confidentiality, (4) mistreatment of the patient (incompetence, double agentry), and (5) illegal activities (insurance, billing, insider stock trading).

Sexual Boundary Violations

For a psychiatrist to engage a patient in a sexual relationship is unethical. Furthermore, legal sanctions against such behavior make the ethical question moot. Psychiatrists who violate this ethical principle are subject to various criminal law statutes. Rape charges have been used against such psychiatrists; sexual assault and battery charges also have been used to convict psychiatrists.

Also, patients who have been victimized sexually by psychiatrists and other physicians have won damages in malpractice suits. Insurance carriers for the APA and the AMA no longer insure against patient–therapist sexual relations, and the carriers exclude liability for any such sexual activity.

The issue of whether sexual relations between an ex-patient and a therapist violate an ethical principle, however, remains controversial. Proponents of the view that "Once a patient, always a patient," insist that any involvement with an ex-patient—even if it leads to marriage—is unethical. They maintain that a transferential reaction that always exists between the patient and the therapist prevents a rational decision about their emotional or sexual union. Others insist that, if a transferential reaction still exists, the therapy is incomplete and that as autonomous human beings, ex-patients should not be subjected to paternalistic moralizing by physicians. Accordingly, they believe that no sanctions should prohibit emotional or sexual involvement by ex-patients and their psychiatrists. Some psychiatrists maintain that a reasonable time should elapse before such a liaison. The length of the "reasonable" period remains controversial: some have suggested 2 years. Other psychiatrists maintain that any period of prohibited involvement with an ex-patient is an unnecessary restriction. The majority of psychiatrists, as well as the APA, believe that it is always unethical, and their code of ethics states: "Sexual activity with a current or *former* patient is unethical."

Although not spelled out in *The Principles*, sexual activity with a patient's family member is also unethical. This principle is most important when the psychiatrist is treating a child or adolescent. Most training programs in child and adolescent psychiatry emphasize that the parents are patients too and that the ethical and legal proscriptions apply to parents (or parent surrogates) as well as to the child. Nevertheless, some psychiatrists misunderstand this concept. Sexual activity between a doctor and a patient's family member is also unethical.

As an example of an egregious violation, the *Medical Board of California*

Action Report (July 2006) reported on a psychiatrist who had a 7-year affair with a patient who had schizophrenia. The doctor not only had sex with the patient but also had her procure prostitutes with whom he and the patient had group sex. He paid for their services by providing them with prescriptions for controlled substances and went so far as to bill Medi-Cal for these encounters as group therapy. The state revoked the physician's license, and he was also criminally convicted of fraud.

Nonsexual Boundary Violations

The *doctor–patient relationship* is the relationship between a doctor and a patient to provide and obtain treatment. That relationship has boundaries both around it and within it. Either person may cross the boundary.

Not all boundary-crossings are boundary violations. For example, a patient may say to a doctor, "I left my money at home, can you lend me cash for the parking garage?" The patient has invited the doctor to cross the doctor–patient boundary and set up a lender–borrower relationship as well. Depending on the doctor's theoretical orientation, the clinical situation with the patient, and other factors, the doctor may elect to cross the boundary. Whether the boundary-crossing is also a boundary violation is debatable. A *boundary violation* is a boundary-crossing that is exploitative. It gratifies the doctor's needs at the expense of the patient. The doctor is responsible for preserving the boundary and for ensuring that they hold boundary-crossings to a minimum and that exploitation does not occur.

A supervisor told a psychiatry resident never to accept gifts from patients. In the course of treating a young girl with schizophrenia, the patient offered her a modest Christmas gift (a cotton scarf), which she refused to accept. The resident explained, gently, that this was against the "rules of the hospital." The next day the patient attempted suicide. She experienced the resident's refusal to accept the gift as a profound rejection, which she could not tolerate. The case illustrates the need to understand the dynamics of gift-giving and the transferential meaning to the patients of rejecting (or accepting) the gift.

There is a story (possibly apocryphal) of how Freud, who was an inveterate cigar smoker, was offered a box of difficult-to-find Havana

cigars by a patient during his analysis. Freud accepted the cigars and then proceeded to ask his patient to explore his motivations in offering the gift. Freud's reasons for accepting the cigars are more evident than the patient's unconscious motivation for giving them, about which no information is available.

Harm to the patient is not a component of a boundary violation. For example, using information supplied by the patient (e.g., a stock tip) is an unethical boundary violation, although no apparent harm may come to the patient. For purposes of discussion, nonsexual boundary violations come in several arbitrary (overlapping and not mutually exclusive) categories.

Business. Almost any business relationship with a former patient is problematic, and almost any business relationship with a current patient is unethical. Naturally, the circumstance and location may play a significant role in this admonition. In a rural area or a small community, a doctor might be treating the only pharmacist (or plumber or couch upholsterer) in town; then, when doing business with the pharmacist-patient, the doctor tries to keep boundaries in check. Ethical psychiatrists try to avoid doing business with a patient or a patient's family member or asking a patient to hire one of their family members. Ethical psychiatrists avoid investing in a patient's business and collaborating with a patient in a business deal.

Ideologic Issues. Ideologic issues can cloud judgment and may lead to ethical lapses. Any clinical decision should reflect what is best for the patient; the psychiatrist's ideology should not be a factor in the decision. A psychiatrist who is consulted by a patient with an illness should tell the patient what forms of treatment are available to treat the illness and allow the patient to decide on a course of treatment. Naturally, psychiatrists should recommend the treatment that they feel is in the best interest of the patient, but ultimately, the patient should be free to choose.

Social. We should consider the particular locale and circumstances in any discussion of the behavior of an ethical psychiatrist in social situations. The overarching principle is that the boundaries of the psychiatrist–patient relationship should be respected. Furthermore, if options exist, they should be

exercised in favor of the patient. Problems often arise in treatment situations when friendships develop between the psychiatrist and the patient. Objectivity is compromised, therapeutic neutrality is impaired, and factors outside the consciousness of either party may play a destructive role. During treatment, the psychiatrist should avoid such a friendship. Similarly, psychiatrists should not treat their social friends for the same set of reasons. Obviously, in an emergency, a person does what a person must.

Financial. For psychiatrists who practice in the private sector, dealing with the patient about money is a part of treatment. Issues surrounding setting the fee, collecting the fee, and other financial matters are grist for the mill. Even so, they must observe ethical concerns. *The Principles* advises the doctor on such matters as charging for missed appointments and other contractual problems. Financial issues are a frequent source of ethics complaints against doctors. The doctor must recognize the power that these issues have in the therapeutic relationship. Because the psychotherapeutic relationship is so much like a social relationship—the office looks like a living room; the doctor wears regular clothes; some patients might, without recognizing it, assume that a friendship exists that forgives payment of a fee. When they receive the bill, their feelings, even though they are unconscious, are ruffled. We cannot sufficiently emphasize the point that psychiatrists dispense their services in a contractual context. Early in their careers, psychiatrists are often reluctant to discuss fees openly out of a sense of embarrassment over discussing money or a sense of protecting the patient.

How an ethical psychiatrist handles the situation when a patient temporarily or permanently runs out of money is essential. Many options are available—some more problematic than others. The psychiatrist can undoubtedly lower the fee, but caution is needed because a fee lowered to the point of inadequate compensation for the treatment may evoke countertransference resentment. The number of patients receiving a reduced fee is a similar consideration. Running up a bill can also be a problem. Is there an expectation of eventually being paid? Ultimately, the psychiatrist may have to alter the frequency of sessions. Any psychiatrist who sees private patients will eventually face these problems.

Confidentiality

Confidentiality refers to the therapist's responsibility not to release information learned in the course of treatment to third parties. *Privilege* refers to the patient's right to prevent disclosure of information from treatment in judicial hearings. Psychiatrists must maintain confidentiality because it is an essential ingredient of psychiatric care; it is a prerequisite for patients to be willing to speak freely to therapists. Violating confidentiality by gossiping embarrasses people and violates nonmaleficence. Violation of confidentiality also breaks the promise that a psychiatrist has explicitly or implicitly made to keep material confidential.

Confidentiality must also give way to the responsibility to protect others when a patient makes a credible threat to harm someone. The situation becomes complicated when the risk is not to a particular individual, such as when a doctor is impaired, or someone's mental state adversely affects his or her performance of a dangerous job, such as police work, firefighting, or use of dangerous machinery. Erosion has also arisen from the demands of an insurance company for detailed information. Psychiatrists should tell patients if they are going to release their information, under what circumstances, and when they do. They are not required to warn a patient when they report the abuse of a child or a threat to others.

There are various settings in which we may use patient data ethically. The general rule for doing so is to disclose only that information that is truly necessary. In teaching, research, and supervision, we should avoid using personal information that might allow others to identify a patient unless it is necessary. In ward rounds and case conferences, in which one presents patient material, we should remind those present that what they hear should not be repeated.

Confidentiality endures after death, with the ethical obligation to withhold information unless the next of kin provides consent. A subpoena is not an automatic license to release the entire record. A psychiatrist can petition the judge for an in-camera (private) review to define what precise information they must disclose.

Ethics in Managed Care

Psychiatrists have specific responsibilities toward patients treated in managed care settings, including the responsibilities to disclose all treatment options,

exercise appeal rights, continue emergency treatment, and cooperate reasonably with utilization reviewers.

Responsibility to Disclose. Psychiatrists have a continuing responsibility to the patient to obtain informed consent for treatments or procedures. The psychiatrist should disclose all the treatment options, even those not covered under the terms of a managed care plan. Most states have enacted legislation making gag rules illegal that limit information about treatment provided to patients under managed care.

Responsibility to Appeal. The AMA Council on Ethical and Judicial Affairs states that physicians have an ethical obligation to advocate for any care that they believe will materially benefit their patients, regardless of any allocation guidelines or gatekeeper directives.

Responsibility to Treat. Physicians are liable for failure to treat their patients within the defined standard of care. The treating physician has the sole responsibility to determine what is medically necessary. Psychiatrists must be careful not to discharge suicidal or violent patients prematurely merely because a managed care company does not approve continued coverage of benefits.

Responsibility to Cooperate with Utilization Review. The psychiatrist should cooperate with utilization reviewers' requests for information on proper authorization from the patient. When the company denies benefits, it is crucial to understand and follow grievance procedures carefully, return telephone calls from review agencies, and provide documented justification for continued treatment.

With the advent of managed care and the need to send periodic progress reports and documentation of signs and symptoms to third-party reviewers to pay for treatment, some psychiatrists may diminish or exaggerate symptomatology. The following case report and discussion illustrate the ethical difficulties psychiatrists face in dealing with managed care.

Mrs. P admitted herself to the hospital because she was afraid she might kill herself. She was experiencing a major depressive episode, but she

improved markedly during the first weeks in Dr. A's ward. Although Dr. A believed that Mrs. P was no longer suicidal, he thought she would benefit significantly from continued hospitalization. Because he knew that Mrs. P could not afford to pay for hospitalization and that the insurance company would only pay if the patient were suicidally depressed, he decided not to document Mrs. P's improvement. He noted in the chart that "the patient continues to have a risk of suicide."

Does Dr. A engage in deception? Yes, he intentionally misleads by what he writes and what he omits writing in the chart. Although what he writes is true in some literal sense, his statement is misleading in the context of treatment. Mrs. P is not suicidally depressed in the way that she was.

What Dr. A omits from the chart is also deceptive. Whether a particular omission is deceptive depends, in part, on the roles and expectations of the people involved. Not telling a colleague that one dislikes his tie is not a deception. It is merely polite unless the role or relationship involves the expectation that one offers a candid opinion. Dr. A's case is different. His professional role is to document the patient's course, and the expectation is that he will note any significant improvement. Thus, his failure to document Mrs. P's progress accurately is a kind of deception.

The second and more difficult question is whether deception is justified in this instance. The answer depends on the reasons for and against the deception and the alternatives available. The reasons for this deception are apparent. Dr. A's aim and primary obligation are to help the patient. He believes that Mrs. P would benefit significantly from continued hospitalization that she cannot afford. He may also believe that it is unfair for the insurance company to refuse to pay for the inpatient treatment of nonsuicidal depression and that his deception rectifies that unfair practice.

Important reasons also exist against this deception. The first concerns honesty and social trust. It is a good thing if people can rely on what others say and write. Without some honesty and trust, many social exchanges and practices would be impossible. Deception, even for beneficent purposes, has real potential to damage social trust. A risk exists that deception may damage people's trust in the profession of

psychiatry and even patients' trust in their psychiatrists. Damage to trust may, in turn, compromise treatment.

The second reason concerns future medical treatment. If Mrs. P seeks medical treatment in the future, the physicians who attend her will read the misleading notes. If they believe that the notes are an accurate account of the previous treatment, they may suggest an inappropriate treatment for the present problem. Even if they doubt the record's accuracy, the psychiatrist has deprived their colleagues of an accurate history and report. In either case, the prior deception can hinder treatment.

The third reason concerns obligations and coverage policies. Dr. A seems to ignore the obligation that he has to the population that is covered by the insurance policy. He shifts a burden onto this population by forcing the insurance company to pay for treatment that it did not agree to cover. Perhaps the insurance company should pay for inpatient treatment in cases such as Mrs. P's; perhaps its policies are unreasonable and unfair. However, Dr. A's deception does not challenge the insurance company and pressure it to change its policy, nor does his deception encourage patients and their families to contest the company's policies. The use of deception simply circumvents, in an ad hoc way, a policy that should be challenged and discussed.

Dr. A also seems to ignore his obligation to future patients. By introducing an inaccuracy into the chart, he compromises the value of medical records research. His deception works, in a small way, to deprive future patients of the benefit of the research that relies on medical records.

One should also consider alternatives to deception. One alternative is to tailor the chart. Another alternative is to describe Mrs. P's response accurately and to discharge her to outpatient care. However, a third alternative exists. Dr. A can accurately document the patient's course and can recommend continued hospitalization. He can petition the insurance company for coverage. If the insurance company decides not to approve further inpatient care for the patient, Dr. A can appeal that decision. This alternative is more time consuming, and nothing guarantees that it will succeed, but it avoids all the problems associated with the use of deception.

Impaired Physicians

A physician may become impaired as the result of psychiatric or medical disorders or the use of mind-altering and habit-forming substances (e.g., alcohol and drugs). Many illnesses can interfere with the cognitive and motor skills required to provide competent medical care. Although the legal responsibility to report an impaired physician varies, depending on the state, the ethical responsibility remains universal. We should report an incapacitated physician to an appropriate authority, and the reporting physician is required to follow the specific hospital, state, and legal procedures. A physician who treats an impaired physician should not be required to monitor the impaired physician's progress or fitness to return to work. An independent physician or group of physicians who have no conflicts of interest should perform the monitoring.

Most states have a division that investigates professional misconduct, usually overseen by their board of health. The definitions of professional misconduct differ by state but invariably include practicing while impaired. Professional misconduct complaints derive mainly from the public in addition to insurance companies, law enforcement agencies, and doctors, among others. Many states also have a physician health committee, often independent of the disciplinary board, which helps to ensure that impaired physicians receive appropriate treatment and monitoring.

Physicians in Training

It is unethical to delegate authority for patient care to anyone who is not appropriately qualified and experienced, such as a medical student or a resident, without adequate supervision from an attending physician. Residents are physicians in training and, as such, must provide a good deal of patient care. Within a healthy, ethical teaching environment, residents and medical students may care for many ill patients. However, this care should be supervised and supported by highly trained and experienced physicians. Patients have the right to know the level of training of their care providers and should be informed about the resident's or medical student's level of training. Residents and medical students should know and acknowledge their

limitations and should ask for supervision from experienced colleagues as necessary.

Physician Charter on Professionalism

In 2001, a movement to clarify the concept of "professionalism" was begun by the American Board of Internal Medicine. A set of principles called the *Physician Charter on Professionalism* was developed, which describes what it means for physicians to perform at their highest and most ethical level. Table 27-1 lists the principles and commitments of professional behaviors in the *Physician Charter on Professionalism* to which all physicians (including psychiatrists) should adhere.

Table 27-2 considers some common ethical questions that psychiatrists may face.

Table 27-1
Physician Charter on Professionalism

Fundamental Principles

- **Primacy of patient welfare**. Altruism contributes to the trust central to doctor–patient relationships. Market forces, societal pressures, and administrative exigencies must not compromise this principle.
- **Patient autonomy**. Physicians must be honest with patients and empower them to make informed decisions about treatment.
- **Social justice**. Physicians should work actively to eliminate discrimination in health care, whether based on race, gender, socioeconomic status, ethnicity, religion, or any other social category.

A Set of Commitments

- **Professional competence**. Physicians must be committed to lifelong learning. The profession as a whole must strive to see that all of its members are competent.
- **Honesty with patients**. Physicians must ensure that patients are completely and honestly informed before consenting to a treatment; they must be empowered to decide about the course

of therapy. Physicians should also acknowledge that medical errors that injure patients sometimes occur. If a patient is injured through error, he or she should be informed promptly because failure to do so seriously compromises patient and societal trust.

- **Patient confidentiality**. Fulfilling the commitment to confidentiality is more pressing now than ever before given the widespread use of electronic information systems for compiling patient data.
- **Maintaining appropriate relations with patients**. Physicians should never exploit patients for any sexual advantage, personal financial gain, or other private purpose.
- **Improving quality of care**. This commitment entails both maintaining clinical competence and working collaboratively with other professionals to reduce medical error, increase patient safety, minimize overuse of health care resources, and optimize the outcomes of care.
- **Improving access to care**. Physicians must individually and collectively strive to reduce barriers to equitable health care.
- **Just distribution of finite resources**. Physicians should be committed to working with other physicians, hospitals, and payers to develop guidelines for cost-effective care. The physician's professional responsibility for appropriate allocation of resources requires scrupulous avoidance of superfluous tests and procedures.
- **Scientific knowledge**. Physicians have a duty to uphold scientific standards, to promote research, and to create new knowledge and ensure its appropriate use.
- **Maintaining trust by managing conflicts of interest**. Physicians have an obligation to recognize, disclose to the general public, and address conflicts of interest. Relationships between industry and opinion leaders should be disclosed.
- **Professional responsibilities**. Physicians are expected to participate in the process of self-regulation, including remediation and discipline of members who have failed to meet professional standards.

Table 27-2
Ethical Questions and Answers

Topic	Question	Answer
Abandonment	How can psychiatrists avoid being charged with patient abandonment on retirement?	Retiring psychiatrists are not abandoning patients if they provide their patients with sufficient notice and make every reasonable effort to find follow-up care for the patients.
	Is it ethical to provide only outpatient care to a seriously ill patient who may require hospitalization?	This could constitute abandonment unless the outpatient practitioner or agency arranges for their patients to receive inpatient care from another provider.
Bequests	A dying patient bequeaths his or her estate to his or her treating psychiatrist. Is this ethical?	No. Accepting the bequest seems improper and exploitational of the therapeutic relationship. However, it may be ethical to accept a token bequest from a deceased patient who named his or her psychiatrist in the will without that psychiatrist's knowledge.
Competency	Is it ethical for psychiatrists to perform vaginal examinations? Hospital physical examinations?	Psychiatrists may provide nonpsychiatric medical procedures if they are competent to do so and if the procedures do not preclude effective psychiatric

		treatment by distorting the transference. Pelvic examinations carry a high risk of distorting the transference and would be better performed by another clinician.
	Can ethics committees review issues of physician competency?	Yes. Incompetency is an ethical issue.
Confidentiality	Must confidentiality be maintained after the death of a patient?	Yes. Ethically, confidences survive a patient's death. Exceptions include protecting others from imminent harm or proper legal compulsions.
	Is it ethical to release information about a patient to an insurance company?	Yes, if the information provided is limited to that which is needed to process the insurance claim.
	Can a videotaped segment of a therapy session be used at a workshop for professionals?	Yes, if informed, uncoerced consent has been obtained, anonymity is maintained, the audience is advised that editing makes this an incomplete session, and the patient knows the purpose of the videotape.
	Should a physician report mere	No. A physician must make several assessments before

	suspicion of child abuse in a state requiring reporting of child abuse?	deciding whether to report suspected abuse. One must consider whether abuse is ongoing, whether abuse is responsive to treatment, and whether reporting will cause potential harm. Check specific statutes. Make safety for potential victims the top priority.
Conflict of interest	Is there a potential ethical conflict if a psychiatrist has both psychotherapeutic and administrative duties in dealing with students or trainees?	Yes. You must define your role in advance to the trainees or students. Administrative opinions should be obtained from a psychiatrist who is not involved in a treatment relationship with the trainee or student.
Diagnosis without examination	Is it ethical to offer a diagnosis based only on review of records to determine, for insurance purposes, if suicide was the result of illness?	Yes.
	Is it ethical for a supervising psychiatrist to sign a diagnosis on an insurance form for services	Yes, if the psychiatrist ensures that proper care is given and the insurance form clearly indicates the role of supervisor and supervisee.

	provided by a supervisee when the psychiatrist has not examined the patient?	
Exploitation (also see Bequests)	What constitutes exploitation of the therapeutic relationship?	Exploitation occurs when the psychiatrist uses the therapeutic relationship for personal gain. This includes adopting or hiring a patient as well as sexual or financial relationships.
Fee splitting	What is fee splitting?	Fee splitting occurs when one physician pays another for a patient referral. This would also apply to lawyers giving a forensic psychiatrist referrals in exchange for a percentage of the fee. Fee splitting may occur in an office setting if the psychiatrist takes a percentage of his or her office mates' fees for supervision or expenses. Costs for such items or services must be arranged separately. Otherwise, it would appear that the office owner could benefit from referring patients to a colleague in the office. Fee splitting is illegal.
Informed consent	Is it ethical to refuse to divulge	No. It is the patient's decision, not the therapist's.

	information about a patient who has agreed to give this information to those requesting it?	
	Is informed consent needed when presenting or writing about case material?	Not if the patient is aware of the supervisory or teaching process and confidentiality is preserved.
Moonlighting	Can psychiatric residents ethically “moonlight”?	They can if their duties are not beyond their ability, if they are properly supervised, and if the moonlighting does not interfere with their residency training.
Reporting	Should psychiatrists expose or report unethical behavior of a colleague or colleagues? Can a spouse bring an ethical complaint?	Psychiatrists are obligated to report colleagues’ unethical behavior. A spouse with knowledge of unethical behavior can bring an ethical complaint as well.
Research	How can ethical research be performed with subjects who cannot give informed consent?	Consent can be given by a legal guardian or via a living will. Incompetent persons have the right to withdraw from the research project at any time.
Retirement	See Abandonment.	

Supervision	What are the ethical requirements when a psychiatrist supervises other mental health professionals?	The psychiatrist must spend sufficient time to ensure that proper care is given and that the supervisee is not providing services that are outside the scope of his or her training. It is ethical to charge a fee for supervision.
Taping and recording	Can videotapes of patient interviews be used for training purposes on a national level (e.g., workshops, board examination preparation)?	Appropriate and explicit informed consent must be obtained. The purpose and scope of exposure of the tape must be emphasized in addition to the resulting loss of confidentiality.

Table by Eugene Rubin, M.D. Data derived from the American Medical Association's Principles of Medical Ethics.

Military Psychiatry

Psychiatrists in the military face unique ethical problems because confidentiality does not exist under the military code of conduct. Psychiatrists, when treating military patients, are obligated to warn them regarding these limits. The reasoning is related to concepts of military necessity; however, many experts have pointed out the problems with this rule, as many soldiers may avoid needed care rather than risk exposure. Given the concerns about the rates of suicide in the military, there is growing pressure to revise this standard. Anecdotally many military psychiatrists choose to use their judgment as to what they are required to reveal to a patient's superiors.

28 Forensic and Legal Issues

"*Forensic*" is from Latin and means "of the forum." In Rome, criminal cases were presented in a public forum, hence the modern connotation of the term is relating to courts of law. At various times, psychiatry and the law intersect. Forensic psychiatry is the branch of psychiatry that examines this intersection. This chapter considers some of the legal aspects of psychiatry.

MEDICAL MALPRACTICE

Medical malpractice is a tort or civil wrong. It is a wrong resulting from a physician's negligence. Simply put, negligence means doing something that a physician with a duty to care for the patient should not do, or not doing something they should, as defined by current medical practice. Usually, expert witnesses help to establish the standard of care. Also, journal articles; professional textbooks, such as the *Kaplan and Sadock's Comprehensive Textbook of Psychiatry;* professional practice guidelines; and ethical practices promulgated by professional organizations all help to establish the standard of care.

To prove malpractice, the plaintiff (e.g., patient, or family) must establish by a preponderance of evidence that (1) a doctor–patient relationship existed that created a *duty* of care, (2) a *deviation* from the standard of care occurred, (3) the patient was *damaged*, and (4) the deviation *directly* caused the damage.

These elements of a malpractice claim are sometimes called the *4 Ds* (duty, deviation, damage, and direct causation).

Each of the four elements of a malpractice claim must be present, or there can be no finding of liability. For example, a psychiatrist whose negligence is

the direct cause of harm to an individual (physical, psychological, or both) is not liable for malpractice if no doctor–patient relationship existed to create a duty of care. Psychiatrists are not likely to be successfully sued if they advise on a radio program, particularly if they begin with the caveat that there is no doctor–patient relationship intended from the general advice-giving. No malpractice claim will be sustained against a psychiatrist if a patient's worsening condition is unrelated to negligent care. Not every adverse outcome is the result of negligence. Psychiatrists cannot guarantee correct diagnoses and treatments. When the psychiatrist provides due care, they may make mistakes without necessarily incurring liability. Most psychiatric cases are complicated. Psychiatrists make judgment calls when selecting a particular treatment course among the many options that may exist. In hindsight, the decision may prove wrong but not be a deviation in the standard of care.

In addition to negligence suits, patients can sue psychiatrists for the intentional torts of assault, battery, false imprisonment, defamation, fraud or misrepresentation, invasion of privacy, and intentional infliction of emotional distress. In an intentional tort, wrongdoers intend harm to another person or realize, or should have realized, that such harm is likely to result from their actions. For example, telling a patient that sex with the therapist is therapeutic perpetrates a fraud. Most malpractice policies do not provide coverage for intentional torts.

Negligent Prescription Practices

Negligent prescription practices usually include exceeding recommended dosages and then failing to adjust the medication level to therapeutic levels, unreasonable mixing of drugs, prescribing medications that are not indicated, prescribing too many drugs at one time, and failing to disclose medication effects. Elderly patients frequently take a variety of drugs prescribed by different physicians. We should only prescribe multiple psychotropic medications with special care because of possible harmful interactions and adverse effects. We should also carefully document our reasons for prescribing multiple medications.

Psychiatrists who prescribe medications must explain the diagnosis, risks, and benefits of the drug within reason and as circumstances permit (Table 28-

1). Obtaining informed consent can be problematic if a psychiatric patient has diminished cognitive capacity because of mental illness or chronic brain impairment. In these cases, a substitute health care decision maker may need to provide consent.

We should obtain informed consent each time we change a medication and introduce a new drug. If a medication injures a patient and the doctor did not inform them of this risk, there may be sufficient grounds for a malpractice action.

The question is often asked: How frequently should patients be seen for medication follow-up? The answer is that we should see patients according to their clinical needs. There is no stock answer about the frequency of visits. The longer the time interval between visits, however, the higher the likelihood of adverse drug reactions and clinical developments. Patients taking medications should probably not go beyond 6 months for follow-up visits. Managed care policies that do not reimburse for frequent follow-up appointments can result in a psychiatrist prescribing large amounts of medications. The psychiatrist is duty-bound to provide appropriate treatment to the patient, quite apart from managed care or other payment policies.

There are several other areas of negligence involving medication that may result in malpractice actions. A psychiatrist may fail to treat adverse effects that they have, or should have, recognized. They may also fail to monitor a patient's compliance with prescription limits or fail to prescribe the appropriate amount of medication. Prescribing addictive drugs to a vulnerable patient creates a risk, as can failing to seek appropriate consultation when indicated. Finally, stopping a medication inappropriately can be a cause of a malpractice action.

Split Treatment

In split treatment, the psychiatrist provides medication, and a nonmedical therapist conducts the psychotherapy. The following vignette illustrates a possible complication.

Table 28-1
Informed Consent: Reasonable Information to Be Disclosed

Although there exists no consistently accepted standard for information disclosure for any given medical or psychiatric situation, as a rule of thumb, five areas of information are generally provided:

1. Diagnosis—description of the condition or problem
2. Treatment—nature and purpose of proposed treatment
3. Consequences—risks and benefits of the proposed treatment
4. Alternatives—viable alternatives to the proposed treatment, including risks and benefits
5. Prognosis—projected outcome with and without treatment

Table by RI Simon, M.D.

A psychiatrist provided medications for a depressed 43-year-old woman. A master's level counselor saw the patient for outpatient psychotherapy. The psychiatrist saw the patient for 20 minutes during the initial evaluation and prescribed a tricyclic drug, and the patient was prescribed sufficient drugs for follow-up in 3 months. The psychiatrist initially diagnosed recurrent major depression. The patient denied suicidal ideation but had markedly diminished appetite and sleep. The patient had a long history of recurrent depression with suicide attempts. There were no further discussions between the psychiatrist and the counselor, who saw the patient once a week for 30 minutes in psychotherapy. Within 3 weeks, after a failed romantic relationship, the patient stopped taking her antidepressant medication, started to drink heavily, and committed suicide with an overdose of alcohol and antidepressant drugs. The patient's family sued the counselor and psychiatrist for negligent diagnosis and treatment.

Psychiatrists must do an adequate evaluation, obtain prior medical records, and understand that no such thing as a partial patient exists. Split treatments are potential malpractice traps because patients can "fall between the cracks" of fragmented care. The psychiatrist retains full responsibility for the patient's care in a split-treatment situation. This responsibility does not preempt the responsibility of the other mental health professionals involved

in the patient's treatment. Section V, annotation 3 of the *Principles of Medical Ethics with Annotations Especially Applicable to Psychiatry*, states: "When the psychiatrist assumes a collaborative or supervisory role with another mental health worker, he/she must expend sufficient time to assure that proper care is given."

In managed care or other settings, a marginalized role of merely prescribing medication apart from a working doctor–patient relationship does not meet generally accepted standards of good clinical care. The psychiatrist must be more than just a medication technician. Fragmented care in which the psychiatrist only dispenses medication while remaining uninformed about the patient's overall clinical status constitutes substandard treatment that may lead to a malpractice action. At a minimum, such a practice diminishes the efficacy of the drug treatment itself or may even lead to the patient's failure to take the prescribed medication.

Split-treatment situations require that the psychiatrist remain fully informed of the patient's clinical status as well as the nature and quality of treatment the patient is receiving from the nonmedical therapist. In a collaborative relationship, the psychiatrist and therapist share the responsibility for the patient's care according to their qualifications and limitations. The responsibilities of each discipline do not diminish those of the other disciplines. The treatment team should explain the separate responsibilities of each discipline to the patient. The psychiatrist and the nonmedical therapist must periodically evaluate the patient's clinical condition and requirements to determine whether the collaboration should continue. On termination of the collaborative relationship, both parties treating the patient should inform the patient either separately or jointly. In split treatments, if the patient sues the nonmedical therapist, the collaborating psychiatrist will likely be sued also and vice versa.

Psychiatrists who prescribe medications in a split-treatment arrangement should be able to hospitalize a patient if it becomes necessary. If the psychiatrist does not have admitting privileges, they should make prearrangements with other psychiatrists who can hospitalize patients if emergencies arise. Many community mental health organizations, group psychiatry practices, and managed care companies rely on split treatment, and this is a potential malpractice minefield.

PRIVILEGE AND CONFIDENTIALITY

Privilege

Privilege is the right to maintain secrecy or confidentiality in the face of a subpoena. Privileged communications are statements made by certain persons within a relationship—such as husband–wife, priest–penitent, or doctor–patient—that the law protects from forced disclosure on the witness stand. In the case of the doctor–patient relationship, the right of privilege belongs to the patient, not to the physician so that the patient can waive the right.

Psychiatrists, who are licensed to practice medicine, may claim medical privilege, but privilege has some qualifications. For example, this privilege does not exist in military courts, regardless of whether the physician is in the military. Also, the state where the trial takes place is irrelevant even if the state recognizes such privilege as military courts are not under the jurisdiction of the states.

In 1996, the United States Supreme Court recognized a psychotherapist–patient privilege in *Jaffee v. Redmon.* Emphasizing the critical public and private interests served by the psychotherapist–patient privilege, the court wrote:

Because we agree with the judgment of the state legislatures and the Advisory Committee that a psychotherapist-patient privilege will serve a "public good transcending the normal predominant principle utilizing all rational means for ascertaining truth"… we hold that confidential communications between a licensed psychotherapist and her patients in the course of diagnosis or treatment are protected from compelled disclosure under Rule 501 of the Federal Rules of Evidence.

Confidentiality

A long-held premise of medical ethics binds physicians to hold secret all information given by patients. This professional obligation is called *confidentiality.* Confidentiality applies to certain populations and not to others; a group that is within the circle of confidentiality shares information without receiving specific permission from a patient. Such groups include, in addition to the physician, other staff members treating the patient, clinical

supervisors, and consultants.

A subpoena can force a psychiatrist to breach confidentiality, and courts must be able to compel witnesses to testify for the law to function adequately. A subpoena ("under penalty") is an order to appear as a witness in court or at a deposition. Physicians usually are served with a *subpoena duces tecum*, which requires that they also produce their relevant records and documents. Although the power to issue subpoenas belongs to a judge, they are routinely issued at the request of an attorney representing a party to an action.

In bona fide emergencies, we can release information in as limited a way as feasible to carry out necessary interventions. We should try, time allowing, to obtain the patient's permission, and we should always debrief the patient after an emergency as to what information we released.

As a rule, clinical information may be shared with the patient's permission —preferably written permission, although oral permission suffices with proper documentation. Each release is good for only one piece of information, and the psychiatrist should obtain permission for each subsequent release, even to the same party. Permission overcomes only the legal barrier, not the clinical one; the release is permission, not an obligation. If a clinician believes that the information may be destructive, they should discuss this with the patient, and they can refuse the release, with some exceptions.

Third-Party Payers and Supervision. Increased insurance coverage for health care is precipitating a concern about confidentiality and the conceptual model of psychiatric practice. Today, insurance covers about 70 percent of all health care bills. An insurance carrier must be able to obtain information with which it can assess the administration and costs of various programs to provide coverage.

Quality control of care necessitates that confidentiality is not absolute; it also requires a review of individual patients and therapists. The therapist in training must breach a patient's confidence by discussing the case with a supervisor. Institutionalized patients who have been ordered by a court to get treatment must have their individualized treatment programs submitted to a mental health board.

Discussions about Patients. In general, psychiatrists have multiple

loyalties: to patients, to society, and the profession. Through their writings, teaching, and seminars, they can share their acquired knowledge and experience and provide information that may be valuable to other professionals and the public. It is not easy to write or talk about a psychiatric patient without breaching the confidentiality of the relationship. Unlike physical ailments, which we can usually discuss without anyone recognizing the patient, a psychiatric history usually entails a discussion of distinguishing characteristics. Psychiatrists have an obligation not to disclose identifiable patient information (and, perhaps, any descriptive patient information) without appropriate informed consent. Failure to obtain informed consent could result in a claim based on breach of privacy, defamation, or both.

The Internet and Social Media. Psychiatrists and other mental health professionals must be aware of the legal implications of discussing patients over the Internet. Internet communications about patients are not confidential, are subject to hacking, and are open to legal subpoenas. Some psychiatrists have blogged about patients thinking they were sufficiently disguised only to find that others do recognize them, including the involved patient. Some professional organizations have electronic mailing lists in which they ask advice about patients from their colleagues or make referrals and, in so doing, provide detailed information about the patient, which others can trace. Similarly, using social media to communicate about patients is equally risky.

Child Abuse. In many states, all physicians must take a course on child abuse for medical licensure. All states now legally require that psychiatrists (along with others), when suspecting child abuse, must immediately report this to an appropriate agency. In this situation, confidentiality is decisively limited by legal statute because potential or actual harm to vulnerable children outweighs the value of confidentiality in a psychiatric setting. Although many complex psychodynamic nuances accompany the required reporting of suspected child abuse, such reports generally are considered ethically justified.

HIGH-RISK CLINICAL SITUATIONS

Tardive Dyskinesia

It is estimated that at least 10 to 20 percent of patients and perhaps as high as 50 percent of patients treated with first-generation antipsychotics for more than 1 year exhibit some tardive dyskinesia. These figures are even higher for elderly patients. Despite the possibility for many tardive dyskinesia–related suits, relatively few psychiatrists have been sued. Also, patients who develop tardive dyskinesia may not have the physical energy and psychological motivation to pursue litigation. Allegations of negligence involving tardive dyskinesia occur when there is a failure to evaluate a patient properly, a failure to obtain informed consent, a negligent diagnosis of a patient's condition, and a failure to monitor.

Suicidal Patients

Psychiatrists may face legal action when their patients commit suicide. This is particularly true when psychiatric inpatients kill themselves. Psychiatrists are assumed to have more control over inpatients, making the suicide preventable.

The evaluation of suicide risk is one of the most complex, dauntingly difficult clinical tasks in psychiatry. Suicide is a rare event. In our current state of knowledge, clinicians cannot accurately predict when or if a patient will commit suicide. No professional standards exist for predicting who will or will not commit suicide. Professional standards do exist for assessing suicide risk, but at best, only the degree of suicide risk can be judged clinically after a comprehensive psychiatric assessment.

A review of the case law on suicide reveals that certain affirmative precautions should be taken with a suspected or confirmed suicidal patient. For example, failing to perform a reasonable assessment of a suicidal patient's risk for suicide or implement an appropriate precautionary plan will likely render a practitioner liable. The law tends to assume that suicide is preventable if it is foreseeable. Courts carefully scrutinize suicide cases to determine if a patient's suicide was foreseeable. *Foreseeability* is a deliberately vague legal term that has no comparable clinical counterpart, a common sense rather than a scientific construct. It does not (and should not) imply that clinicians can predict suicide. Foreseeability should not be confused with preventability, however. In hindsight, many suicides seem preventable that were not foreseeable.

Violent Patients

Psychiatrists who treat violent or potentially violent patients may be sued for failure to control aggressive outpatients and for the discharge of violent inpatients. Psychiatrists could be sued for failing to protect society from the violent acts of their patients if it was reasonable for the psychiatrist to have known about the patient's violent tendencies and if the psychiatrist could have done something that could have safeguarded the public. In the landmark case *Tarasoff v. Regents of the University of California*, the California Supreme Court ruled that mental health professionals have a duty to protect identifiable, endangered third parties from imminent threats of serious harm made by their outpatients. Since then, courts and state legislatures have increasingly held psychiatrists to a fictional standard of having to predict future behavior (dangerousness) of their potentially violent patients. Research has consistently demonstrated that psychiatrists cannot predict future violence with any dependable accuracy.

The duty to protect patients and endangered third parties is primarily a professional and moral obligation and, only secondarily, a legal duty. Most psychiatrists acted to protect both their patients and others threatened by violence long before *Tarasoff*.

If a patient threatens harm to another person, most states require that the psychiatrist perform some intervention that might prevent the harm from occurring. In states with duty-to-warn statutes, the states define the options available to psychiatrists and psychotherapists. In states offering no such guidance, health care providers should use their clinical judgment and act to protect endangered third persons. Typically, a variety of options to warn and protect are clinically and legally available, including voluntary hospitalization, involuntary hospitalization (when meeting civil commitment requirements), warning the intended victim of the threat, notifying the police, adjusting medication, and seeing the patient more frequently. Warning others of danger, by itself, is usually insufficient. Psychiatrists should consider the *Tarasoff* duty to be a national standard of care, even if they practice in states that do not have a duty to warn and protect.

Tarasoff I. The 1976 case *Tarasoff v. Regents of the University of California* (now known as *Tarasoff I*) raised the issue of the legal duty to warn. In this

case, Prosenjit Poddar, a student and a voluntary outpatient at the mental health clinic of the University of California, told his therapist that he intended to kill a student readily identified as Tatiana Tarasoff. Realizing the seriousness of the intention, the therapist, with the concurrence of a colleague, decided to commit Poddar for observation under a 72-hour emergency psychiatric detention provision of the California commitment law. The therapist notified the campus police, both orally and in writing that Poddar was dangerous and should be committed.

Concerned about the breach of confidentiality, the therapist's supervisor vetoed the recommendation and ordered all records relating to Poddar's treatment destroyed. At the same time, the campus police temporarily detained Poddar but released him on his assurance that he would "stay away from that girl." Poddar stopped going to the clinic when he learned from the police about his therapist's recommendation to commit him. Two months later, he carried out his previously announced threat to kill Tatiana. The young woman's parents thereupon sued the university for negligence.

As a consequence, the California Supreme Court, which deliberated the case for an unprecedented time of about 14 months, ruled that a physician or a psychotherapist who has reason to believe that a patient may injure or kill someone should warn the potential victim.

The discharge of the duty imposed on the therapist to warn intended victims against danger may take one or more forms, depending on the case. Therefore, stated the court, it may call for the therapist to notify the intended victim or others likely to notify the victim of the danger, to notify the police, or to take whatever other steps are reasonably necessary under the circumstances.

The *Tarasoff I* ruling does not require therapists to report a patient's fantasies; instead, it requires them to report an intended homicide. The therapist must exercise sound judgment to decide when this is the case.

Tarasoff II. In 1982, the California Supreme Court issued a second ruling in the case of *Tarasoff v. Regents of the University of California* (now known as *Tarasoff II*), which broadened its earlier ruling, extending the duty to warn, to include the duty to protect.

The *Tarasoff II* ruling has stimulated intense debates in the medicolegal field. Lawyers, judges, and expert witnesses argue the definition of

protection, the nature of the relationship between the therapist and the patient, and the balance between public safety and individual privacy.

Clinicians argue that the duty to protect hinders treatment because a patient may not trust a doctor if confidentiality is not maintained. Furthermore, because it is not easy to determine whether a patient is sufficiently dangerous to justify long-term incarceration, unnecessary involuntary hospitalization may occur because of a therapist's defensive practices.

As a result of such debates in the medicolegal field, since 1976, the state courts have not made a uniform interpretation of the *Tarasoff II* ruling (the duty to protect). In general, clinicians should note whether a specific identifiable victim seems to be in imminent and probable danger from the threat of an action contemplated by a mentally ill patient. The imminent harm should also be potentially serious or severe. Usually, the patient must be a danger to another person and not to property; the therapist should take clinically reasonable action.

HOSPITALIZATION

All states provide for some form of involuntary hospitalization. Such action usually is taken when psychiatric patients present a danger to themselves or others in their environment to the extent that their urgent need for treatment in a closed institution is evident. Individual states allow involuntary hospitalization when patients are unable to care for themselves adequately.

The doctrine of *parens patriae* allows the state to intervene and to act as a surrogate parent for those who are unable to care for themselves or who may harm themselves. In English common law, *parens patriae* ("father of his country") dates to the time of King Edward I and originally referred to a monarch's duty to protect the people. The US. common law transformed the doctrine into a paternalism in which the state acts for persons who are mentally ill and for minors.

The statutes governing hospitalization of persons who are mentally ill generally have been designated commitment laws, but psychiatrists have long considered the term to be undesirable. *Commitment* legally means a warrant for imprisonment. The American Bar Association and the American Psychiatric Association have recommended that state governments replace the term *commitment* with the less offensive and more accurate term

hospitalization, which most states have adopted. Although this change does not correct past mistakes, the emphasis on hospitalization is in keeping with psychiatrists' interest in treatment rather than punishment.

Procedures of Admission

Four procedures of admission to psychiatric facilities have been endorsed by the American Bar Association to safeguard civil liberties and to make sure that no one can capriciously force a person into a mental hospital. Although each of the 50 states has the power to enact its laws on psychiatric hospitalization, the procedures outlined here are gaining much acceptance.

Informal Admission. Informal admission operates on the general hospital model, in which the procedure for a psychiatric admission is the same as that for other patients. Under such circumstances, the ordinary doctor–patient relationship applies, with the patient free to enter and to leave, even against medical advice.

Voluntary Admission. In cases of voluntary admission, patients apply in writing for admission to a psychiatric hospital. They may come to the hospital on the advice of a personal physician, or they may seek help on their own. In either case, we would admit patients if an examination reveals the need for hospital treatment. The patient is free to leave, even against medical advice.

Temporary Admission. We may use a temporary admission for patients who are so senile or so confused that they require hospitalization and are not able to make decisions on their own and for patients who are so acutely disturbed that they must be admitted immediately to a psychiatric hospital on an emergency basis. Under the procedure, a hospital would admit a person on the written recommendation of one physician. After admitting the patient, a psychiatrist or the hospital staff must confirm the need for hospitalization. The procedure is temporary because we cannot hold these patients against their will for more than a set time, usually 15 days.

Involuntary Admission. Involuntary admission involves the question of whether patients are suicidal and, thus, a danger to themselves or homicidal

and thus a danger to others. Because these persons lack insight into their illness, a relative or friend may make the application for admission to a hospital. After making the application, at least two physicians must examine the patient, and if both physicians confirm the need for hospitalization, the hospital can admit the patient.

Involuntary hospitalization involves an established procedure for written notification of the next of kin. Furthermore, the patients have access at any time to legal counsel, who can bring the case before a judge. If the judge does not think that there is an indication for hospitalization, that judge can order the patient's release.

Involuntary admission allows us to hospitalize a patient for a set time, usually defined by the state and often in the range of 60 days. After this time, if the patient is to remain hospitalized, the case must be reviewed periodically by a board consisting of psychiatrists, nonpsychiatric physicians, lawyers, and other citizens not connected with the institution.

Involuntarily hospitalized persons who believe that they should be released have the right to file a petition for a writ of habeas corpus. Under the law, those who believe that they have been illegally deprived of liberty can proclaim a writ of habeas corpus. The legal procedure asks a court to decide whether a patient was hospitalized without due process of law. The courts must hear this case immediately, regardless of how the motion is filed. Hospitals are obligated to submit the petitions to the court immediately.

RIGHT TO TREATMENT

Among the rights of patients, the right to the standard quality of care is fundamental. This right has been litigated in highly publicized cases under the slogan of "right to treatment."

In 1966, Judge David Bazelon, speaking for the District of Columbia Court of Appeals in *Rouse v. Cameron,* noted that the purpose of involuntary hospitalization is treatment and concluded that the absence of treatment draws into question the constitutionality of the confinement. Treatment in exchange for liberty is the logic of the ruling. In this case, the patient was discharged on a writ of habeas corpus, the basic legal remedy to ensure liberty. Judge Bazelon further held that if alternative treatments that infringe less on personal liberty are available, involuntary hospitalization cannot take

place.

Alabama Federal Court judge Frank Johnson was more venturesome in the decree he rendered in 1971 in *Wyatt v. Stickney*. The *Wyatt* case was a class-action proceeding brought under newly developed rules that sought not release but treatment. Judge Johnson ruled that persons civilly committed to a mental institution have a constitutional right to receive such individual treatment as will give them a reasonable opportunity to be cured or to have their mental condition improved. Judge Johnson set out minimum requirements for staffing, specified physical facilities, and nutritional standards and required individualized treatment plans.

The new codes, more detailed than the old ones, include the right to be free from excessive or unnecessary medication; the right to privacy and dignity; the right to the least restrictive environment; the unrestricted right to be visited by attorneys, clergy, and private physicians; and the right to refuse lobotomies, electroconvulsive treatments, and other procedures without fully informed consent. Patients can be required to perform therapeutic tasks but not hospital chores unless they volunteer for them and receive the federal minimum wage as payment. This requirement is an attempt to eliminate the practice of peonage, in which state hospitals forced psychiatric patients to work at menial tasks, without payment, for the benefit of the state.

In several states today, medication or electroconvulsive therapy cannot be forcibly administered to a patient without first obtaining court approval, which may take as long as 10 days.

RIGHT TO REFUSE TREATMENT

The right to refuse treatment is a legal doctrine that holds that, except in emergencies, we cannot force patients to accept treatment against their will. An “emergency” is a condition in clinical practice that requires immediate intervention to prevent death or severe harm to the patient or another person or to prevent deterioration of the patient’s clinical state.

In the 1976 case of *O’Connor v. Donaldson*, the Supreme Court of the United States ruled that harmless mentally ill patients cannot be confined against their will without treatment if they can survive outside. According to the Court, a finding of mental illness alone cannot justify a state’s confining persons in a hospital against their will. Instead, involuntarily confined

patients must be considered dangerous to themselves or others or possibly so unable to care for themselves that they cannot survive outside. As a result of the 1979 case of *Rennie v. Klein*, patients have the right to refuse treatment and to use an appeal process. As a result of the 1981 case of *Roger v. Oken*, patients have an absolute right to refuse treatment, but a guardian may authorize treatment.

Many rightly question psychiatrists' ability to predict dangerousness. Also, many psychiatrists worry about the risk entailed by involuntarily hospitalizing a patient if the patient can then sue them for monetary damages for infringing on the patient's civil rights.

CIVIL RIGHTS OF PATIENTS

Because of several clinical, public, and legal movements, criteria for the civil rights of persons who are mentally ill, apart from their rights as patients, have been both established and affirmed.

Least Restrictive Alternative

The principle of *least restrictive alternative* holds that patients have the right to receive the least restrictive means of treatment for the requisite clinical effect. Therefore, if it is possible to treat a patient as an outpatient, we should not pursue commitment. Similarly, if it is safe to treat a patient in an open ward, we should not seclude them.

Although reasonably straightforward on first reading, the difficulty arises when clinicians attempt to apply the concept to choose among involuntary medication, seclusion, and restraint as the intervention of choice. Distinguishing among these interventions based on restrictiveness proves to be a purely subjective exercise fraught with personal bias. Moreover, each of these three interventions is both more and less restrictive than each of the other two. Nevertheless, we should make an effort to think in terms of restrictiveness when deciding how to treat patients.

Visitation Rights

Patients have the right to receive visitors and to do so at reasonable hours (customary hospital visiting hours). Hospitals have to allow for the fact that

at certain times, a patient's clinical condition may not permit visits. We should document when this is the case, as we should not suspend such rights without good reason.

Specific categories of visitors are not limited to the regular visiting hours; these include a patient's attorney, private physician, and members of the clergy—all of whom, broadly speaking, have unrestricted access to the patient, including the right to privacy in their discussions. Even here, a bona fide emergency may delay such visits. Again, the patient's needs come first. Under similar reasoning, we should curtail specific noxious visits (e.g., a patient's relative bringing drugs into the ward).

Communication Rights

Patients should generally have free and open communication with the outside world by telephone or mail, but this right varies regionally to some degree. Some jurisdictions charge the hospital administration with responsibility for monitoring the communications of patients. In some areas, hospitals must make available reasonable supplies of paper, envelopes, and stamps for patient's use.

Specific circumstances affect communication rights. A patient hospitalized with an associated criminal charge of making harassing or threatening phone calls should not have unrestricted access to the telephone, and similar considerations apply to mail. As a rule, however, patients should be allowed private telephone calls, and we should not invade their privacy by listening in or opening their mail.

Private Rights

Patients have several rights to privacy. In addition to confidentiality, they are allowed private bathroom and shower space, secure storage space for clothing and other belongings, and adequate floor space per person. They also have the right to wear their clothes and to carry their own money.

Economic Rights

Apart from special considerations related to incompetence, psychiatric patients generally are permitted to manage their financial affairs. One feature of this fiscal right is the requirement that we pay patients if they work in the

institution (e.g., gardening or preparing food). This right often creates tension between the valid therapeutic need for activity, including jobs, and exploitative labor. A consequence of this tension is that some hospitals have had to eliminate valuable occupational, vocational, and rehabilitative programs because of the failure of legislatures to supply the funding to pay wages to patients who participate in these programs.

Table 28-2
Indications and Contraindications for Seclusion and Restraint

Indications
Prevent clear, imminent harm to the patient or others
Prevent significant disruption to treatment program or physical surroundings
Assist in treatment as part of ongoing behavior therapy
Decrease sensory overstimulation[a]
Patient's voluntary reasonable request
Contraindications
Extremely unstable medical and psychiatric conditions[b]
Delirious or demented patients who are unable to tolerate decreased stimulation[b]
Overtly suicidal patients[b]
Patients with severe drug reactions or overdoses or who require close monitoring of drug dosages[b]
For punishment or convenience of staff

[a]Seclusion only.

[b]Unless close supervision and direct observation are provided.

Data from *The Psychiatric Uses of Seclusion and Restraint (Task Force Report No. 22)*. Washington, DC: American Psychiatric Association.

SECLUSION AND RESTRAINT

Seclusion and restraint raise complex legal issues. Seclusion and restraint have both indications and contraindications (Table 28-2). Seclusion and

restraint have become increasingly regulated over the past decade.

Legal challenges to the use of restraints and seclusion have been brought on behalf of institutionalized persons with psychiatric illnesses or cognitive disabilities. Typically, these lawsuits do not stand alone but are part of a challenge to a wide range of alleged abuses.

In general, courts hold, or consent decrees provide that hospitals can only implement restraints and seclusion when a patient creates a risk of harm to self or others, and no less restrictive alternative is available. Table 28-3 lists additional restrictions.

Table 28-3
Restrictions for Seclusion and Restraint

Restraints and seclusion can be implemented only when a patient creates a risk of harm to self or others and no less restrictive alternative is available.
Restraint and seclusion can only be implemented by a written order from an appropriate medical official.
Orders are to be confined to specific, time-limited periods.
A patient's condition must be regularly reviewed and documented.
Any extension of an original order must be reviewed and reauthorized.

INFORMED CONSENT

Lawyers representing an injured claimant now invariably add to a claim of negligent performance of procedures (malpractice) an informed consent claim as another possible area of liability. Ironically, this is one claim under which there is no requirement for expert testimony. The usual claim of medical malpractice requires the litigant to produce an expert to establish that the defendant physician departed from accepted medical practice. However, in a case in which the physician did not obtain informed consent, the fact that the treatment was technically well performed, was in accord with the generally accepted standard of care, and effected a complete cure is immaterial. As a practical matter, however, unless the treatment had adverse consequences, a complainant will not get far with a jury for actions based solely on an

allegation that the doctor performed treatment without consent.

In the case of minors, the parent or guardian must give consent to medical treatment. By statute, most states, however, list specific diseases and conditions that a minor can consent to have treated—including venereal disease, pregnancy, substance dependence, alcohol abuse, and contagious diseases. In an emergency, a physician can treat a minor without parental consent. The trend is to adopt the so-called mature minor rule, which allows minors to consent to treatment under ordinary circumstances. As a result of the Supreme Court's 1967 *Gault* decision, all juveniles must now be represented by counsel, must be able to confront witnesses, and must be given proper notice of any charges. Emancipated minors have the rights of an adult when they can show that they are living as adults with control over their own lives.

Consent Form

The essential elements of a consent form should include a fair explanation of the procedures and their purposes. The form should identify those procedures that are experimental. Also, the form should describe any attendant discomforts and risks than can be expected, as well as the benefits that are reasonable to expect. The form should also disclose appropriate alternative procedures that may be advantageous to the patient with an offer to answer any inquiries concerning the procedures. Finally, the form should explain that the patient is free to withdraw patient consent and to discontinue participation in the project or activity at any time without prejudice.

Some theorists suggest that a standardized discussion that covers the issues noted above can substitute for a form. In such a case, it would be essential to document the discussion.

CHILD CUSTODY

The action of a court in a child custody dispute centers on the child's best interests. The maxim reflects the idea that a natural parent does not have an inherent right to be named a custodial parent, but the presumption, although a bit eroded, remains in favor of the mother in the case of young children. As a rule, the courts presume that the welfare of a child of tender years generally is best served by maternal custody when the mother is a good and fit parent.

Giving the mother custody may also serve her best interest, as many parents may not otherwise ever resolve the pain of losing a child, but her best interest is not to be equated ipso facto with the best interest of the child. Care and protection proceedings are the court's interventions in the welfare of a child when the parents are unable to care for the child.

More fathers are asserting custodial claims. In about 5 percent of all cases, fathers are named custodians. With more women going to work outside the home, and more men assuming the primary role in child care, the traditional rationale for maternal custody has less force today than it did in the past.

Currently, every state has a statute allowing a court, usually a juvenile court, to assume jurisdiction over a neglected or abused child and to remove the child from parental custody. It usually orders that a welfare or probation department supervise the care and custody of the child.

TESTAMENTARY AND CONTRACTUAL CAPACITY AND COMPETENCE

Courts may ask psychiatrists to evaluate patients' testamentary capacities or their competence to make a will. Three psychological abilities are necessary to prove this competence. Patients must know the nature and the extent of their bounty (property), the fact that they are making a bequest, and the identities of their natural beneficiaries (spouse, children, and other relatives).

When probating a will, one of the heirs or another person may challenge its validity. Judgment in such cases must rely on reconstruction, using data from documents and from expert psychiatric testimony, of the testator's mental state at the time they wrote the will. When someone cannot, or chooses not, to write a will, all states provide for the distribution of property to the heirs. If there are no heirs, the estate goes to the public treasury.

Witnesses at the signing of a will, which might include a psychiatrist, may attest that the testator was rational at the time of executing the will. In unusual cases, a lawyer may videotape the signing to safeguard the will from attack. Ideally, persons who are thinking of making a will and believe that there may be questions about their testamentary competence should hire a forensic psychiatrist to perform a dispassionate examination antemortem to validate and record their capacity.

An incompetence proceeding and the appointment of a guardian may be

necessary when a family member is spending the family's assets, and the property is in danger of dissipation, as in the case of patients who are elderly, have cognitive disabilities, are dependent on alcohol, or have psychosis. An issue is whether such persons are capable of managing their affairs. A guardian appointed to take control of the property of one deemed incompetent, however, cannot make a will for the ward (the incompetent person).

We determine competence based on a person's ability to make a sound judgment—to weigh, to reason, and to make reasonable decisions. Competence is task-specific, not general; the capacity to weigh decision-making factors (competence) often is best demonstrated by a person's ability to ask pertinent and knowledgeable questions after explaining the risks and benefits. Although physicians (especially psychiatrists) often give opinions on competence, only a judge's ruling converts the opinion into a finding; a patient is not competent or incompetent until the court so rules. The diagnosis of a mental disorder is not, in itself, sufficient to warrant a finding of incompetence. Instead, the mental disorder must cause impairment in judgment for the specific issues involved. After they have been declared incompetent, persons lose specific rights: they cannot make contracts, marry, start a divorce action, drive a vehicle, handle their property, or practice their professions. A formal courtroom proceeding decides incompetence, and the court usually appoints a guardian who will best serve a patient's interests. Another hearing is necessary to declare a patient competent. Admission to a mental hospital, even involuntarily, does not automatically mean that a person is incompetent.

Competence also is essential in contracts because a contract is an agreement between parties to do a specific act. A contract is invalid if, when it was signed, one of the parties was unable to comprehend the nature and effect of his or her act. The marriage contract is subject to the same standard and thus can be voided if either party did not understand the nature, duties, obligations, and other characteristics entailed at the time of the marriage. In general, however, the courts are unwilling to declare a marriage void based on incompetence.

Whether competence is related to wills, contracts, or the making or breaking of marriages, the fundamental concern is a person's state of awareness and capacity to comprehend the significance of the particular

commitment made.

Durable Power of Attorney

A modern development that permits persons to make provisions for their anticipated loss of decision-making capacity is called a *durable power of attorney.* The document permits the advance selection of a substitute decision maker who can act without the necessity of court proceedings when the signatory becomes incompetent through illness or progressive dementia.

CRIMINAL LAW

Competence to Stand Trial

The Supreme Court of the United States stated that the prohibition against trying someone who is mentally incompetent is fundamental to the US system of justice. Accordingly, the court, in *Dusky v. the United States,* approved a test of competence that seeks to ascertain whether a criminal defendant "has sufficient present ability to consult with his lawyer with a reasonable degree of rational understanding—and whether he has a rational as well as factual understanding of the proceedings against him."

Competence to Be Executed

One of the new areas of competence to emerge in the interface between psychiatry and the law is the question of a person's competence to be executed. The requirement for competence in this area is believed to rest on three general principles. First, a person's awareness of what is happening is supposed to heighten the retributive element of the punishment. Punishment is meaningless unless the person is aware of it and knows the punishment's purpose. Second, a competent person who is about to be executed is believed to be in the best position to make whatever peace is appropriate with his or her religious beliefs, including confession and absolution. Third, a competent person who is about to be executed preserves, until the end, the possibility (admittedly slight) of recalling a forgotten detail of the events or the crime that exonerate the person.

The need to preserve competence was supported recently in the Supreme Court case of *Ford v. Wainwright.* However, no matter the outcome of legal

struggles with this question, most medical bodies have gravitated toward the position that it is unethical for any clinician to participate, no matter how remotely, in state-mandated executions; a physician's duty to preserve life transcends all other competing requirements. Major medical societies, such as the American Medical Association (AMA), believe that doctors should not participate in the death penalty. A psychiatrist who agrees to examine a patient slated for execution may find the person incompetent based on a mental disorder and may recommend a treatment plan, which, if implemented, would ensure the person's fitness to be executed. Although room exists for a difference of opinion regarding whether or not a psychiatrist should become involved, the authors of this text agree with the AMA.

Criminal Responsibility

According to criminal law, committing a socially harmful act is not the sole criterion of whether a crime has been committed. Instead, the objectionable act must have two components: voluntary conduct (*actus reus*) and evil intent (*mens rea*). An evil intent cannot exist when an offender's mental status is so deficient, so abnormal, or so diseased to have deprived the offender of the capacity for rational intent. The law can be invoked only when an illegal intent is implemented. Neither behavior, however harmful, nor the intent to harm is, in itself, a ground for criminal action.

M'Naghten Rule. The precedent for determining legal responsibility was established in 1843 in the British courts. The so-called M'Naghten rule, which, until recently, has determined criminal responsibility in most of the United States, holds that persons are not guilty by reason of insanity if they labored under a mental disease such that they were unaware of the nature, the quality, and the consequences of their acts or if they were incapable of realizing that their acts were wrong. Moreover, to absolve persons from punishment, a delusion used as evidence must be one that, if true, would be an adequate defense. If the delusional idea does not justify the crime, such persons are presumably held responsible, guilty, and punishable. The M'Naghten rule is known commonly as the right–wrong test.

The M'Naghten rule derives from the famous M'Naghten case of 1843. When Daniel M'Naghten murdered Edward Drummond, the private secretary

of Robert Peel, M'Naghten had been suffering from delusions of persecution for several years, had complained to many persons about his "persecutors," and finally had decided to correct the situation by murdering Robert Peel. When Drummond came out of Peel's home, M'Naghten shot Drummond, mistaking him for Peel. The jury, as instructed under the prevailing law, found M'Naghten not guilty by reason of insanity. In response to questions about what guidelines could be used to determine whether a person could plead insanity as a defense against criminal responsibility, the English chief judge wrote:

1. To establish a defense on the ground of insanity, it must be clearly proved that, at the time of committing the act, the party accused was laboring under such a defect of reason, from disease of the mind, as not to know the nature and quality of the act he was doing, or if he did know it, he did not know he was doing what was wrong.
2. Where a person labors under partial delusions only and is not in other respects insane and as a result commits an offense, he must be considered in the same situation regarding responsibility as if the facts with respect to which the delusion exists were real.

According to the M'Naghten rule, the question is not whether the accused knows the difference between right and wrong in general, instead, it is whether the defendant understood the nature and the quality of their act and whether they knew the difference between right and wrong—specifically whether the defendant knew the act was wrong or perhaps thought the act was correct, a delusion causing the defendant to act in legitimate self-defense.

Jeffery Dahmer killed 17 young men and boys between June 1978 and July 1991. Most of his victims were either gay or bisexual. He would meet and select his prey at gay bars or bathhouses and then lure them by offering them money for posing for photographs or simply to enjoy some beer and videos. Then he would drug them, strangle them, masturbate on the body or have sex with the corpse, dismember the body, and dispose of it. Sometimes he would keep the skull or other body parts as souvenirs.

On July 13, 1992, Dahmer changed his plea to guilty by means of insanity. The jury, however, decided that Dahmer's meticulous murder

plans and the systematic way that he disposed of his victims' bodies was evidence that Dahmer could control his behavior. All of the testimony bolstered the notion that, as with most serial killers, Dahmer knew what he was doing and knew right from wrong. Finally, the jury did not accept the defense that Dahmer experienced a mental illness to the degree that it had disabled his thinking or behavioral controls. Dahmer was sentenced to 15 consecutive life terms or a total of 957 years in prison. An inmate killed him on November 28, 1994.

Irresistible Impulse. In 1922, a committee of jurists in England reexamined the M'Naghten rule. The committee suggested broadening the concept of insanity in criminal cases to include the irresistible impulse test, which rules that a person charged with a criminal offense is not responsible for an act if the act was committed under an impulse that the person was unable to resist because of mental disease. The courts interpret this concept such that it has been called the *policeman-at-the-elbow law.* In other words, the court grants an impulse to be irresistible only when it can be determined that the accused would have committed the act even if a policeman had been at the accused person's elbow. To most psychiatrists, this interpretation is unsatisfactory because it covers only a small, select group of those who are mentally ill.

Durham Rule. In the case of *Durham v. the United States,* Judge Bazelon handed down a decision in 1954 in the District of Columbia Court of Appeals. The decision resulted in the product rule of criminal responsibility, namely that an accused person is not criminally responsible if his or her unlawful act was the product of mental disease or mental defect. In the Durham case, Judge Bazelon expressly stated that the purpose of the rule was to get good and complete psychiatric testimony. He sought to release the criminal law from the theoretical straitjacket of the M'Naghten rule, but judges and juries in cases using the *Durham* rule became mired in confusion over the terms *product, disease,* and *defect.* In 1972, some 18 years after the rule's adoption, the Court of Appeals for the District of Columbia, in *United States v. Brawner* discarded the rule. The court—all nine members, including Judge Bazelon—decided in a 143-page opinion to throw out its *Durham* rule

and to adopt in its place the test recommended in 1962 by the American Law Institute in its model penal code, which is the law in the federal courts today.

Model Penal Code. In its model penal code, the American Law Institute recommended the following test of criminal responsibility: Persons are not responsible for criminal conduct if, at the time of such conduct, as a result of mental disease or defect, they lacked substantial capacity either to appreciate the criminality (wrongfulness) of their conduct or to conform their conduct to the requirement of the law. The term *mental disease or defect* does not include an abnormality manifested only by repeated criminal or otherwise antisocial conduct.

Subsection 1 of the American Law Institute rule contains five operative concepts: mental disease or defect, lack of substantial capacity, appreciation, wrongfulness, and conformity of conduct to the requirements of law. The rule's second subsection, stating that repeated criminal or antisocial conduct is not, of itself, to be taken as mental disease or defect, aims to keep the sociopath or psychopath within the scope of criminal responsibility.

Guilty but Mentally Ill. Some states have established an alternative verdict of guilty but mentally ill. Under guilty but mentally ill statutes, this alternative verdict is available to the jury if the defendant pleads not guilty by reason of insanity. Under an insanity plea, four outcomes are possible: not guilty, not guilty by reason of insanity, guilty but mentally ill, and guilty.

The problem with finding someone guilty but mentally ill is that it is an alternative verdict without a difference. It is the same as finding the defendant just plain guilty. The court must still impose a sentence on the convicted person. Although the convicted person supposedly receives psychiatric treatment, if necessary, this treatment provision is available to all prisoners.

OTHER AREAS OF FORENSIC PSYCHIATRY

Emotional Damage and Distress

A rapidly rising trend in recent years is to sue for psychological and emotional damage, both secondary to physical injury or as a consequence of witnessing a stressful act and from the suffering endured under the stress of

such circumstances as concentration camp experiences. The German government heard many of these claims from persons detained in Nazi camps during World War II. In the United States, the courts have moved from a conservative to a liberal position in awarding damages for such claims. Psychiatric examinations and testimony are sought in these cases, often by both the plaintiffs and the defendants.

Recovered Memories

Patients alleging recovered memories of abuse have sued parents and other alleged perpetrators. In several instances, the alleged victimizers have sued therapists who, they claim, negligently induced false memories of sexual abuse. In an about-face, some patients have recanted and joined forces with others (usually their parents) to sue therapists.

Courts have handed down multimillion-dollar judgments against mental health practitioners. A fundamental allegation in these cases is that the therapist abandoned a position of neutrality to suggest, persuade, coerce, and implant false memories of childhood sexual abuse. The guiding principle of clinical risk management in recovered memory cases is the maintenance of therapist neutrality and the establishment of sound treatment boundaries. Table 28-4 lists the risk management principles that should be considered when evaluating or treating a patient who recovers memories of abuse in psychotherapy.

Table 28-4
Risk Management Principles for Cases of Recovered Memories of Abuse in Psychotherapy

1. Maintain therapist neutrality: Do not suggest abuse.
2. Stay clinically focused: Provide adequate evaluation and treatment for patients presenting problems and symptoms.
3. Carefully document the memory-recovery process.
4. Manage personal bias and countertransference.
5. Avoid mixing treater and expert witness roles.
6. Closely monitor supervisory and collaborative therapy relationships.

7. Clarify nontreatment roles with family members.
8. Avoid special techniques (e.g., hypnosis or sodium amobarbital [Amytal]) unless clearly indicated; obtain consultation first.
9. Stay within professional competence: Do not take cases that you cannot handle.
10. Distinguish between narrative truth and historical truth.
11. Obtain consultation in problematic cases.
12. Foster patient autonomy and self-determination: Do not suggest lawsuits.
13. In managed care settings, inform patients with recovered memories that more than brief therapy may be required.
14. When making public statements, distinguish personal opinions from scientifically established facts.
15. Stop and refer, if uncomfortable with a patient who is recovering memories of childhood abuse.
16. Do not be afraid to ask about abuse as part of a competent psychiatric evaluation.

Worker's Compensation

The stresses of employment can cause or accentuate mental illness. Patients are entitled to be compensated for their job-related disabilities or to receive disability retirement benefits. A psychiatrist is often called on to evaluate such situations.

Civil Liability

Psychiatrists who sexually exploit their patients are subject to civil and criminal actions in addition to ethical and professional licensure revocation proceedings. Malpractice is the most common legal action (Table 28-5).

Table 28-5
Sexual Exploitation: Legal and Ethical Consequences

Civil lawsuit
Negligence

Loss of consortium
Breach-of-contract action
Criminal sanctions (e.g., statutory, adultery, sexual assault, rape)
Civil action for intentional tort (e.g., battery, fraud)
License revocation
Ethical sanctions
Dismissal from professional organizations

Table by RI Simon, M.D.

Table 28-6
Patients' Rights under the Privacy Rule

Physicians must give the patient a written notice of his or her privacy rights; the privacy policies of the practice; and how patient information is used, kept, and disclosed. A written acknowledgment should be taken from the patient verifying that he or she has seen such notice.
Patients should be able to obtain copies of their medical records and to request revisions to those records within a stated amount of time (usually 30 days). Patients do not have the right to see psychotherapy notes.
Physicians must provide the patient with a history of most disclosures of their medical history on request. Some exceptions exist. The APA Committee on Confidentiality has developed a model document for this requirement.
Physicians must obtain authorization from the patient for disclosure of information other than for treatment, payment, and health care operations (these three are considered to be routine uses, for which consent is not required). The APA Committee on Confidentiality has developed a model document for this requirement.
Patients may request another means of communication of their protected information (e.g., request that the physician contact them at a specific phone number or address).
Physicians cannot generally limit treatment to obtaining patient

authorization for disclosure of their information for nonroutine uses. Patients have the right to complain about Privacy Rule violations to the physician, their health plan, or to the Secretary of HHS.

APA, American Psychiatric Association; HHS, Department of Health and Human Services.

Health Insurance Portability and Accountability Act

The Health Insurance Portability and Accountability Act (HIPAA) was passed in 1996 to address the medical delivery system's mounting complexity and its rising dependence on electronic communication. The act orders that the federal Department of Health and Human Services (HHS) develop rules protecting the transmission and confidentiality of patient information, and all units under HIPAA must comply with such rules.

The Privacy Rule, administered by the Office for Civil Rights (OCR) at HHS, protects the confidentiality of patient information (Table 28.6).

End-of-Life Issues and Palliative Care

29.1 Death, Dying, and Bereavement

DEATH AND DYING

Definitions

The terms *death* and *dying* require definition: Whereas *death* may be considered the absolute cessation of vital functions, *dying* is the process of losing these functions. Dying may also be seen as a developmental concomitant of living, a part of the birth-to-death continuum. Living may entail numerous mini-deaths—the end of growth and its potential, health-compromising illnesses, multiple losses, decreasing vitality and growing dependency with aging, and dying. Dying, and the individual's awareness of it, imbues humans with values, passions, wishes, and the impetus to make the most of the time.

Two terms that have been used with increased frequency in recent years refer to the quality of living as death comes near. A *good death* is one that is free from avoidable distress and suffering for patients, families, and caregivers and is reasonably consistent with clinical, cultural, and ethical standards. A *bad death*, in contrast, is characterized by needless suffering, a dishonoring of the patient or family's wishes or values, and a sense among participants or observers that norms of decency have been offended.

Uniform Determination of Death Act. The President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral

Research published its definition of death in 1981. Working with the American Bar Association, the American Medical Association (AMA), and the National Conference of Commissioners on Uniform State Laws, the commission established that one who has sustained either (1) irretrievable cessation of circulatory and respiratory functions or (2) irretrievable cessation of all functions of the entire brain, including the brainstem, is dead. The determination of death must be per accepted medical standards.

Generally accepted criteria for determining brain death require a series of neurologic and other assessments. For children, particular guidelines apply. They generally specify two assessments separated by an interval of at least 48 hours for those between the ages of 1 week and 2 months, 24 hours for those between the ages of 2 months and 1 year, and 12 hours for older children; additional confirmatory tests may also be advisable under some circumstances. Brain death criteria usually are not applied to infants younger than 7 days. Table 29-1 lists the clinical criteria for brain death in adults and children.

Legal Aspects of Death

According to law, physicians must sign the death certificate, which attests to the cause of death (e.g., congestive heart failure or pneumonia). They must also attribute the death to natural, accidental, suicidal, homicidal, or unknown causes. A medical examiner, coroner, or pathologist must examine anyone who dies unattended by a physician and perform an autopsy to determine the cause of death. In some cases, a psychological autopsy is performed: A person's sociocultural and psychological background is examined retrospectively by interviewing friends, relatives, and doctors to determine whether mental illness, such as a depressive disorder, was present. For example, a determination can be made that a person died because he or she was pushed (murder) or because he or she jumped (suicide) from a high building. Each situation has clear medical and legal implications.

Stages of Death and Dying

Elisabeth Kübler-Ross, a psychiatrist and thanatologist, made a comprehensive and useful organization of reactions to impending death. A dying patient seldom follows a regular series of responses that can be

identified; no established sequence applies to all patients. Nevertheless, the following five stages proposed by Kübler-Ross are widely encountered.

Stage 1: Shock and Denial. On being told that they are dying, persons initially react with shock. They may appear dazed at first and then may refuse to believe the diagnosis; they may deny that anything is wrong. Some persons never pass beyond this stage and may go from doctor to doctor until they find one who supports their position. The degree to which denial is adaptive or maladaptive appears to depend on whether a patient continues to obtain treatment even while denying the prognosis. In such cases, physicians must communicate to patients and their families, respectfully and directly, necessary information about the illness, its prognosis, and the options for treatment. For effective communication, physicians must allow for patients' emotional responses and reassure them that they will not be abandoned.

Stage 2: Anger. Persons become frustrated, irritable, and angry at being ill. They commonly ask, "Why me?" They may become angry at God, their fate, a friend, or a family member; they may even blame themselves. They may displace their anger onto the hospital staff members and the doctor, whom they blame for the illness. Patients in the stage of anger are challenging to treat. Doctors who have difficulty understanding that anger is a predictable reaction and is a displacement may withdraw from patients or transfer them to other doctors' care.

Table 29-1
Clinical Criteria for Brain Death in Adults and Children

Coma
Absence of motor responses
Absence of pupillary responses to light and pupils at midposition with respect to dilatation (4–6 mm)
Absence of corneal reflexes
Absence of caloric responses
Absence of gag reflex
Absence of coughing in response to tracheal suctioning

Absence of sucking and rooting reflexes
Absence of respiratory drive at a $Paco_2$ that is 60 or 20 mm Hg above normal baseline values
Interval between two evaluations, according to patient's age
Term to 2 mo old, 48 hr
>2 mo to 1 yr old, 24 hr
>1 yr to <18 yr old, 12 hr
≥18 yr old, interval optional
Confirmatory tests
Term to 2 mo old, two confirmatory tests
>2 mo to 1 yr old, one confirmatory test
>1 yr to <18 yr old, optional
≥18 yr old, optional

$PaCO_2$, partial pressure of arterial carbon dioxide.

Reprinted from Wijdicks EF. The diagnosis of brain death. *N Engl J Med*. 2001;344:1215–1221, with permission.

Physicians treating angry patients must realize that the anger being expressed cannot be taken personally. An empathic, nondefensive response can help defuse patients' anger and can help them refocus on their deep feelings (e.g., grief, fear, loneliness) that underlie the anger. Physicians should also recognize that anger may represent patients' desire for control in a situation in which they feel completely out of control.

Stage 3: Bargaining. Patients may attempt to negotiate with physicians, friends, or even God; in return for a cure, they promise to fulfill one or many pledges, such as giving to charity and attending church regularly. Some patients believe that if they are good (compliant, nonquestioning, cheerful), the doctor will make them better. The treatment of such patients involves making it clear that they will be taken care of to the best of the doctor's abilities and that everything that can be done will be done, regardless of any action or behavior on the patients' part. Patients must also be encouraged to participate as partners in their treatment and to understand that being a good patient means being as honest and straightforward as possible.

Stage 4: Depression. In the fourth stage, patients show clinical signs of depression—withdrawal, psychomotor retardation, sleep disturbances, hopelessness, and, possibly, suicidal ideation. The depression may be a reaction to the effects of the illness on their lives (e.g., loss of a job, economic hardship, helplessness, hopelessness, and isolation from friends and family) or it may be in anticipation of the loss of life that will eventually occur. A major depressive disorder with vegetative signs and suicidal ideation may require treatment with antidepressant medication or electroconvulsive therapy (ECT). All persons feel some sadness at the prospect of their death, and normal sadness does not require biologic intervention. However, major depressive disorder and active suicidal ideation can be alleviated and should not be accepted as normal reactions to impending death. A person who suffers from major depressive disorder may be unable to sustain hope, which can enhance the dignity and quality of life and even prolong longevity. Studies have shown that some terminally ill patients can delay their death until after a loved one's significant event, such as the graduation of a grandson from college.

Stage 5: Acceptance. In the stage of acceptance, patients realize that death is inevitable, and they accept the universality of the experience. Their feelings can range from a neutral to a euphoric mood. Under ideal circumstances, patients resolve their feelings about the inevitability of death and can talk about facing the unknown. Those with strong religious beliefs and a conviction of life after death sometimes find comfort in the ecclesiastical maxim, "Fear not death; remember those who have gone before you and those who will come after."

Near-Death Experiences

Near-death descriptions are often strikingly similar. They often involve an out-of-body experience of viewing one's body and overhearing conversations, feelings of peace, hearing a distant noise, entering a dark tunnel, leaving the body behind, meeting dead loved ones, witnessing beings of light, returning to life to complete unfinished business, and deep sadness on leaving this new dimension. This pattern of sensations and perceptions is usually described as peaceful and loving; it feels real to participants, who

distinguish it from dreams or hallucinations. These experiences provoke sweeping lifestyle changes, such as fewer material concerns, a heightened sense of purpose, a belief in God, joy of life, compassion, less fear of death, an enhanced approach to life, and intense feelings of love. In a similar vein, hospice nurses have described experiences among terminally ill patients of visions that may include a sense of the presence of departed loved ones, of spiritual beings, of bright light, or of being in a particular place, often described with a sense of warmth and love. Although such "visions" do not readily lend themselves to scientific investigation and thus are not legitimized, patients may benefit from discussing them with clinicians. A term to describe this experience is *unio mystica*, which refers to an oceanic feeling of mystic unity with infinite power.

Life Cycle Considerations about Death and Dying

The clinical diversity of death-related attitudes and behaviors between children and adults has its roots in developmental factors and age-dependent differences in causes of death. As opposed to adults, who usually die from chronic illness, children are apt to die from sudden, unexpected causes. Almost half of the children who die between the ages of 1 and 14 years and nearly 75 percent of those who died in late adolescence and early adulthood die from accidents, homicides, and suicides. With their characteristics of violence, suddenness, and mutilation, such unnatural causes of death are extraordinary stressors for grieving survivors. Bereaved parents and siblings of dead young children and teenagers often feel victimized and traumatized by their losses; their grief reactions resemble posttraumatic stress disorder (PTSD). Devastating family disruptions can occur, and surviving siblings risk having their emotional needs put on the back burner, ignored, or completely unnoticed.

Children. Children's attitudes toward death mirror their attitudes toward life. Although they share with adolescents, adults, and elderly adults similar fears, anxieties, beliefs, and attitudes about dying, some of their interpretations and reactions are age specific. None welcome it without ambivalence, and all temper their acceptance with healthy doses of denial and avoidance. Dying children are often aware of their condition and want to

discuss it. They often have more sophisticated views about dying than their medically well counterparts, engendered by their failing health, separation from parents, subjection to painful procedures, and the deaths of hospital chums.

At the preschool, preoperational stage of cognitive development, death is seen as a temporary absence, incomplete and reversible, like departure or sleep. Separation from the primary caretaker(s) is the main fear of preschool-age children. This fear surfaces as an increase in nightmares, more aggressive play, or concern about the deaths of others rather than direct discourse. Terminally ill children may assume responsibility for their death, feeling guilty for dying. Preschool children may be unable to relate the treatment to the illness, instead of viewing treatment as punishment and family separation as rejection. They need reassurance that they are loved, have done nothing wrong, are not responsible for their illness, and will not be abandoned.

School-age children manifest concrete-operational thinking and recognize death as a final reality. They, however, view death as something that happens to older people, not to them. Between the ages of 6 and 12 years, children have active fantasies of violence and aggression, often dominated by themes of death and killing. School-age children ask questions about serious illness and death if encouraged to do so; however, if they receive cues that the subject is taboo, they may withdraw and participate less fully in their care. Facilitating open discussion and updating children with relevant information, including prognostic changes, can be very helpful. Also, children may need help coping with peers and school demands. Teachers should be informed and updated. Classmates may need education and assistance to help them understand the situation and respond appropriately.

Adolescents. Capable of formal cognitive operations, adolescents understand that death is inevitable and final but may not accept that their death is possible. The significant fears of dying teenagers parallel those of all teenagers. These include losing control, being imperfect, and being different. Concerns about body image, hair loss, or loss of bodily control can generate resistance to continuing treatment. Alternating emotions of despair, rage, grief, bitterness, numbness, terror, and joy are typical. The potential for withdrawal and isolation is high because teenagers may equate parental support with loss of independence or may deny their fears of abandonment by

actually repulsing friendly gestures. Teenagers must be included in all decision-making processes surrounding their deaths. Many are capable of great courage, grace, and dignity in facing death.

Adults. Some of the most often expressed fears of adult patients entering hospice care, listed in the approximate order of frequency, include fears of (1) separation from loved ones, homes, and jobs; (2) becoming a burden to others; (3) losing control; (4) what will happen to dependents; (5) pain or other worsening symptoms; (6) being unable to complete life tasks or responsibilities; (7) dying; (8) being dead; (9) the fears of others (reflected fears); (10) the fate of the body; and (11) the afterlife. Problems in communication arise out of trepidation, making it essential for those involved in health care to provide environments of trust and safety in which people can begin to talk about uncertainties, anxieties, and concerns.

Late-age adults often accept that their time has come. Their main fears include long, painful, and disfiguring deaths; prolonged vegetative states; isolation; and loss of control or dignity. Elderly patients may talk or joke openly about dying and sometimes welcome it. In their 70s and beyond, they rarely harbor illusions of indestructibility—most have already had several close calls: Their parents have died, and they have gone to funerals of friends and relatives. Although they may not be happy to die, they can be reconciled to it.

According to Erik Erikson, the eighth and final stage in the life cycle brings a sense of either integrity or despair. As elderly adults enter the last phase of their lives, they reflect on their pasts. When they have taken care of their affairs, have been relatively successful, and have adapted to the triumphs and disappointments of life, they can look back with satisfaction and only a few regrets. The integrity of the self allows people to accept inevitable disease and death without fear of succumbing helplessly. If elderly individuals look back on life as a series of missed opportunities or personal misfortunes, however, they feel a sense of bitter despair, a preoccupation with what might have been if only this or that had happened. Then death is fearsome because it symbolizes emptiness and failure.

Management

Caring for a dying patient is highly individual. Caretakers need to deal with death honestly, tolerate wide ranges of affects, connect with suffering patients and bereaved loved ones, and resolve routine issues as they arise. Although each therapeutic relationship between a patient and health provider has a uniqueness derived from the patient's and health provider's gender, constitution, life experience, age, stage of life, resources, faith, culture, and other considerations, major themes confront all health providers caring for dying patients.

BEREAVEMENT, GRIEF, AND MOURNING

Bereavement, *grief*, and *mourning* are terms that apply to the psychological reactions of those who survive a significant loss. Grief is the subjective feeling precipitated by the death of a loved one. The term is used synonymously with mourning, although, in the strictest sense, mourning is the process by which grief is resolved; it is the societal expression of post bereavement behavior and practices. Bereavement means the state of being deprived of someone by death and refers to being in the state of mourning. Regardless of the fine points that differentiate these terms, the experiences of grief and bereavement have sufficient similarities to warrant a syndrome that has signs, symptoms, a demonstrable course, and an expected resolution.

Normal Bereavement Reactions

The first response to loss, *protest*, is followed by a more extended period of *searching* behavior. As hope to reestablish the attachment bond diminishes, searching behaviors give way to *despair* and *detachment* before bereaved individuals eventually *reorganize* themselves around the recognition that the lost person will not return. Although the bereaved ultimately learn to accept the reality of death, they also find psychological and symbolic ways of keeping the memory of the deceased person very much alive. Grief work allows the survivor to redefine his or her relationship to the deceased person and to form new but enduring ties.

Duration of Grief. Most societies mandate modes of bereavement and time for grieving. In contemporary America, bereaved individuals are expected to return to work or school in a few weeks, to establish equilibrium within a few

months, and to be capable of pursuing new relationships within 6 months to 1 year. Ample evidence suggests that the bereavement process does not end within a prescribed interval; certain aspects persist indefinitely for many otherwise high-functioning, typical individuals.

The most lasting manifestation of grief, especially after spousal bereavement, is loneliness. Often present for years after the death of a spouse, loneliness may, for some, be a daily reminder of the loss. Other common manifestations of protracted grief occur intermittently. For example, a man who has lost his wife may experience elements of acute grief every time he hears her name or sees her picture on the nightstand. Usually, these reactions become increasingly short-lived over time, dissipating within minutes and become tinged with positive and pleasant affects. Such bittersweet memories may last a lifetime. Thus, most grief does not fully resolve or permanently disappear; instead, grief becomes circumscribed and submerged only to reemerge in response to specific triggers.

Anticipatory Grief

In *anticipatory grief*, grief reactions are brought on by the slow dying process of a loved one through injury, illness, or high-risk activity. Although anticipatory grief may soften the blow of the eventual death, it can also lead to premature separation and withdrawal while not necessarily mitigating later bereavement. At times, the intensification of intimacy during this period may heighten the actual sense of loss even though it prepares the survivor in other ways.

Anniversary Reactions. When the trigger for an acute grief reaction is a special occasion, such as a holiday or birthday, the rekindled grief is called an *anniversary reaction.* It is not unusual for anniversary reactions to occur each year on the same day the person died or, in some cases, when the bereaved individual becomes the same age the deceased person was at the time of death. Although these anniversary reactions tend to become relatively mild and brief over time, they can be experienced as the reliving of one’s original grief and prevail for hours or days.

Mourning

From earliest history, every culture records its own beliefs, customs, and behaviors related to bereavement. Specific patterns include rituals for mourning (e.g., wakes or Shiva), for disposing of the body, for invocation of religious ceremonies, and periodic official remembrances. The funeral is the prevailing public display of bereavement in contemporary North America. The funeral and burial service acknowledge the real and final nature of the death, countering denial; they also garner support for the bereaved, encouraging tribute to the dead, uniting families, and facilitating community expressions of sorrow. If cremation replaces burial, ceremonies associated with the dissemination of the ashes perform similar functions. Visits, prayers, and other ceremonies allow for continuing support, coming to terms with reality, remembering, emotional expression, and concluding unfinished business with the deceased. Several cultural and religious rituals provide purpose and meaning, protect the survivors from isolation and vulnerability, and set limits on grieving. Subsequent holidays, birthdays, and anniversaries serve to remind the living of the dead and may elicit grief as real and fresh as the original experience; over time, these anniversary grievings become attenuated but often remain in some form.

Bereavement

Because bereavement often evokes depressive symptoms, it may be necessary to demarcate normal grief reactions from major depressive disorder (Table 29-2). DSM-5 took a significant step from DSM-IV in that it removed the bereavement exclusion from a major depressive disorder so that we can diagnose individuals experiencing a recent loss as having major depression if we believe that is the case. To acknowledge that some persons may have a syndrome of disabling grief that is not depression, DSM-5 proposed criteria for persistent complex bereavement, which they included as a condition for further study. ICD-10 considers this an adjustment disorder and includes the grief reaction as a category of that disorder. Table 29-3 summarizes the criteria for each approach.

Complicated Bereavement

Complicated bereavement has a confusing array of terms to describe it —*abnormal, atypical, distorted, morbid, traumatic*, and *unresolved*, to name

a few types. Three patterns of complicated, dysfunctional grief syndromes have been identified—chronic, hypertrophic, and delayed grief. These are not diagnostic categories within DSM-5 but are descriptive syndromes that, if present, may be prodromal of a major depressive disorder.

Table 29-2
Differentiating the Depressive Symptoms Associated with Bereavement from Major Depression

Bereavement	Major Depressive Disorder
Symptoms may meet syndromal criteria for major depressive episode, but the survivor rarely has morbid feelings of guilt and worthlessness, suicidal ideation, or psychomotor retardation	Any symptoms as defined by DSM-5
Considers self-bereaved	May consider self-weak, defective, or bad
Dysphoria often triggered by thoughts or reminders of the deceased	Dysphoria is often autonomous and independent of thoughts or reminders of the deceased
Onset is within the first 2 mo of bereavement	Onset at any time
Duration of depressive symptoms is less than 2 mo	Depression often becomes chronic, intermittent, or episodic
Functional impairment is transient and mild	Clinically significant distress or impairment

No family or personal history of major depression	Family or personal history of major depression

Table 29-3
Approaches to Diagnosing Bereavement

	DSM-5	ICD-10
Diagnostic name	Persistent Complex Bereavement Disorder (list under “conditions for further study”)	Adjustment Disorder, Grief Reaction
Duration	Experiences symptoms from each group of symptoms below, more days than not, for 12 mo (adults) or 6 mo (children)	Occurs while adapting to a period of life change
Symptoms	Since the death of someone close to them, experiencing following symptoms, out of proportion or inconsistent with sociocultural norms (Symptom group B) • Longing for the deceased • Sorry/pain about the death • Preoccupied with the lost person • Preoccupied with the circumstances surrounding the death	Distress/Emotional disturbance • Depression • Anxiety • Worry • Difficulty coping • Difficulty planning • Difficulty carrying out daily routines • Disturbance of conduct (adolescents)

	(Symptom group C) • Difficulty accepting the death • Cannot believe or is numb to the loss • Difficulty thinking about positive memories • Bitter or angry about the loss • Self-blame • Avoids things that remind them of the lost person • Wants to die to be with the person • Cannot trust others • Feels alone/detached • Feels empty or unable to function without the lost person • Trouble seeing their purpose independent of the lost person • Trouble/reluctance pursuing other interests	
Required number of symptoms	Symptom group B: 1 symptom Symptom group C: 6 symptoms	Any combination of the above
Psychosocial consequences of symptoms	Distress of functional impairment	Usually interferes with functioning

Symptoms specifiers	With traumatic bereavement: the death was violent (homicide, suicide), and the bereaved is preoccupied with the suffering that preceded death

Chronic Grief. The most common type of complicated grief is chronic grief, often highlighted by bitterness and idealization of the dead person. Chronic grief is most likely to occur when the relationship between the bereaved and the deceased had been extremely close, ambivalent, or dependent; or when social supports are lacking, and friends and relatives are not available to share the sorrow over the extended time needed for most mourners.

Hypertrophic Grief. Most often seen after a sudden and unexpected death, bereavement reactions are extraordinarily intense in hypertrophic grief. Customary coping strategies are ineffectual to mitigate anxiety, and withdrawal is frequent. When one family member is experiencing a hypertrophic grief reaction, disruption of family stability can occur. Hypertrophic grief frequently takes on a long-term course, albeit one attenuated over time.

Delayed Grief. Absent or inhibited grief when one usually expects to find overt signs and symptoms of acute mourning is referred to as delayed grief. This pattern is marked by prolonged denial; anger and guilt may complicate its course.

Traumatic Bereavement. Traumatic bereavement refers to grief, which is both chronic and hypertrophic. This syndrome is characterized by recurrent, intense pangs of grief with persistent yearning, pining, and longing for the deceased; recurrent intrusive images of the death; and a distressing admixture of avoidance and preoccupation with reminders of the loss. Positive memories are often blocked or excessively sad, or they are experienced in prolonged states of reverie that interfere with daily activities. A history of

psychiatric illness appears to be frequent in this condition, as is a very close, identity-defining relationship with the deceased person.

Medical or Psychiatric Illnesses Associated with Bereavement. Medical complications include exacerbations of existing diseases and vulnerability to new ones; fear for one's health and more trips to the doctor; and an increased mortality rate, especially in men. The highest relative mortality risk is found immediately after bereavement, particularly from ischemic heart disease. The greatest effect of bereavement on mortality is for men younger than 65 years. Higher mortality rates in bereaved men than in bereaved women are due to increase in the relative risk of death by suicide, accident, cardiovascular disease, and some infectious diseases. In widows, the relative risk of death from cirrhosis and suicide may increase. In both sexes, bereavement appears to exacerbate health-compromising behaviors, such as increased alcohol consumption, smoking, and the use of over-the-counter medications.

Psychiatric complications of bereavement include an increased risk for major depressive disorder, prolonged anxiety, panic, and posttraumatic stress–like syndrome; increased alcohol, drug, and cigarette consumption; and an increased risk of suicide. Because of their psychosocial, emotional, and cognitive immaturity, bereaved children may be especially vulnerable to psychopathology.

Bereavement and Depression. Although symptoms overlap, grief can be distinguished from a full depressive episode. Most bereaved individuals experience intense sadness, but only a few meet DSM-5 criteria for a major depressive episode. Grief is a complex experience in which positive emotions take their place beside the negative ones. Grief is fluid and changing, an evolving state in which emotional intensity gradually lessens, and positive, comforting aspects of the lost relationship come to the fore. Pangs of grief are stimulus bound, related to internal and external reminders of the deceased person. This condition differs from depression, which is more pervasive and characterized by significant difficulties experiencing self-validating, positive feelings. Grief is a fluctuating state with individual variability, in which cognitive and behavioral adjustments are progressively made until the bereaved individual can hold the deceased person in a comfortable place in

memory, and a satisfying life can be resumed. By contrast, a major depressive episode consists of a recognizable and stable cluster of debilitating symptoms accompanied by a protracted, enduring low mood. Major depressive episode tends to be persistent and associated with poor work and social functioning, pathologic psychoneuroimmunological function, and other neurobiologic changes unless treated.

Bereavement and Posttraumatic Stress Disorder. Unnatural and violent deaths, such as homicide, suicide, or death in the context of terrorism, are much more likely to precipitate PTSD in surviving loved ones than are natural deaths. In such circumstances, themes of violence, victimization, and volition (i.e., the choice of death over life, as in the case of suicide) are intermixed with other aspects of grief, and traumatic distress marked by fear, horror, vulnerability, and disintegration of cognitive assumptions ensues. Disbelief, despair, anxiety symptoms, preoccupation with the deceased person, and the circumstances of the death, withdrawal, hyperarousal, and dysphoria are more intense and more prolonged than they are under nontraumatic circumstances, and an increased risk may exist for other complications. Although treatment studies in survivors of sudden death are few and far between, most experts agree that initial attention should be focused on traumatic distress, that a role is seen for both pharmacotherapy and psychotherapy, and that self-help support groups can be enormously beneficial.

Biologic Perspectives

Grief is both a physiologic and emotional response. During acute grief (as with other stressful events), persons may experience disruption of biologic rhythms. Grief is also accompanied by impaired immune functioning, including decreased lymphocyte proliferation and impaired functioning of natural killer cells. Whether the immune changes are clinically significant has not been established, but the mortality rate for widows and widowers following the death of a spouse is higher than that in the general population. Widowers appear to be at risk longer than widows.

Phenomenology of Grief. Bereavement reactions include intense feeling states; invoke a variety of coping strategies; and lead to alterations in

interpersonal relationships, biopsychosocial functioning, self-esteem, and world view that can last indefinitely. Manifestations of grief reflect the individual's personality, previous life experiences, and past psychological history; the significance of the loss; the nature of the bereaved person's relationship with the deceased person; the existing social network; intercurrent life events; health; and other resources. Despite individual variations in the bereavement process, investigators have proposed grieving process models, which include at least three partially overlapping phases or states: (1) initial shock, disbelief, and denial; (2) an intermediate period of acute discomfort and social withdrawal; and (3) a culminating period of restitution and reorganization. As with Kübler-Ross' stages of dying, the grieving stages do not prescribe a correct course of grief; instead, they are general guidelines describing an overlapping and fluid process that varies with the survivors (Table 29-4).

Table 29-4
Phases of Grief

Shock and denial (min, days, wk)
Disbelief and numbness
Searching behaviors: pining, yearning, and protest
Acute anguish (wk, mo)
Waves of somatic distress
Withdrawal
Preoccupation
Anger
Guilt
Lost patterns of conduct
Restless and agitated
Aimless and amotivational
Identification with the bereaved
Resolution (mo, yr)
Have grieved
Return to work
Resume old roles

Acquire new roles
Reexperience pleasure
Seek companionship and love of others

LIFE CYCLE PERSPECTIVES ABOUT BEREAVEMENT

Bereavement during Childhood and Adolescence

Approximately 4 percent of North American children lose one or both parents by the age of 15 years; sibling death is the second most commonly experienced bereavement. Grief reactions are colored by developmental levels and concepts of death and may not resemble adult reactions. Children may display minimal grief at the time of death and experience the full effect of the loss later. Grieving children may not withdraw and dwell on the person who died, but instead, may throw themselves into activities. Indifference, anger, or misbehavior may be displayed rather than the sadness; behaviors can be erratic and labile. Strong feelings of anger and fears of abandonment or death may show up in the behavior of grieving children. Children often play death games as a way of working out their feelings and anxieties. These games are familiar to the children and provide safe opportunities to express their feelings. Although they may seem to show grief only occasionally and briefly, in reality, a child's grief often lasts longer than that of an adult.

Mourning in children may need to be addressed again and again as the child ages. Children will think about the loss repeatedly, especially during critical times in their lives, such as going to camp, graduating from school, getting married, or giving birth to their children. A child's grief can be influenced by his or her age, personality, developmental stage, earlier experiences with death, and relationship with the deceased person. The surroundings, cause of death, and family members' ability to communicate with one another and to continue as a family after death can also affect grief. The child's ongoing need for care, his or her opportunity to share feelings and memories, the parent's ability to cope with stress, and the child's steady relationships with other adults are other factors that may influence grief. Even older children frequently feel abandoned or rejected when a parent dies and may show hostility toward the deceased or the surviving parent, now perceived as one who might also "abandon" them. They may feel responsible

because of earlier misbehavior or because they said or wished that that person would die at some time.

Children younger than 2 years may show loss of speech or diffuse distress. Children younger than 5 years are apt to respond with eating, sleeping, and bowel and bladder dysfunctions. Intense feelings of sadness, fear, and anxiety can occur, but these feelings are not persistent and tend to alternate between longer lasting normal states. School-age children may become phobic or hypochondriacal, withdrawn, or pseudomature, and school performance and peer relations often suffer. Adolescents, as with adults, run the gamut in expressing bereavement, ranging from behavioral problems, somatic symptoms, and erratic moods to stoicism. Whereas adolescent boys losing a parent may become delinquent, girls may turn to a sexual pattern for comfort and reassurance. Behavioral disturbances and depression are familiar at all ages. Rates of depressive episodes in bereaved children and adolescents are as high as in bereaved adults.

Bereaved children must be treated in a manner that considers their levels of emotional and cognitive maturity. They need to be told that death is real and irreversible and that they are blameless. Feelings and concerns should be expressed, and questions should be invited and answered with simplicity, candor, and clarity. Children, as with adults, need rituals to commemorate their loved ones; attendance at the funeral and participation in mourning may be beneficial first steps.

Bereavement during Adulthood

No consensus exists on which type of loss is associated with the most severe reactions. Although the death of a spouse is often ranked as the most stressful life event, some have argued that losing a child is even more profound. The death of a child is a particular sorrow, a lifelong loss for surviving mothers, fathers, brothers, sisters, grandparents, and other family members. A child’s death is a life-altering experience. The deaths of parents and siblings in adult life have not achieved much systematic study, but they are generally considered relatively mild compared with the loss of a spouse or child.

Grief appears most intense for the mother in late perinatal losses (stillbirths or neonatal deaths rather than miscarriages) and often is reexperienced during subsequent pregnancies. Sudden infant death syndrome is particularly

problematic in that death is sudden and unexpected. Parents may experience extra guilt or blame each other, often resulting in subsequent marital difficulties.

The surviving family members, friends, or lovers of individuals who have died from acquired immunodeficiency syndrome (AIDS) are uniquely challenged. The illness carries with it the stigmata of the illness itself and the gay community in general; it carries with it caretakers' fear of contracting the illness, and it is most prevalent in people who are in the prime of life. Asymptomatic infection may permit the infected person and those close to him or her time to adapt to the diagnosis. When a person who is human immunodeficiency virus (HIV) positive begins to manifest symptoms of opportunistic infection or associated cancer; however, the illness again becomes a threat. Coping with emotional reality is arduous and complicated. Often caretakers, as well as HIV-positive patients, wish for death, which can evoke feelings of guilt. For bereaved lovers, their own HIV status, multiple losses, and other concurrent stressors can complicate recovery. Gay men who have lost lovers to AIDS may be more depressed, consider suicide more often, and be more vulnerable to illicit drug use than are other bereaved individuals.

Elderly adults face more losses than individuals at other phases of the life cycle, and intense loneliness may be a lasting memorial to those who have died. For highly impaired elders who lose a spouse they depended on for daily functions or who was their sole source of companionship, bereavement reactions are profound.

Grief Therapy

Persons in normal grief seldom seek psychiatric help because they accept their reactions and behaviors as appropriate. Accordingly, a bereaved person should not routinely see a psychiatrist or psychologist unless a markedly divergent reaction to the loss is noted. For example, under usual circumstances, a bereaved person does not make a suicide attempt; if someone seriously contemplates suicide, psychiatric intervention is indicated.

When professional assistance is sought, it usually involves a request for sleeping medication from a family physician. A mild sedative to induce sleep may be useful in some situations, but antidepressant medication or

antianxiety agents are rarely indicated in normal grief. Bereaved persons may have to go through the mourning process, however painful it is, for a successful resolution to occur. Narcotizing patients with drugs interferes with the normal process that ultimately can lead to a desired outcome.

Because grief reactions can develop into a depressive disorder or pathologic mourning, specific counseling sessions for bereaved individuals are often valuable. Grief therapy is an increasingly important skill. In regularly scheduled sessions, grieving persons are encouraged to talk about feelings of loss and about the person who has died. Many bereaved persons have difficulty recognizing and expressing angry or ambivalent feelings toward a deceased person, and they must be reassured that these feelings are normal.

Grief therapy need not be conducted only on a one-to-one basis; group counseling is also useful. Self-help groups also have great value in some instances. About 30 percent of widows and widowers report that they become isolated from friends, withdraw from social life, and thus experience feelings of isolation and loneliness. Self-help groups offer companionship, social contacts, and emotional support; they eventually enable their members to reenter society in a meaningful way. Bereavement care and grief therapy have been most effective with widows and widowers. The necessity for this therapy stems, in part, from the contraction of the family unit; extended family members are no longer available to provide the needed emotional support and guidance during the mourning period.

29.2 Palliative Care

Psychological symptoms are nearly universal at the end of life. Psychiatric syndromes occur with an increased but definable frequency and have different age and gender distribution. For example, anxiety and depression are as common in men as in women. Psychiatric classification remains an essential framework on which to base clinical observations, but it was not designed with dying patients in mind. Hence, for such patients, it is pragmatically useful to think of a few syndromes for which this exists. The most common ones are anxiety states, depressive states, and confusional

states. These frequently coexist and overlap. Rarely, specific phobias of needles, enclosures, and the like may interfere with comfort and should be addressed, adapting the usual treatments to the patient's medical status. Occasionally, an emotional crisis or exacerbation of symptoms can be identified as an adjustment disorder, but it is occurring against the backdrop of other severe symptoms, so technically, it does not meet diagnostic criteria. However, this should not prevent the consultant from identifying the precipitating factor and defusing the response in the usual ways. Major psychotic disorders become submerged by the increasing symptomatology of the active dying process and only require specific attention when the patient is not actively dying and when the psychotic symptoms are separated from and superimposed on the symptoms of the illness.

PREVALENCE

Much of the research on prevalence has been done in cancer and AIDS and shows a marked increase in psychiatric conditions near the end of life. Severe depressive symptoms were found in from 25 to 77 percent in a sample of hospitalized cancer patients, although stricter criteria find 15 percent with major depression and another 15 percent having severe depressive symptoms. The prevalence of delirium rises from a range from 25 to 40 percent to as high as 85 percent with increasingly advanced disease. The association of psychiatric symptoms with pain was demonstrated in one of several consistent studies in which 39 percent of patients with a psychiatric diagnosis reported significant pain compared with 19 percent for those without a psychiatric diagnosis. In a sample of inpatients with AIDS, 65 percent had an organic mental disorder, and 27 percent had major depression. The financial cost of psychiatric disorders can be inferred from a study in which patients with a psychiatric diagnosis remained in the hospital 60 days longer than those without a psychiatric diagnosis.

Most commonly, terminally ill patients demonstrate an intertwining of anxiety and depression. These are difficult to tease apart, and the term *negative affect* has been suggested to define them as a symptom complex. It is hard not to feel grief at what is being lost and fear about the ultimate unknown. Individuals whose deep faith in an afterlife animates their spirit are an exception, and, even among them, many describe coexisting regret at the

loss of their temporal life and its furnishings.

GENERAL TREATMENT PRINCIPLES

Because the improved quality of life is the primary goal, pharmacologic treatment and any other measures that bring symptom relief should be instituted rapidly while an integrated plan for psychological and family interventions is being designed and set into motion. Psychiatric syndromes in this group are often secondary to medical conditions; hence, an etiologic diagnosis often yields useful clues to prevention and improved management. It should be sought simultaneously as long as the search is in line with treatment goals.

ANXIETY IN PATIENTS WITH ADVANCED DISEASE

Anxiety can be the presenting symptom for almost all medical disorders and can occur as a side effect from many medications. However, in patients with advanced disease, it usually presents with somatic symptoms, such as restlessness, hyperactivity, tachycardia, gastrointestinal (GI) distress, nausea, insomnia, shortness of breath, numbness, or tremor. It lowers the threshold for pain, worsens functional impairment, and increases the distress experienced in all comorbid conditions. It often interferes with the patient's ability to cooperate with other treatments or to relate optimally with loved ones. Patients refer to fear, worry, apprehension, or ruminations more often than to anxiety per se.

Mr. S, a 50-year-old physical therapist with newly diagnosed advanced lung cancer, was noted by his family to be anxious to the point of having panic symptoms when his wife would leave his bedside to attend to chores. He would start hyperventilating, would feel short of breath, would become restless and unable to concentrate on anything, and would be overwhelmed with morbid ruminations about his future. He was upset and felt guilty at having become overly dependent on his wife. He was taught relaxation and breathing exercises and was treated with clonazepam, which brought about a marked resolution of his anxiety. Mr. S felt more relaxed, less anxious, and more resilient and became able to

withstand periods of solitude without difficulty. (Courtesy of Marguerite Lederberg, M.D.)

DEPRESSION IN PATIENTS WITH ADVANCED DISEASE

Depressive symptoms are also common in advanced disease and are associated with the same existential factors found with anxiety. Studies have found a prevalence ranging from 9 percent, using the strictest criteria, to 58 percent, with less demanding ones. Risk factors include a previous history or family history. Having a way of differentiating somatic effects of disease from the neurovegetative criteria of major depression is especially daunting in terminally ill patients.

Table 29-5 describes the Endicott Substitution Criteria, which have been found to perform as well as the DSM criteria for depression and go further in that they also reflect the clinical observation which classically described that depressive thoughts and feelings are not universal in terminally ill patients and, when present, reflect depression just as they do in physically healthy patients.

Table 29-5
Endicott Substitution Criteria for Depression

Physical-Somatic Symptoms	Psychological Symptom Substitute
Changes in appetite or weight, or both	Tearfulness, depressed appearance
Sleep disturbance	Social withdrawal, decreased talkativeness
Fatigue, loss of energy	Brooding, self-pity, pessimism
Memory and concentration deficits, indecisiveness	Lack of reactivity

Although there are not many studies on the treatment of depression in terminally ill individuals, the available studies and a large body of clinical

experience with medically ill patients show that the pharmacologic treatment of depression can be useful even when definable medical causes exist and even in the last days of life.

A patient with diabetes and end-stage renal disease who had been on dialysis for 2 years was diagnosed with depression with marked insomnia and was started on 15 mg by mouth every day of mirtazapine, which helped her sleep immediately and showed an antidepressant effect within 3 weeks. Four weeks later, she was admitted to the hospital in congestive heart failure for what was to be her terminal admission. She did not wish to give up the antidepressant but now felt oversedated and wished that she could be more alert during the day to interact with her loved ones. She was started on methylphenidate 5 mg by mouth twice daily, after which she was more alert, engaged, and communicative with her family. On her death, her family was grateful to have been able to connect with her until the end.

CONFUSIONAL STATES IN PATIENTS WITH ADVANCED DISEASE

The prevalence of delirium rises to 85 percent in patients with advanced disease. If one includes the last hours of life, it nears 100 percent unless the patient lapses rapidly into a coma or dies of an acute event, such as pulmonary embolus. Acute events are always unexpected and traumatize the survivors even though they knew full well that the patient was near the end of life. Some patients slip into an irreversible coma, leaving families in a bedside vigil, which may give them a period of adaptation before the final instant of death. However, for some 75 to 85 percent of patients, death is associated with a period of delirium.

Patients frequently experience some disorientation, impaired memory, concentration, and altered arousal as they become increasingly ill. These symptoms may remain mild or may be the harbingers of full delirium. Clinicians should be aware that mild and early signs of delirium are often mistaken for depression, anxiety, and poor coping.

A psychiatric consultation was sought to evaluate depression in a 56-year-old practicing attorney with pancreatic cancer. His moderately severe back pain was being treated with morphine. The patient was noted by the inpatient staff to be more withdrawn, disengaged, and quiet, making poor eye contact and sleeping most of the day.

On examination, the psychiatric consultant found Mr. K to have disturbed arousal and to be mildly confused and disoriented. His speech was slow and his thought process disorganized. Mr. K admitted to intermittently experiencing visual hallucinations that he had been too embarrassed to report earlier to the nursing staff.

Mr. K was diagnosed with a hypoactive delirium secondary to opioid medications. He was treated with a low dose of olanzapine, 2.5 mg at bedtime. Mr. K's sensorium improved dramatically. He became alert, fully oriented, and better related, without any perceptual disturbances or thought disorder. This treatment was accomplished without needing to decrease his much-needed pain medications.

DISEASE-SPECIFIC CONSIDERATIONS

Different illnesses bring special issues. For example, a patient on dialysis can opt for death three times a week and is more vulnerable to acting on feelings of depression, anger, hopelessness, and reactions to family neglect or conflict. Patients with cancer must acknowledge possible death while hoping for a cure or remission. Treatment decisions in the face of a disease that is less and less treatable become increasingly difficult and can cause acute anxiety. Stem cell transplant patients experience high levels of anxiety and depression because they are getting a last chance with high stakes and high risks. The availability of organ transplants has created a large population of patients who wait, knowing that they may die while waiting for a cure that could be just around the corner. Neurodegenerative disorders are associated with increased physical disability and dependence. When there is associated loss of cognitive faculties, the problems may be behavioral. Otherwise, depression is frequent, although not an inevitable problem. Many patients state that they will not tolerate complete immobility and dependence, yet when the time comes, they go on life supports and stay on them. It has been

shown in several settings that as patients become increasingly ill, they accept an increasingly limited quality of life as worth living and opt for more onerous, less promising treatments if they offer even a small chance of help.

PATIENT–FAMILY UNIT

The intensity of family relationships becomes even more significant during the terminal period. The response of family members can be a conspiracy of silence. Nothing is sadder than a bedside where family members are tense and silent because they want to protect the patient by not talking about dying, and the patient is tense and silent because he or she is protecting the family by not talking about things that will upset them. Instead of closeness, expressions of gratitude, apologies, reminiscences, and farewells, there is a distance, and the patient is dying alone even though others physically surround the patient.

The psychiatrist can use family sessions to open patient–family dialogues. He or she can identify discrepant views of the illness, can deal with conflicts regarding treatment, and can explore concerns regarding an absent member, all of which undermine patient support and medical management. A major crisis, such as the imminent loss of a member, destabilizes the family structure, creating an opportunity for the psychiatrist to promote adaptive change and reconstitution. *Family-centered grief therapy,* which initially includes the patient and continues after the patient's death, provides a natural setting for such interventions.

When an older adolescent dropped out of college to take over her dying mother's duties, the family subtly discouraged her return to school after her mother's death. Psychiatric intervention allowed the patient to play a part in reorganizing family roles in a way that made it more possible for her daughter to continue her studies.

DECISION POINTS, ADVANCE DIRECTIVES, PROXIES, AND SURROGATES

This section reviews the transitions and decisions that characterize the end of

life.

Transition to Palliative Care

The transition to palliative care is not always clear. As soon as a diagnosis of an incurable disease is made, a cure is no longer the goal of care. However, if death is distant or even if some life extension can still be obtained, the patient and family focus on this positive goal. The physician is under no illusion about the future but has the delicate task of promoting short-term gains without obliterating the awareness of what lies ahead. Only when the nearness of death is acknowledged can thoughtful decisions be made about palliative care.

Where to Die?

Unattended Deaths. Many traumatic or unexpected deaths become known from a catastrophic phone call. The traumatized family then needs help to absorb the loss, to cope with the circumstances, and to come to some kind of closure. It is not realized how much the experience of living through the illness, death, and the funeral rites is crucial to the normal resolution of the mourning process.

An unexpected death, even an understandable one, such as a heart attack, leaves an aching sense of unfinished business over and above the expected grief. If the person was the victim of a crime, obsessive thoughts might be difficult to repress, and grief may turn to unquenchable anger with profound psychological disruption. It is also difficult, if not impossible, for survivors to make peace with suicide.

Emergency departments, police departments, and religious and community institutions should be equipped with a list of referral resources to help survivors of traumatic deaths. Psychiatric input can include program development and consultation to a wide range of professionals and individuals. Families must be helped to construct their ritual whereby they acknowledge to themselves and others the finality of their loss and perhaps create a place, if not a grave, around which to center their memorializing.

Attended Deaths. Patients can die in an acute hospital, in nursing homes, in hospices, and at home, with or without hospice support.

Most patients still die in acute care hospitals, having received active care until shortly before they die. This may occur because death is sudden or because the family or patient needed to be in a place where “everything is being done.” Fortunately, a growing number of hospitals have palliative care teams that provide appropriate care in the acute hospital setting.

Many patients die in nursing homes without the benefit of special care. This unfortunate situation could be remedied by bringing formal hospice care into nursing homes, but funding sources and turf issues need to be settled before it can become routine practice.

Inpatient hospice care was the first model of care to be developed and is warmly remembered by grateful families whose multiple human needs and those of their loved ones had been met in ways that they had not been trained to expect. As hospice gained acceptance, the insufficiency of inpatient beds encouraged the development of home hospice. Its existence has, in turn, encouraged more families to elect to keep dying patients at home.

In a home hospice program, the patient is evaluated and accepted in the usual manner but stays at home. The patient and family receive extensive instruction about what to expect. They are helped to obtain necessary materials, taught how to use them, and helped to obtain as much home help as they need. All the while, they receive medical supervision, nursing care, and emotional support with 24-hour phone availability and routine daily contacts.

Without this kind of help, a good death at home can be challenging to achieve. With it, patients feel safe from the abandonment that is so commonly feared, and families feel safe from the terror of an unmanageable event. The families of these patients work hard, but they are more likely to feel competent and in control. They experience more of a sense of achievement and less of the gnawing sense of inadequacy that is otherwise common.

CARING FOR THE DYING PATIENT

Marguerite S. Lederberg, M.D., at Memorial Sloan Kettering Cancer Center in New York makes the following observation:

A dying human being whose physical, social, emotional, and spiritual needs

are being effectively attended to seldom demands to be helped to commit suicide, and the family members—given proper help and support—derive a deep sense of peace from having helped their loved one to die feeling loved and secure.

One of the most critical tasks for a physician caring for a dying patient is to determine when the time for curative care has ceased. It is only then that palliative care can begin. Some physicians are so upset by death that they are reluctant to use palliative methods; instead, they continue to treat the patient knowing that efforts are futile. Alternatively, they resort to using so-called heroic methods that do not prevent death, and that may produce needless suffering. Ideally, physicians should strive to extend the patient's life and decrease suffering; at the same time, they must accept death as a defining characteristic of life. Some physicians, however, develop dysfunctional attitudes about death, which they reinforce throughout their lives in their experiences and training. It has been postulated that doctors are more frightened of death than members of other professional groups and that many enter the study of medicine so they may gain control of their mortality using the defense mechanism of intellectualization. Risk factors that can interfere with a physician's ability to care optimally for dying patients are listed in Table 29-6. These factors range from overidentifying with the patient to being fearful of death, as mentioned.

Physicians able to deal with death and dying can communicate effectively in several areas: diagnosis and prognosis, the nature of the terminal illness, advance directives about life-sustaining treatment, hospice care, legal and ethical issues, grief and bereavement, and psychiatric care. Also, palliative care physicians must be skilled in pain management, especially in the use of potent opioids—the gold standard of drugs used for pain relief. In 1991, the American Board of Pain Medicine was established to ensure that physicians treating patients in pain were both qualified to do so and were kept up to date on the latest advances in the field.

Table 29-6
Risk Factors for the Development of Aversive Reactions in Physicians

The physician:

- Identifies with the patient: looks, profession, age, character, and so on.
- Identifies the patient with someone in his or her own life.
- Is currently dealing with a sick family member.
- Is recently bereaved or dealing with unresolved loss or grief issues.
- Feels professionally insecure.
- Is fearful of death and disability.
- Is unconsciously reflecting feelings felt or expressed by the patient or family.
- Cannot tolerate high and protracted levels of ambiguity or uncertainty.
- Carries a psychiatric diagnosis, such as depression or substance abuse.

Adapted from Meier DE, Back AL, Morrison RS The inner life of physicians and care of the seriously ill. *JAMA*. 2001;286:3007–3014, with permission.

COMMUNICATION

After a diagnosis and prognosis have been made, physicians need to talk to the patient and the patient's family. Formerly, doctors subscribed to a conspiracy of silence, believing that their patient's chances for recovery would improve if they knew less, because news of impending death might bring despair. The standard of care is to be honest and open toward a patient. The question is no longer whether to tell a patient, but when and how. In 1972, the American Hospital Association drafted the Patient's Bill of Rights, declaring that patients have the "right to obtain complete, current information regarding diagnosis, treatment, and prognosis in terms the patient can be reasonably expected to understand."

Breaking Bad News

When breaking news of impending death to the patient, as when relating any bad news, diplomacy and compassion should be the guiding principles. Often, the bad news is not entirely related during one meeting but instead is absorbed gradually over a series of separate conversations. Preparations,

including scheduling sufficient time for the visit, researching pertinent information such as test results and facts about the case, and even arranging furniture can help make the patient feel comfortable.

If possible, these conversations should take place in a private, suitable space with the patient on equal terms with the physician (i.e., the patient dressed and the physician seated). If it is possible and desired by the patient, the patient's spouse or partner should be present. The treating physician should explain the current situation to the patient in clear, simple language even when speaking to highly educated patients. Information may need to be repeated, or additional meetings may be necessary to communicate all of the information. A gentle, sensible approach will help modulate the patient's denial and acceptance. At no time should physicians take their patient's angry comments personally, and they should never criticize the patient's response to the bad news.

Physicians can signal their availability for honest communication by encouraging and answering questions from patients. Estimates on how long a patient has to live are usually inaccurate and thus should not be given, or given with that caveat. Also, physicians should make it clear to their patients that they are willing to see them through until death occurs. Ultimately, physicians must choose how much information to give and when based on each patient's needs and capacities.

The same general approaches apply as physicians seek to comfort members of the patient's family. Helping family members deal with feelings about the patient's illness can be just as important as comforting the patient because family members are often the primary source of emotional support for patients.

Telling the Truth

Tactful honesty is the doctor's most valuable aid. Honesty, however, need not preclude hope or guarded optimism. It is essential to be aware that if 85 percent of patients with a particular disease die in 5 years, 15 percent are still alive after that time. When deciding when and what to tell a patient about their prognosis, we should consider our commitment to the principle of "do no harm." In general, most patients want to know the truth about their condition. Various studies of patients with malignancies show that 80 to 90

percent want to know their diagnosis.

Doctors, however, should ask patients how much they want to know because some persons do not want to know all the facts about their illness. Such patients, if told the truth, deny that they ever were told, and they cannot participate in end-of-life decisions, such as the use of life-sustaining equipment. The patients who openly request that they not be given “bad news” are often those who most fear death. Physicians should deal with these fears directly, but if the patient still cannot bear to hear the truth, someone closely related to the patient must be informed.

Informed Consent

In the United States, informed consent is legally required for both conventional and experimental treatment. Patients must be given sufficient information about their diagnosis, prognosis, and treatment options to make knowledgeable decisions. This information includes a discussion of potential risks and benefits, available alternative treatments, and the results of not receiving treatment. This approach may come at some psychological cost; severe anxiety and occasional psychiatric decompensation can occur when patients feel overburdened by demands to make decisions. Nevertheless, patients respond best to doctors who explain the various options in detail. Physicians must be prepared to deal with difficult questions posed by patients. Some of them are listed in Table 29-7.

End-of-life discussions are challenging, mainly because they can influence how patients make informed choices.

TERMINAL CARE DECISIONS

Modern society is poorly equipped to cope with the life-and-death decisions spawned by technology. When it first emerged, cardiopulmonary resuscitation was enthusiastically supported by the medical profession. It was endowed with magical power and eventually became a ritualized rite rather than an optional medical treatment. That practice played into the therapeutic activism characteristic of many physicians. By the end of the 20th century, however, a countermovement began. First, the right to refuse treatment was established, mostly because of synergy between the consumer movement and the bioethics movement, with its emphasis on patient autonomy. Next, the

legality of DNR orders and the moral equivalence of stopping and not starting treatment were established. The medical profession was less enthusiastic than the public about these changes, perhaps because practitioners know too well the emotional ambiguities that surround death and must repeatedly experience them.

Table 29-7
Some Difficult Questions from Patients

"Why me?"
"Why didn't you catch this earlier? Did you make a mistake?"
"How long do I have?"
"What would you do in my shoes?"
"Should I try experimental therapy?"
"Should I go to a 'medical mecca' for treatment or a second opinion?"
"If my suffering gets really bad, will you help me die?"
"Will you work with me all the way through to my death, no matter what?"

From Quill TF. Perspectives on care at the close of life. Initiating end-of-life discussions with seriously ill patients: Addressing the "elephant in the room". *JAMA*. 2000;284:2502–2507, with permission.

Table 29-8
Persistent Vegetative State

No evidence of awareness of self or environment; no interaction with others
No meaningful response to stimuli
No receptive or expressive language
Return of sleep–wake cycles, arousal, even smiling, frowning, yawning
Preserved brainstem or hypothalamic autonomic functions to permit survival
Bowel and bladder incontinence
Variably preserved cranial nerve and spinal reflexes

Brain Death and Persistent Vegetative State

In an attempt to deal with these ambiguities, the concept of brain death emerged. Brain death is associated with the loss of higher brain functions (e.g., cognition) and all brain stem functions (e.g., pupillary and reflex eye movement), respiration, and gag and corneal reflexes. Determination of brain death is a generally accepted criterion for death. Some clinicians advocate an absence of brain waves on electroencephalography (EEG) to confirm the diagnosis.

The American Academy of Neurology defined the persistent vegetative state as a condition in which no awareness exists of self or environment associated with severe neurologic damage (Table 29-8). The medical treatment provides no benefits to patients in a persistent vegetative state, and after the diagnosis is established, DNR and do-not-intubate (DNI) orders can be followed and life-sustaining methods (e.g., feeding tubes, ventilators) can be removed.

In 1976, the case of Karen Ann Quinlan made international headlines when her parents sought the assistance of a judge to discontinue the use of a ventilator in their daughter, who was in a persistent vegetative state. Ms. Quinlan's physician had refused her parents' request to remove the ventilator because they said they feared that they might be held civilly or even criminally liable for her death. The New Jersey Supreme Court ruled that competent persons have a right to refuse life-sustaining treatment and that this right should not be lost when a person becomes incompetent. Because the court believed that the physicians were unwilling to withdraw the ventilator because of the fear of legal liability, not precepts of medical ethics, it devised a mechanism to grant the physicians prospective legal immunity for taking this action. The New Jersey Supreme Court ruled that after a prognosis, confirmed by a hospital ethics committee, that "no reasonable possibility of a patient returning to a cognitive, sapient state," exists, life-sustaining treatment can be removed, and no one involved, including the physicians, can be held civilly or criminally responsible for the death.

The publicity surrounding the Quinlan case motivated two independent developments: It encouraged states to enact "living will" legislation that

provided legal immunity to physicians who honored patients' written "advance directives," specifying how they would want to be treated if they ever became incompetent. It also encouraged hospitals to establish ethics committees that could attempt to resolve similar treatment disputes without going to court. (Courtesy of Annas GJ. "Culture of Life" politics at the bedside—the case of Terri Schiavo. *N Eng J Med*. 2005;352:1710–1715.)

Advance Directives

Advance directives are wishes and choices about medical intervention when the patient's condition is considered terminal. Advance directives, which are legally binding in all 50 states, include three types: living will, health care proxy, and DNR and DNI orders.

Living Will. In a living will, a mentally competent patient gives specific instructions that doctors must follow when the patient cannot communicate with them because of illness. These instructions may include rejection of feeding tubes, artificial airways, and any other measures to prolong life.

Health Care Proxy. Also known as a *durable power of attorney*, the health care proxy gives another person the power to make medical decisions if the patient cannot do so. That person, also known as the surrogate, is empowered to make all decisions about terminal care based on what he or she thinks the patient would want.

Do-Not-Resuscitate and Do-Not-Intubate Orders. These orders prohibit doctors from attempting to resuscitate (DNR) or intubate (DNI) the patient who is in extremis. DNR and DNI orders are made by the patient who is competent to do so. They can be made part of the living will or expressed by the health care proxy. Figure 29-1 is an infographic that includes a checklist of important items to consider when making an advanced directive.

The Uniform Rights of the Terminally Ill Act, drafted by the National Conference of Commissioners on Uniform State Laws was approved and recommended for enactment in all states. This act authorizes an adult to control the decisions regarding the administration of life-sustaining treatment

by executing a declaration instructing a physician to withhold or to withdraw life-sustaining treatment if the person is in a terminal condition and cannot participate in medical treatment decisions. In 1991, the Federal Patient Self-Determination Act became law in the United States. It required that all health care facilities (1) provide each patient admitted to a hospital with written information about the right to refuse treatment, (2) ask about advance directives, and (3) keep written records of whether the patient has an advance directive or has designated a health care proxy.

Today, patients who have left no advance directives or who are legally incompetent to do so have access to hospital ethics committees that hold active legal and ethical debates about these issues. These ethics committees are also of help to doctors, who can gain both legal and moral support when recommending that no further treatment occur. It is much easier for all parties, however, if the patient has advance directives or a proxy. Ideally, physicians should initiate discussions with patients about advance directives and proxies early even while the patient is healthy. The patient should be reminded that these early formulations can be modified but that even having preliminary advance directives will ensure that treating physicians observe the patient's wishes in the event of an emergency.

CARING FOR THE FAMILY

Family members play an essential role as caregivers to terminally ill patients and have needs of their own that often go unrecognized. Their responsibilities can be overwhelming, especially if only one family member is available or if family members themselves are infirm or elderly. Table 29-9 lists some family caregiving tasks. Many of these tasks require long hours of work or supervision that can lead to physical and emotional fatigue. One study of caregivers reports that 25 to 30 percent lost their jobs, and more than half moved to lower-paying jobs to accommodate the need for flexibility. The highest stress level was found in families who cared for a terminally ill patient at home, mainly when the death occurred in the home and realized in retrospect that they would have preferred an environment in which death occurs in the presence of skilled caretakers.

GETTING YOUR AFFAIRS IN ORDER:
Advance Care Planning

Making healthcare decisions for yourself or someone who is no longer able to do so can be overwhelming. That's why it's important to get a clear idea about preferences and arrangements while you can make decisions and participate in legal and financial planning together.

Use this checklist to ensure healthcare and financial arrangements are in place before serious illness or a healthcare crisis.

- ☑ **Start discussions** early with your loved one while everyone can still help make decisions.

- ☑ **Create documents** that communicate **healthcare**, **financial management**, and **end of life** wishes for yourself and the people you care for, with legal advice as needed.

- ☑ **Review plans regularly**, and update documents as circumstances change.

- ☑ **Put important papers in one place.** Make sure a trusted family member or friend knows the location and any instructions.

- ☑ **Make copies** of **healthcare directives** to be placed in all medical files, including information on every doctor seen.

- ☑ **Give permission** in advance for a doctor or lawyer to talk directly with a caregiver as needed.

- ☑ **Reduce anxiety** about funeral and burial arrangements by planning ahead.

Advance Care planning checklist. (Source: National Institute on Aging, https://www.nia.nih.gov/health/infographics/getting-your-affairs-order-advance-care-planning.)

Table 29-9
Tasks of Family Members of Dying Individuals

1. Administering medications
2. Dealing with adverse effects of medications
3. Providing help with, or actually performing, activities of daily living
4. Changing wound dressing
5. Managing ambulatory infusion pumps or other equipment
6. Providing symptom management (e.g., for pain, nausea and vomiting, shortness of breath, seizures, and terminal agitation)
7. Notifying the nurse or doctor when they are needed
8. Shopping for needed items and picking up prescriptions
9. Providing a presence and companionship
10. Attending to spiritual and religious needs
11. Carrying out advance directives
12. Managing financial matters

Dying at Home

Depending on the patient's wishes and the specific disease, the choice to die at home is one that should be explored. Although it is more burdensome on a family than dying in a hospital or hospice, death at home can be a welcome alternative for the patient and family seeking to spend quality time together. A home care team can assess a home for its suitability and suggest ways to facilitate activities of daily living, including modifications to furniture; hospital bed leasing; and installation of assistive devices, such as handrails and commodes. The family's care can be supplemented with house calls by

physicians, nurses, therapists, and chaplains. In any case, the family must know what their responsibilities are and must be well prepared to care for the patient. Recently, hospice home care was approved by Medicare and is being more widely used.

Family therapy sessions allow family members to explore feelings about death and dying. They serve as a forum in which anticipatory grief and mourning can take place. The ability to share feelings can be cathartic, especially if guilt is involved. Family members often have to deal with feelings of guilt about past interactions with the dying patient. Family sessions also help to achieve consensus about the patient's advance directives. If family members disagree about the patient's wishes, the medical staff may be unable to act. In such cases, legal action may be needed to resolve family disputes about what course of action to pursue.

PALLIATIVE CARE

Palliative care is the most critical part of end-of-life care. It refers to providing relief from the suffering caused by pain or other symptoms of a terminal disease. Although this is most commonly associated with analgesic drug administration, many other medical interventions and surgical procedures fall under the umbrella of palliative care because they can make the patient more comfortable. Monitors and their alarms, peripheral and central lines, phlebotomy, measurement of signs, and even supplemental oxygen are usually discontinued to allow the patient to die peacefully. Relocating the patient to a quiet, private room (as opposed to an intensive care unit) and allowing family members to be present is another critical palliative care modality.

The shift from active, curative treatment to palliative care is sometimes the first tangible sign that the patient will die, a transition that is emotionally difficult for everyone concerned about the patient to accept. The discontinuation of machines and measurements, which, up until this point, have been an integral part of the hospital experience, can be extremely disconcerting to the patient, family members, and even other physicians. Indeed, if these parties are not active in planning this transition, it can easily seem that persons have given up on the patient.

Because of this difficulty, palliative care is sometimes avoided altogether

(i.e., curative treatment is continued until the patient dies). This approach is likely to cause problems if it is adopted merely to avoid the reality of impending death. A well-negotiated transition to palliative care often decreases anxiety after the patient and family go through an appropriate anticipatory grief reaction. Furthermore, a positive emotional outcome is much more likely if the physician and staff project a conviction that palliative care will be an active, involved process, without a hint of withdrawal or abandonment. When this does not occur or when the family cannot tolerate the transition, the ensuing stress frequently results in a need for psychiatric consultation.

A 36-year-old physician with end-stage leukemia was seen in psychiatric consultation because he reported seeing the “angel of death” at the foot of his hospital bed. He described the experience as frightening and inexplicable. The consultant asked the patient, “Are you afraid that you are going to die?” That was the first time anyone had mentioned death or dying in any context to the patient. He welcomed the opportunity to talk openly about his fears to the medical staff and his family and eventually died a peaceful death.

Psychiatric consultation is indicated for patients who become severely anxious, suicidal, depressed, or overtly psychotic. In each instance, appropriate psychiatric medication can be prescribed to provide relief. Patients who are suicidal do not always have to be transferred to a psychiatric service. An attendant or nurse can be assigned to the patient on a 24-hour basis (one-on-one coverage). In such instances, the relationship that develops between the observer and the patient may have therapeutic overtones, especially with patients whose depression is related to a sense of abandonment. Patients who are terminal and who are at high risk for suicide are usually in pain. When pain is relieved, suicidal ideation is likely to diminish. A careful evaluation of suicide potential is required for all patients. A premorbid history of past suicide attempts is a high-risk factor for suicide in terminally ill patients. In patients who become psychotic, impaired cognitive function secondary to metastatic lesions to the brain must always be considered. Such patients respond to antipsychotic medications, and

psychotherapy may also be of use.

PAIN MANAGEMENT

Types of Pain

Dying patients are subject to several different kinds of pain, as summarized in Table 29-10. The distinctions are important because they call for different treatment strategies; whereas somatic and visceral pain is responsive to opiates, neuropathic and sympathetically maintained pain may require adjuvant medications in addition to opiates. Most patients with advanced cancer, for example, have more than one kind of pain and require complex treatment regimens.

Treatment of Pain

It cannot be overemphasized that pain management should be aggressive, and treatment should be multimodal. A good pain regimen may require several drugs or the same drug used in different ways and administered via different routes. For example, intravenous morphine can be supplemented by self-administered oral “rescue” doses, or intravenous bolus doses can supplement a continuous epidural drip. Transdermal patches may provide baseline concentrations in patients for whom intravenous or oral intake is difficult. Patient-controlled analgesia systems for intravenous opiate administration result in better pain relief with lower amounts dispensed than in staff-administered dosing.

Table 29-10
Types of Pain

Nociceptive Pain	
Somatic pain	Usually, but not always constant, aching, gnawing, and well localized (e.g., bone metastases)
Visceral pain	Usually, but not always constant, deep, squeezing, poorly localized, with possible cutaneous referral (e.g., pleural effusion leading to deep chest pain,

	diaphragmatic irritation referred to the shoulder)
Neuropathic pain	Burning dysesthetic pain with shock-like paroxysms associated with direct damage to peripheral receptors, afferent fibers, or the central nervous system, leading to loss of central inhibitory modulation and spontaneous firing (e.g., phantom limb pain; can involve sympathetic somatic afferents)
Psychogenic pain	Variable characteristics secondary to psychological factors in the absence of medical factors; rare as a pure phenomenon in patients with cancer but often an additional factor in the presence of organic pain

Courtesy of Marguerite S. Lederberg, M.D. and Jimmie C. Holland, M.D.

Opioids commonly cause delirium and hallucinations. A frequent mechanism of psychotoxicity is the accumulation of drugs or metabolites whose durations of analgesia are shorter than their plasma half-lives (morphine, levorphanol, and methadone). The use of drugs such as hydromorphone, which have half-lives closer to their analgesic duration, can relieve the problem without loss of pain control. Cross-tolerance is incomplete between opiates; hence, several should be tried in any patient with the dosage lowered when switching drugs. Table 29-11 lists opioid analgesics.

The benefits of maintenance analgesia administration in terminally ill patients compared with as-needed administration cannot be overemphasized. Maintenance dosing improves pain control, increases drug efficiency, and relieves patient anxiety, but as-needed orders allow pain to increase while waiting for the drug to be given. Moreover, as-needed analgesia administration perversely sets up the patient for staff complaints about drug-seeking behavior. Even when maintenance treatment is used, extra doses of medication should be available for breakthrough pain, and repeated use of these medications should signal the need to raise the maintenance dose. Depending on their previous experiences with opioid analgesics and their weight, it is not unusual for some patients to require 2 g or more of morphine

per day for relief of symptoms.

Knowing doses of different drugs and different routes of administration is essential to avoid accidental undermedication. For example, when changing a patient from intramuscular to oral morphine use, the intramuscular dose must be multiplied by 6 to avoid causing the patient pain and provoking drug-seeking behavior. Many adjuvant drugs used for pain are psychotropic with which psychiatrists are familiar, but in some cases, their analgesic effect is separate from their primary psychotropic effect. Commonly used adjuvants include antidepressants, mood stabilizers (e.g., gabapentin) phenothiazines, butyrophenones, antihistamines, amphetamines, and steroids. They are particularly crucial in neuropathic and sympathetically maintained pain, for which they can be the mainstay of treatment.

Table 29-11
Opioid Analgesics for Management of Pain

Drug and Equianalgesic Dose Relative Potency	Dose (mg IM or Oral)	Plasma Half-Life (hr)[a]	Starting Oral Dose[b] (mg)	Available Commercial Preparations
Morphine	10 IM 60 oral	3–4	30–60	Oral: tablet, liquid, slow-release tablet Rectal: 5–30 mg Injectable: SC, IM, IV, epidural, intrathecal
Hydromorphone	1.5 IM 7.5 oral	2–3	2–18	Oral: tablets: 1, 2, 4 mg Injectable: SC, IM, IV 2 mg/mL, 3 mg/mL, and 10 mg/mL
Methadone	10 IM 20 oral	12–24	5–10	Oral: tablets, liquid Injectable: SC, IM, IV
Levorphanol	2 IM 4 oral	12–16	2–4	Oral: tablets Injectable: SC, IM, IV
Oxymorphone	1	2–3	NA	Rectal: 10 mg Injectable: SC, IM, IV
Heroin	5 IM 60 oral	3–4	NA	NA
Meperidine	75 IM 300 oral	3–4 (normeperidine 12–16)	75	Oral: tablets Injectable: SC, IM, IV
Codeine	130 oral 200 oral	3–4	60	Oral: tablets in combination with acetylsalicylic acid, acetaminophen, liquid
Oxycodone[c]	15 oral 30 oral	—	5	Oral: tablets, liquid, oral formulation in combination with acetaminophen (tablet and liquid) and aspirin (tablet)

IM, intramuscular; IV, intravenous; NA, not applicable; SC, subcutaneous.

[a]The time of peak analgesia in nontolerant patients ranges from ½ to 1 hour and the duration from 4 to 6 hours. The peak analgesic effect is delayed, and the duration is prolonged after oral administration.

[b]Recommended starting IM doses; the optimal dose for each patient is determined by titration, and the maximal dose is limited by adverse effects.

[c]A long-acting sustained-release form of oxycodone (Oxycontin) has been abused by drug addicts, and its use has been criticized because of this; however, it is a very useful preparation available in 10-, 20-, 40-, and 160-mg doses that need to be taken once every 12 hours. It is used as a maintenance therapy for severe persistent pain.

Adapted from Foley K. Management of cancer pain. In: DeVita VT, Hellman S, Rosenberg SA, eds. *Cancer: Principles and Practice of Oncology*. 4th ed. Philadelphia, PA: JB Lippincott; 1993:936, with permission.

Other developments in pain management include more intrusive procedures, such as nerve blocks or the use of continuous epidural infusions.

Additionally, radiation therapy, chemotherapy, and even surgical resection can be considered as pain management modalities in palliative care. Short courses of radiotherapy or chemotherapy can be used to shrink tumors or manage metastatic lesions that cause pain or impairment. In patients with end-stage Hodgkin disease, for example, systemic chemotherapy can improve the patient's quality of life by decreasing tumor burden. Surgical resection of invasive tumors, most notably breast carcinomas, can be useful for the same reason.

PALLIATION OF OTHER SYMPTOMS

Symptom management is a high priority in palliative care. Patients are often more concerned about the day-to-day distress of their symptoms than they are about their impending death, which may not be as real to them. Table 29-12 lists common end-of-life symptoms. A comprehensive approach to palliation involves attending to these end-of-life symptoms as well as pain. Sources of distress include psychiatric symptoms, such as anxiety and physical symptoms. Foremost among physical symptoms are those involving the GI system, including diarrhea, constipation, anorexia, nausea, vomiting, and bowel obstruction. Other significant symptoms include insomnia, confusion, mouth sores, dyspnea, cough, pruritus, decubitus ulcers, and urinary frequency or incontinence. Caretakers should follow these symptoms carefully and establish appropriate early and aggressive care for these symptoms before they become burdensome.

An effective treatment for nausea and vomiting associated with chemotherapy is the use of Δ-tetrahydrocannabinol (THC), the active ingredient of marijuana. The oral synthetic cannabinoid, dronabinol (Marinol), is used in 1- to 2-mg doses every 8 hours. The use of marijuana cigarettes to deliver THC is believed to be more effective than pills. Proponents say that its absorption is faster and antiemetic properties are more potent via the pulmonary system. Repeated attempts to legalize marijuana cigarettes for medical use have met with only limited success in this country.

A 47-year-old man with incurable lung cancer who had been treated unsuccessfully with chemotherapy and radiotherapy had been suffering

from intractable dyspnea for 1 week. His family, nursing, and other staff were increasingly upset by his difficulty breathing and his pleas for relief. The attending physician refused to prescribe anything more substantial than codeine. The palliative care team at the hospital intervened at the family's request. Relief was obtained with the use of 5 to 10 mg of an intravenous bolus of morphine every 15 minutes. When the patient became comfortable, a continuous drip of intravenous morphine was instituted, complemented by subcutaneous morphine as needed.

Table 29-12
Common End-of-Life Symptoms/Signs

Symptom/Sign	Comments	Management/Care
Cachexia	All terminal disease states are associated with cachexia secondary to anorexia and dehydration	Feeding tubes useful in some cases; small sips of water of help
Delusions	Common in terminal state	Antipsychotic medication useful
Delirium/Confusion	Occurs in nearly 90% of all terminal patients but is reversible in over 50%	Can be reversed if cause is found and treatable; may respond to antipsychotic and/or pain medication
Depression or anxiety	Psychological factors, e.g., fear of death, abandonment and/or physiologic factors, e.g., pain, hypoxia	Antianxiety and antidepressant medication of use; opioids have strong antianxiety effects
Dysphagia	Seen in neurologic	Attention to oral care,

	disease, e.g., multiple sclerosis, amyotrophic lateral sclerosis	e.g., ice chips, lip balm; adjust to upright position when feeding
Dyspnea or cough	Associated with severe anxiety; fear of suffocation in extreme case; common in lung cancer patients	Opioids, supplemental oxygen, bronchodilators of use
Fatigue	Most common occurrence in terminal illness	Psychostimulants can be used for relief
Incontinence	Associated with radiation induced fistulas	Keep patient clean and dry; use indwelling or condom catheter if necessary
Nausea or vomiting	Side effect of radiation and chemotherapy	Antiemetics, e.g., metoclopramide, prochlorperazine; marijuana of use
Loss of skin integrity	Decubiti most common on weight-bearing areas	Turn body frequently; elbow and hip pads; inflating mattresses
Pain	Pain medications can be administered orally, sublingually, by injection or infusion, or via skin patch	Opioids are the gold standard

Data from National Coalition on Health Care (NCHC) and the Institute for Healthcare Improvement (IHI). Promises to Keep: Changing the Way We Provide Care at the End of Life, release, October 12, 2000.

The AMA supports the position that patients with a terminal condition require substantial doses of opioids regularly and should not be denied drugs for fear of producing physical dependence.

HOSPICE CARE

In 1967, the founding of St. Christopher's Hospice in England by Cicely Saunders launched the modern hospice movement. Several factors in the 1960s propelled the development of hospices, including concerns about inadequately trained physicians, inept terminal care, gross inequities in health care, and neglect of elderly adults. Life expectancy had increased, and heart disease and cancer were becoming more common. Saunders emphasized an interdisciplinary approach to symptom control, care of the patient and family as a unit, the use of volunteers, continuity of care (including home care), and follow-up with family members after a patient's death. The first hospice in the United States, Connecticut Hospice, opened in 1974. By 2000, more than 3,000 hospices were open in the United States. Round-the-clock pain control with opioids is an essential component of hospice management.

In 1983, Medicare began reimbursing hospice care. Medicare hospice guidelines emphasize home care, with benefits provided for a broad spectrum of physician, nursing, psychosocial, and spiritual services at home or, if necessary, in a hospital or nursing home. The patient is eligible for these services if the physician certifies them as having 6 months or less to live. By electing hospice care, patients agree to receive palliative rather than curative treatment. Many hospice programs are hospital-based, sometimes in separate units and sometimes in the form of hospice beds interspersed throughout the facility. Other program models include free-standing hospices and programs, hospital-affiliated hospices, nursing home hospice care, and home care programs. Nursing homes are the site of death for many elderly patients with incurable chronic illness, yet dying nursing home residents have limited access to palliative and hospice care. Families generally express satisfaction with their involvement in hospice care. Savings with hospice care vary, but home care programs generally cost less than conventional institutional care, particularly in the final months of life. Hospice patients are less likely to receive diagnostic studies or such intensive therapy as surgery or chemotherapy; however, a new trend is to allow treatment programs to

continue while the patient remains in the hospice. Hospice care is a proven, viable alternative for patients who elect a palliative approach to terminal care. Also, hospice goals of dignified, comfortable death for terminally ill patients and care for patients and families together have been increasingly adopted in mainstream medicine.

NEONATAL AND INFANT END-OF-LIFE CARE

Advances in reproductive medicine have increased the number of infants born prematurely as well as the number of multiple births. These advances have increased the need for life-sustaining methods of care and have made decisions about when to use palliative care more complicated. Some bioethicists believe that withholding life-sustaining interventions is appropriate under certain circumstances; others maintain that life-sustaining methods should not be used at all. An extensive study of attitudes among neonatologists about end-of-life decisions found no consensus about if and when to terminate life.

For newborns, the decision to forego life-sustaining procedures is usually limited to those children whose death is imminent. Even if their future quality of life is determined to be bleak, most physicians believe that some life is better than no life at all. Physicians who support withholding intensive care consider the following quality-of-life issues: (1) extent of bodily damage (e.g., severe neurologic impairment), (2) the burden that a disabled child will place on the family, and (3) the ability of the child to derive some pleasure from existence (e.g., having an awareness of being alive and being able to form relationships).

The American Academy of Pediatrics permits nontreatment decisions for newborns when the infant is irreversibly comatose or when treatment would be futile and only prolong the process of dying. These standards do not permit the parents to have any input in the decision-making process. In a well-publicized case in England in 2000, doctors decided to surgically separate conjoined twins, even though one would die from the procedure. This procedure occurred despite the objections of the parents, who believed that nature should take its course. Neonatal end-of-life decisions remain in a state of limbo. No clear-cut criteria exist about which patients should receive intensive care and which should receive palliative care.

CHILD END-OF-LIFE CARE

After accidents, cancer is the second most common cause of death in children. Although many childhood cancers are treatable, palliative care is necessary for children with cancers that are not. Children require more support than adults in coping with death. On average, a child does not view death as permanent until the age of about 10 years. Before then, death is viewed as sleep or separation. Therefore, children should be told what they can understand. If they are capable, they should be involved in the decision-making process about treatment plans. Assurances that patients are pain-free and physically comfortable are just as crucial for children as they are for adults.

A unique aspect of end-of-life care in children involves addressing their fear of being separated from their parents. It is helpful to have parents participate in end-of-life care tasks within their capacities. Family sessions with the child in attendance allow feelings to emerge and questions to be answered.

SPIRITUAL ISSUES

There is increasing awareness of the importance of this area to patients, families, and many staff members as well. Several studies have shown that religious beliefs are often associated with mature and active coping methods, and the field of psychological and spiritual interfaces in terminally ill patients is spawning a whole new area of psychological research within the traditional medical establishment. The psychiatric consultant should inquire about faith, its meaning, associated religious practices, and impact on the coping response. It can be a source of strength or guilt at all stages of the disease, ranging from the earliest “What did I do to cause this?” through “Will God give me only what I can carry?” to the poignant life review of the late stage. It is often a primary factor in the reactions to suicidality and attitudes toward terminal care decisions. Mental health professionals should deal with these areas in an unselfconscious and noncondescending manner and work to help patients fully integrate this aspect of their personality into their current crisis. The professional should also work in harmony with the patient’s spiritual guide if one is available. Sometimes an experienced chaplain working with

the appropriate patient can achieve positive results more directly than any psychotherapy. The following case exemplifies how creative pastoral care can relieve suffering.

A young woman was admitted to Calvary Hospital in a terminal state. She was experiencing a severe depression, which she attributed to not being able to see her oldest daughter receive her first communion. Arrangements were made for a ceremonial communion for her daughter to take place at Calvary Hospital. After the ceremony, the patient's mood improved markedly as one of her fears was alleviated, and a religious need was satisfied. As her mood improved, she was able to address other unresolved issues and had quality visits with her children in her remaining days. (From O'Neil MT. Pastoral care. In: Cimino JE, Brescia MJ, eds. *Calvary Hospital Model for Palliative Care in Advanced Cancer*. Bronx, NY: Palliative Care Institute; 1998, with permission.)

ALTERNATIVE AND COMPLEMENTARY MEDICINE

Many patients, when they are told they are terminally ill, seek alternative treatments, ranging from innocuous programs aimed at enhancing general health to more aggressive, harmful, or fraudulent regimens. Although most patients combine the alternative and the traditional, a substantial number favor complementary medicine as the only treatment for their disease.

Complementary methods to cure terminal illness, especially cancer, emphasize a holistic approach, involving purification of the body, detoxification through internal cleansing, and attention to nutritional and emotional well-being. Despite their widespread appeal, not one of these methods has been demonstrated to cure cancer or prolong life, yet all have strong followings bolstered by anecdotal accounts of their efficacy. The popular metabolic therapy attributes cancer and other potentially fatal illnesses to toxins and waste materials accumulating in the body; treatment is based on reversing this process by diet, vitamins, minerals, enzymes, and colonic irrigations. Another approach includes macrobiotic diets or megavitamins to enhance the body's capacity to destroy malignancy. In 1987, the National Research Council recommended minimizing carcinogenic

substances and fat in the diet and increasing whole-grain, fruit, and vegetable consumption as preventive guidelines. Psychological approaches cite maladaptive personality and coping styles as contributors to fatal diseases; treatment consists of shaping a positive attitude. Spiritual approaches aim at achieving harmony between the patient and nature. Some groups use spirituality as a way to ward off illness, which is sometimes seen as an external evil to be exorcised. Immunotherapies have gained popularity in recent years; cancer is attributed to a defective immune system, and restoration of immunocompetency is seen as the cure. Many patients find increased strength to endure the suffering of terminal illness with the help of alternative medicine even though the course of the disease may not be affected. (For a further discussion of alternative medicine, see Chapter 21.)

▲ 29.3 Euthanasia and Physician-Assisted Suicide

EUTHANASIA

From the Greek term for a good death, *euthanasia* means compassionately allowing, hastening, or causing the death of another. Generally, someone resorts to euthanasia to relieve suffering, maintain dignity, and shorten the course of dying when death is inevitable. Euthanasia can be *voluntary* if the patient has requested it or *involuntary* if the decision is made against the patient's wishes or without the patient's consent. Euthanasia can be *passive*—simply withholding heroic lifesaving measures—or *active*—deliberately taking a person's life. Euthanasia assumes that the physician intends to aid and abet the patient's wish to die.

Arguments for euthanasia revolve around patient autonomy and dignified death. One of the most dramatic ways patients can exercise their right to self-determination is by asking that life-sustaining treatment to be withdrawn. If the patient is mentally competent, physicians must respect such wishes. Proponents of active, voluntary euthanasia argue that the same rights should be extended to patients who are not on life-sustaining treatment but also choose to have their physicians help them die.

Opponents of euthanasia also provide strong ethical and medical justification for their position. First, active euthanasia, even if the patient voluntarily requests it, is a form of killing and should never be sanctioned. Second, many patients who request aid in dying may be suffering from depression, which, when treated, will change the patient's mind about wanting to die.

Most medical, religious, and legal groups in the United States are against euthanasia. Both the American Psychiatric Association (APA) and the AMA condemn active euthanasia as illegal and contrary to medical ethics; however, few individuals have been convicted of euthanasia. Most physicians and medical groups in other parts of the world also oppose legalizing euthanasia. In the United Kingdom, for example, the British Medical Association believes that euthanasia is "alien to the traditional ethos and moral focus of medicine" and, if legalized, "would irrevocably change the context of health care for everyone, but especially for the most vulnerable."

The World Medical Association issued the following declaration on euthanasia in October 2019:

The WMA is firmly opposed to euthanasia and physician-assisted suicide… no physician should be forced to participate in euthanasia or assisted suicide, nor should any physician be obliged to make referral decisions to this end.

Separately, the physician who respects the basic right of the patient to decline medical treatment does not act unethically in forgoing or withholding unwanted care, even if respecting such a wish results in the death of the patient. (*Adopted by the 70**th** WMA General Assembly, Tbilisi, Georgia, October 2019*, https://www.wma.net/policies-post/declaration-on-euthanasia-and-physician-assisted-suicide/)

Similarly, the New York State Committee on Bioethical Issues issued a statement declaring its opposition to euthanasia. The committee stated that physicians are obligated to relieve pain and suffering for the dying patient, even at the risk of hastening a patient's death. Physicians, however, should not perform active euthanasia or participate in assisted suicide. The Committee believed that support, comfort, respect for patient autonomy, good communication, and adequate pain control would dramatically decrease

the demand for euthanasia and assisted suicide. They argued that the societal risks of involving physicians in medical interventions to cause a patient's death were too significant to condone active euthanasia or physician-assisted suicide. In response to shifting public opinion and lobbying groups with different views, state laws that banned physician-assisted death in Washington State and New York were sent to the United States Supreme Court, challenging the constitutionality of these prohibitions. In June 1997, the Court unanimously held that terminally ill patients do not have the right to physician aid in dying. The ruling, however, left room for continuing debate and future policy initiatives at the state level.

PHYSICIAN-ASSISTED SUICIDE

In the United States, most of the debate centers on physician-assisted suicide rather than on euthanasia. Some have argued that physician-assisted suicide is a humane alternative to active euthanasia in that the patient maintains more autonomy, remains the actual agent of death, and may be less likely to be coerced. Others believe that the distinctions are capricious in that the intent in both cases is to bring about a patient's death. Indeed, it may be difficult to justify providing a lethal dose of medication to a terminally ill patient (physician-assisted suicide) while ignoring the desperate pleas of another patient who may be even more ill and distressed but who cannot complete the action because of problems with swallowing, dexterity, or strength.

Several degrees are seen to which a physician may assist the suicidal patient to end his or her life. Physician-assisted suicide can involve providing information on ways of committing suicide, supplying a prescription for a lethal dose of medication or a means of inhaling a lethal amount of carbon monoxide, or perhaps even providing a suicide device that the patient can operate.

The controversy over physician-suicide came to national attention surrounding the activities of retired pathologist Jack Kevorkian, who, in 1989, provided his suicide machine to a 54-year-old woman with probable Alzheimer disease. After the woman killed herself with his device, Kevorkian was charged with first-degree murder. The charges were later dismissed because Michigan had no law against physician-assisted suicide. Since that first case, Kevorkian assisted in several more suicides, often for persons he

met on only a few occasions and frequently for persons who did not have a terminal illness. Claiming to have helped more than 130 people take their lives, Kevorkian was sent to prison in 1999, was released in 2006, and died in 2011. His attorneys and followers applauded his courage in easing pain and suffering; his detractors countered that he was a serial mercy killer. Opponents of Kevorkian's methods charged that, without safeguards, consultations, and thorough psychiatric evaluations, patients might search out suicide not because of terminal illness or intractable pain but because of untreated depressive disorders. They argued that suicide rarely occurs in the absence of psychiatric illness. Finding more effective treatments for pain and depression, rather than inventing more sophisticated devices to help desperate patients kill themselves, defines compassionate and effective physician care.

In 1994, Oregon passed a ballot initiative legalizing physician-assisted suicide (Death with Dignity Act), making Oregon the first state in the United States to permit assisted suicides (Table 29-13). An assessment of the first 4 years revealed the following: Patients dying from physician-assisted suicide represent approximately eight of 10,000 deaths. The most common underlying illnesses were cancer, amyotrophic lateral sclerosis, and chronic lower respiratory disease. The three most common end-of-life concerns were loss of autonomy (85 percent), a decreasing ability to participate in activities that made life enjoyable (77 percent), and losing control of bodily functions (63 percent). Eighty percent of the patients were enrolled in hospice programs, and 91 percent died at home. The prescribing physician was present in 52 percent of the cases.

In 2001, Attorney General John Ashcroft attempted to prosecute Oregon doctors who helped terminally ill patients die, claiming that doctor-assisted suicide is not a legitimate medical purpose. The case was brought to the Supreme Court, which in 2006 supported the Oregon law and said the "authority claimed by the attorney general is both beyond his expertise and incongruous with the statutory purposes and design." Since 2001, three other states—Washington (2008), Montana (2009), and Vermont (2011)—have passed laws similar to the one in Oregon.

Table 29-13
Oregon's Assisted Suicide Law

- The patient must be terminally ill and expected to die within 6 mo; mentally competent; fully informed about his or her diagnosis, prognosis, risks, and alternatives, such as comfort care; and be making a voluntary choice.
- A second doctor must agree that the patient is terminally ill, acting on his or her own free will, fully informed, and capable of making health care decisions.
- If either doctor thinks that the patient is suffering from any form of mental illness that could affect his or her judgment, they must refer the patient for counseling.
- The patient must make one written request and two spoken requests.
- The doctor must ask the patient to tell the next of kin, but the patient may decide not to do so.
- The patient is free to change his or her mind at any time.
- There is a 15-day waiting period between the patient making the request and the doctor writing the prescription.
- All information must be written down in the medical records.
- Only people who normally live in Oregon may use the Act.
- Mercy killing, lethal injection, and active euthanasia are not permitted.
- Pharmacists must be told of the prescribed medication's ultimate use.
- Physicians, pharmacists, and health care systems are under no obligation to participate in the Death with Dignity Act.

Despite the abhorrence that many physicians and medical ethicists express regarding physician-assisted suicide, poll after poll shows that as many as two-thirds of Americans favor the legalization of physician-assisted suicide in certain circumstances, and evidence even indicates that the formerly uniform opposition to physician-assisted suicide within the medical community has eroded. Consistent with their positions on active euthanasia, the AMA, APA, and American Bar Association, however, continue to oppose physician-assisted suicide. Recently, the American College of Physicians-American Society of Internal Medicine (ACP-ASIM) expressed its commitment to improving care for patients at the end of life while

recommending against the legalization of physician-assisted suicide. The ACP-ASIM believes physician-assisted suicide raises grave ethical concerns, undermines the physician–patient relationship, and the trust necessary to sustain it alters the medical profession's role in society, and endangers the values American society places on life, especially on the lives of disabled, incompetent, and vulnerable individuals.

The American Association of Suicidology in its 1996 *Report of the Committee on Physician-Assisted Suicide and Euthanasia* concluded that involuntary euthanasia could never be condoned; the report also stated, however, that "intolerable, prolonged suffering of persons in extremis should never be insisted upon, against their wishes, in single-minded efforts to preserve life at all cost." This position acknowledges that patients can die as a result of treatment given to them for the explicit purpose of relieving suffering. However, death associated with palliative care differs significantly from physician-assisted suicide in that death is not the goal of treatment and is not intentional.

How to Deal with Requests for Suicide

To help guide clinicians facing requests for physician-assisted suicide, the AMA's Institute for Ethics proposed an eight-step clinical protocol. Table 29-14 lists these steps.

Table 29-14
The AMA's Recommended Approach to Requests of Physician-Assisted Suicide

1. Evaluation of the patient for depression or other psychiatric conditions that could cause disordered thought
2. Evaluation of the patient's "decision-making competence"
3. Discussion with the patient about his or her goals for care
4. Evaluation and response to the patient's "physical, mental, social, and spiritual suffering"
5. Discussion with the patient about the full range of treatment and

care options

6. Consultation by the attending physician with other professional colleagues

7. Assurance that care plans chosen by the patient are being followed, including removal of unwanted treatment and the provision of adequate pain and symptom relief

8. Discussion with the patient explaining why physician-assisted suicide is to be avoided and why it is not compatible with the principled nature of the care protocol

Psychiatrists view suicide as an irrational act that is the product of mental illness, usually depression. In almost every case in which a patient asks to be put to death, a triad exists of depression associated with an incurable medical condition that causes intolerable pain. In these instances, every effort should be made to provide antidepressants or psychostimulants for depression and opioids for pain. Psychotherapy, spiritual counseling, or both may also be needed. Also, family therapy to help with the stress of dealing with a dying patient may be necessary. Family therapy is also useful because some patients may ask to be put to death because they do not wish to be a burden to their families; others may feel coerced by their families into believing that they are, or will be, a burden and may choose death as a result. Currently, no professional codes countenance euthanasia or assisted suicide in the United States. Therefore, psychiatrists must stand on the side of responsible rescue and treatment.

A distinction also is needed between major depression and suffering. Psychiatrists have not sufficiently studied the nature of suffering. It remains the province of theologians and philosophers. Suffering is a complex mix of spiritual, emotional, and physical factors that transcends pain and other symptoms of a terminal illness. Physicians are more skilled at dealing with depression than with suffering. Anatole Broyard, who chronicled his death in his book *Intoxicated by My Illness*, wrote the following:

> I see no reason or need for my doctor to love me nor would I expect him to suffer with me. I wouldn’t demand a lot of my doctor’s time; I just

wish he would brood on my situation for perhaps 5 minutes, that he would give me his whole mind just once, be bonded with me for a brief space, survey my soul as well as my flesh, to get at my illness, for each man is ill in his own way.

FUTURE DIRECTIONS

Advances in technology bring more complex medical, legal, moral, and ethical controversies regarding life, death, euthanasia, and physician-assisted suicide. Some forms of euthanasia have found a place in modern medicine, and expansion of the boundaries of patients' rights and their ability to choose the way they live and die is inevitable. Both patients and physicians need to be better educated about depression, pain management, palliative care, and quality of life. Medical schools and residency training programs need to give the topics of death, dying, and palliative care the attention they deserve. Society must ensure that economics, ageism, and racism do not get in the way of adequate and humane management of patients with chronic terminal illnesses. Finally, a national health care policy must provide adequate insurance coverage, home care, and hospice services to all appropriate patients. If these mandates are followed, the argument for physician assistance in dying will lose much of its impact.

30 Community Psychiatry

INTRODUCTION

The subject area of public psychiatry embodies a fundamental core of experience and tradition. In the context of the reexamination of American health care initiated by the effect of managed care and the health care reform, the experience of public psychiatry is poised to serve as the foundation for a transformation of behavioral health care.

The term *public* can refer to psychiatric programs, treatments, or institutions paid for by public funds or as objects of public policy, whether paid for or not. The traditional concept of public psychiatry has been expanded to include medical and psychosocial initiatives directed for the public good, whether funded by public or private funds and directed in particular to those who are economically disadvantaged.

The care and treatment offered under public psychiatry are delivered in a variegated mosaic of inpatient and community-based services that are more or less integrated into a coherent network sponsored by public agencies. Funding for public psychiatric services tends to be provided by federally legislated appropriations that are passed through the state, county, and municipal government agencies (such as departments of mental health; substance use treatment services; children, youth, and family services; and public health, social services, education, adult corrections, and juvenile justice agencies). Ultimately, most public psychiatry and community services are provided by not-for-profit community mental health, substance use treatment, child guidance, or health care organizations that are either funded by or subcontracted to government agencies. Thus, the very existence of public and community psychiatric services and the policies and resources

determining how they are delivered are dependent on legislative mandates and fiscal appropriations from all levels of public government.

CONTEMPORARY PUBLIC AND COMMUNITY PSYCHIATRY

There are five themes around which the discussion of contemporary public and community psychiatry is structured: public health, public agencies, evidence-based psychiatry, roles for psychiatrists, and delivery systems.

Public Health

Public health is not merely publicly funded health care but is instead a specific discipline and tradition. It is a complicated field that historically has been defined negatively by the dominance of *personal health*, that is, the health care delivery systems that take care of individual patients. Until the advent of managed care in the 1990s, U.S. health care was an industry mainly organized in terms of individual doctor-entrepreneurs. Each jurisdiction uniquely defined and organized its public health programs, and the particular pattern of personal health practices had a substantial influence—hence the wide variation in public health programs. Nonetheless, as a discipline and tradition, public health's mission is to assure the conditions in which people can be healthy. Public health consists of organized community efforts aimed at the prevention of disease and the promotion of health. It involves many disciplines but rests on the scientific core of epidemiology. It provides an essential template for contemporary public and community psychiatry.

The Surgeon General's report on mental health underscored the necessity of a public health approach to care and rehabilitation for people experiencing mental illness that is "broader in focus than medical models that concentrate on diagnosis and treatment." Although diagnosis and treatment are core areas of expertise for all psychiatrists, the Surgeon General recommended that even when psychiatric diagnosis or treatment is the primary focus for practitioners, researchers, or educators, they should ground their professional activities in a vision and knowledge base that is "*population-based*… encompass[ing] a focus on epidemiologic surveillance, health promotion, disease prevention, and access to services." These fundamental public health functions define the public health perspective in public and community psychiatry. In the

discussion that follows, these four public health components are framed in current terms of health care reform to define a coherent "public health" strategy for public and community psychiatry.

Health Promotion

Psychiatric professionals can contribute substantially to the promotion of public health by working with primary health care professionals and educators to identify and provide front-line treatment and referrals to adults and children who have undetected psychiatric symptoms, subthreshold syndromes, and psychiatric disorders. Collaborative care models bring psychiatric professionals into primary care and school settings as consultants for medical, nursing, and education professionals. These professionals work in those settings, as well as for educators and direct treatment providers to at-risk or psychiatrically impaired individuals.

Furthermore, people with identified mental illness or addictive disorders can benefit from enhanced physical and mental health care, as well as from the alleviation or management of psychiatric symptoms. Achieving or regaining physical or mental health (i.e., recovery) depends not only on genetic and biologic factors but also on a person's or family's access to social and psychological resources and integration into supportive social networks. Illness management (also known as *disease management* or *chronic illness care management*) is a framework that has been adapted from medicine to guide mental health professionals in delivering services that go beyond traditional diagnostic treatment to promote the health and recovery of people with mental illness or addiction. *Illness management* has been defined as "professional-based interventions designed to help people collaborate with professionals in the treatment of their mental illness, reduce their susceptibility to relapses, and cope more effectively with their symptoms… [to] improve self-efficacy and self-esteem and to foster skills that help people pursue their personal goals." Several approaches to illness management have been scientifically and clinically evaluated and have been found to enhance standard psychiatric treatment.

Prevention. Psychiatric disorders most often follow a course over time that begins with an often lengthy period in which prodromal or subthreshold

symptoms or functional problems precede the full onset of a disorder with marked impairment. Intervention with adults, adolescents, or children who are not clinically impaired but who are at high risk or who are manifesting preclinical symptoms or functional problems is an approach to prevention that is cost-effective because it targets a relatively small group of individuals promptly. Examples of high-risk patients include those with a family history of psychiatric or addictive disorders or exposure to extreme stressors, such as violence, neglect, or antisocial behavior. Also, prodromal symptoms and behaviors that would argue for early intervention include periodic or pervasive dysphoria, problems with separation from caregivers, or involvement with deviant peers.

Application of the traditional public health concepts of *primary, secondary,* and *tertiary psychiatry* has been confusing in psychiatry. *Primary prevention* involves addressing the root causes of illness with healthy individuals, to prevent illness before it occurs. *Secondary prevention* involves the early identification and early treatment of individuals with acute or subclinical disorders or *high-risk* persons to reduce morbidity. *Tertiary prevention* attempts to reduce the effects of a disorder on an individual through rehabilitation and chronic illness care management. The Institute of Medicine, to help clarify different aspects of prevention, developed a classification system with three different categories. *Universal* interventions are those intended for the general public, such as immunizations or media campaigns, providing information about illnesses, early warning signs, and resources for health promotion and timely treatment. *Selective* interventions focus on individuals at higher-than-average risk (e.g., persons with prodromal symptoms or a family history of psychiatric disorders) to reduce morbidity by enhancing resilience and preventing the onset of illness. *Indicated interventions* target individuals who are experiencing impairment as a result of illness as early as possible in the course of the illness, to reduce the burden of the illness on the individual, family, community, and treatment system. Psychiatric services most often take the form of indicated interventions, but the smaller number of psychiatric practitioners and researchers who conduct and evaluate selective or universal interventions in public and community settings is making a substantial contribution to the broader health of society.

Prevention interventions are effective with adults with a variety of risk factors or preclinical problems. For example, women who have been raped

are less likely to develop posttraumatic stress disorder (PTSD) if they receive a five-session cognitive-behavioral treatment than if their recovery is left to chance. People with subthreshold symptoms of depression who are identified early by their primary care providers are less likely to develop the full syndrome if their medical treatment includes education about depression and learning skills for coping actively with depressive symptoms or stressors. Prevention with adults must be judiciously designed to address the specific factors that place a person at risk for illness or that enhance the person's ability to cope effectively. For example, brief supportive meetings with people who have experienced a traumatic stressor (e.g., a mass disaster or life-threatening accident) tend to have little benefit and may inadvertently intensify posttraumatic stress. In contrast, a focused cognitive-behavioral approach to teaching skills for coping with traumatic memories and stress symptoms is effective in preventing posttraumatic stress and depressive disorders with adult and child disaster or accident survivors.

Several prevention programs have been developed and evaluated to address physical and mental health risks in childhood and adolescence, incorporating several elements that influence intervention effectiveness. Their broad and systematic implementation, however, has been halting. Some states have made an effort to implement *school-based* interventions involving teachers and the peer group. These tend to be more effective than programs exclusively relying on intervening with parents or children alone. Such interventions in middle childhood have been successful in influencing peer group norms regarding alcohol and substance use, violence and bullying, and depression, thus achieving the dual outcome of reducing immediate initiation of alcohol and substance use and increasing the long-term support within the peer group for sustained abstinence into adolescence. Thus, systems-based *multimodal* interventions simultaneously targeting and developing enhanced relationships among the child, peer group, school personnel, parents, and the wider community tend to be most effective as universal or selected approaches to early prevention of what otherwise may become lifelong behavioral, legal, academic, and addictive problems.

Access to Effective Mental Health Care. Access is a significant problem for most people with severe mental illness or addictions. In the United States, the National Comorbidity Survey (NCS) and the National

Comorbidity Survey-Replication (NCS-R) found that fewer than 40 percent of people with severe psychiatric disorders had received any mental health treatment in the previous year, and fewer than one in six (15 percent) had received minimally adequate mental health services. Young adults, African Americans, people residing in specific geographical areas, people with psychotic disorders, and patients treated by medical but not mental health providers were at the highest risk for inadequate psychiatric treatment. Although income was not a predictor of inadequate treatment, many of the people who did not receive adequate mental health services were likely to be uninsured or underinsured. Such people often cannot access mental health care other than through a primary care provider or clinic or in the public mental health system.

Even when mental illness is identified, people with socioeconomic adversities often do not, or cannot, get adequate mental health services in their communities. For example, although it is estimated that more than 200,000 incarcerated adults in the United States have psychiatric disorders, few were detected or received treatment until they reached jail or prison. Federal and state correctional systems have instituted mental health screening and treatment programs to address psychiatric disorders as a health problem for incarcerated adults and to manage the problematic behavior that can occur in controlled settings as a result of mental illness. On returning to the community, the vast majority of prisoners with psychiatric disorders cease to receive more than minimal mental health services: A recent study found that fewer than one in six (16 percent—strikingly similar to the NCS finding) received steady mental health services, and only one in 20 with addictions received steady substance abuse recovery services. Thus, access to mental health and addiction treatment services is far better *in prison* than in the community! This disparity has caused great concern because of the possibility that correctional facilities may be a de facto system of care for low-income people (often of minority backgrounds) with serious mental illness.

Evidence of severe and pervasive barriers to accessing mental health care can be found in several social crises. Impoverished children and adults increasingly are deferring physical and mental health care until illnesses become chronic and severe and then often do not know or cannot gain entry into any setting for services except public hospital emergency departments.

Children with severe psychiatric or behavioral disorders are being held in emergency department facilities for days and even weeks because the staff cannot locate any available treatment facilities with an appropriate level of care, especially if they are underinsured. People who cannot afford private services thus face daunting obstacles when seeking appropriate mental health care as a result of a severe underfunding of practitioners and programs. The public policy dilemmas that are driven by the ever-increasing cost of health care bear directly on the field of public psychiatry. It also tragically affects the lives of tens or hundreds of thousands of people who do not receive adequate care.

Psychiatry and Public Agencies

Psychiatry's relationship to public sector agencies has, with some specific exceptions, been one of detachment because of the dominance of the private practice models before the advent of managed care and also mainly because of the nature and structure of U.S. social welfare programs. This separation is a divide that often begins during academic preparation, in that many psychiatry training programs eschew meaningful rotations in public sector settings. In contrast to most industrial nations in which comprehensive social welfare reforms have been initiated, U.S. social welfare programs grew incrementally and categorically, that is, one category of service at a time. Large-scale initiatives, such as President Johnson's War on Poverty, have been implemented in piecemeal fashion by fragmented federal, state, and local government bureaucracies and have been vastly reduced through subsequent initiatives, such as the recent changes in federal regulations to "end welfare as we know it." Various social service agencies have been created through a process, and set of alliances called the *iron triangle.* Advocates form an organization to champion a particular cause. Example causes may include blindness, developmental disabilities, primary care, or mental health, among others. The advocates then find key legislative sponsors to advance the cause through legislation and appropriation. This creates a bureaucracy and bureaucrats that join the alliance. Through successive legislative sessions, the alliance of advocates, lawmakers, and bureaucrats builds a more durable and more reliable categorical agency, for example, adults and families with dependent children or people with

biologically based severe mental illness. From the 1930s through the end of the twentieth century, U.S. social welfare agencies were created on this pattern; the system has resulted in generous funding but a hopeless fragmentation of services at local service delivery levels in which each agency depends on separate funding silos that also deliver conflicting rules and regulations.

It has been said that "mental health is not a place." Psychiatrists have a role at the receiving end of every categorical silo, as the clients in each agency experience mental illness. Services for children with severe emotional, mental, or behavioral disturbances are a dramatic case. Five categorical agencies—child welfare, education, primary health, substance abuse, and juvenile justice—all have a responsibility to care for these children (and, indirectly, for their caregivers, including parents and families). Especially for the children with the most severe disabilities, the protective service worker taking a child into court, the special education teacher working day to day with the child, the juvenile probation officer, the substance abuse counselor, and the child's pediatrician all need the consultation and support of a skilled psychiatrist. The situation is similar for adults with severe mental illness, for whom case managers, vocational rehabilitation counselors, basic needs benefits specialists, social workers, psychotherapists, substance abuse counselors, parole or probation officers, legal conservators, visiting nurses, peer specialists, and physicians all may be mandated to deliver services.

Workforce Influences on Contemporary Practice

Shortages in the ranks of psychiatry have been well documented historically, and some project this to continue. However, as the field of psychiatry connects with its science and evidence base (e.g., neuroscience, genetics, pharmacology, outcomes science) while retaining its strength in the meaningful connection with patients and their families, some would argue that the reversal of the shortage trend has begun. The National Institutes of Health (NIH) sponsored Decade of the Brain (the 1990s), and Decade of the Mind (the 2000s) contributed to this change. Medical students are increasingly stimulated to enter the field by recognizing the importance of psychiatry to health care in general, realizing that this is still a field in which the practitioner (and by extension, the interdisciplinary team) is an instrument

of change through integration of contemporary knowledge, skillful learned interactions with patients, and a willingness to commit to providing value. The national aggregate numbers, however, cannot adequately capture the extreme variations that exist geographically; rural and frontier sites are dramatically more likely to experience shortages than more urban environments.

Because subsets of the public sector populations have special needs, responses to their needs have to be correspondingly tailored:

- Children and family needs are expressed differently than those for adults and require different responses.
- Mental illnesses have culturally driven ways of presenting, and interventions must be culturally competent.
- Issues of language (including American Sign Language with deaf and hard of hearing individuals) can complicate diagnosis and treatment.
- The rapidly expanding elderly population will pose significant new challenges for effective treatment.

Just these few examples suggest the sophistication with which education and training must be engineered to meet the existing and changing demands of people in need of services.

Contemporary Evidence Base for Effective Public and Community Psychiatry

Since the 1980s, several structured interventions have been developed to address the gap between what historically has been taught in most psychiatry training programs—typically, an office-, clinic-, or hospital-based approach focusing on diagnoses and pharmacotherapy supplemented by psychotherapy—and the competencies required to deliver or to support the delivery of the full array of psychiatric rehabilitation services. Public and community approaches to psychiatric rehabilitation involve not only pharmacotherapy but also an array of complementary services. These services must be coordinated to assist people with severe mental illness or behavioral disorders. The services much also help patient's families and support systems. Patient's and their loved ones need help with managing symptoms, accessing resources, and using these resources effectively. The goal of this

support is to help patients gain the highest degree of autonomy in the least restrictive setting possible. The competencies required to effect these interventions go beyond the scope of psychiatry, thus requiring that psychiatrists effectively collaborate with other rehabilitation and mental health specialists. Although psychiatrists rarely implement the educational psychotherapy and other interventions involved, psychiatrists should be aware of them and understand how to reinforce them. Hence, familiarity with the manuals that describe how to implement these interventions with fidelity is strongly advised—and increasingly incorporated into psychiatry training.

Evidence-Based Manualized Interventions for Child Psychiatric Rehabilitation. Children with severe emotional disturbances and adolescents with severe behavioral disorders traditionally have been removed from their families and placed in restrictive psychiatric or juvenile justice settings (e.g., psychiatric inpatient wards, residential group homes, and juvenile detention centers). These placements separate the child from the natural family, school, peer group, and community environments, which may provide some benefit by reducing the child's exposure to addiction, conflict, violence, or deviant behavior. However, the placements also deprive the child and family of the opportunity to build better relationships with one another and with other children, families, teachers, and community groups. The second key ingredient to effective public and community child psychiatry comprises interventions that complement pharmacotherapy. Since the 1970s, several rehabilitative approaches for children with severe disorders (and their families) have been developed, tested, and disseminated in replicable manuals and training programs.

Implementation of evidence-based practices is not always easy. It rarely occurs even in clinics and practice groups that are well trained and motivated to use evidence-based treatment models, given that most current systems of payment and service delivery were not designed to accommodate or support the use of science-based interventions such as those highlighted here. Also, evidence-based dissemination and implementation strategies must be deliberately designed to support the initial adoption and sustained use of evidence-based mental health treatment models. For example, a recent study of the implementation of one of the most widely disseminated evidence-based mental health interventions for children and families, multisystemic

therapy (MST), demonstrated that initial training yielded a very positive early rate of adoption of the program with reasonable fidelity to the model. However, only teams that were provided with regular ongoing supervision and support (for supervisors as well as therapists) from expert consultants were able to sustain the initial successes.

Roles of Psychiatrists in Public and Community Psychiatry Multidisciplinary Teams

Psychiatrists in the public sector rarely work in isolation. Most often, psychiatrists work within a team of professionals. The team includes many disciplines, including psychology, social work, nursing, occupational therapy, rehabilitation or addiction counseling, social services, housing, and employment specialists. It also includes nondegreed direct care workers, such as bachelor's degree-level counselors or case managers, high school graduate indigenous outreach workers, peer-support specialists, and family advocates. Each of these members brings unique skills and experience to address the needs of people with severe and persistent mental illnesses. The team, rather than any single provider, assumes responsibility for the ongoing care of each patient across the many levels of services and often for many years. Its success is based on effective communication. Every communication should be explicitly focused on the *client's* (i.e., patient and family) *stated goals*, as well as on the team's technical and logistical issues, to maximize the client's motivation to participate actively and productively in all services by ensuring that the services indeed are patient-centered and collaborative.

Psychiatrists play three primary roles in multidisciplinary psychiatric rehabilitation teams: Conducting psychiatric evaluations, providing pharmacotherapy, and serving as the team's medical director (and, at times, as the administrative supervisor or team leader).

Psychiatric Evaluation and Diagnosis. As with any practice setting, the sine qua non in the public and community setting is a thorough evaluation. This involves a complete history and examination leading to an accurate diagnosis. The goal of evaluation and diagnosis is to develop the most clinically useful individualized approach to treatment and rehabilitation for each patient. Psychiatric evaluations in public and community settings must

include a careful review of the individual's psychosocial strengths and resources. The focus on strengths and resources often is lost or obscured when systemic factors (e.g., eligibility regulations for government funded services or benefits) emphasize disability. It can also limit the individual's or family's access to services or benefits (e.g., welfare-to-work regulations that place a time or other eligibility restrictions on types of temporary aid, such as food stamps or vouchers for household supplies or housing).

Pharmacotherapy. The psychiatrist's most visible role usually is providing pharmacotherapy. The most difficult challenge in public sector mental health settings often is not the technical formulation of an effective medication regimen but instead the arranging of a plan of care so that the patient reliably follows the prescribed regimen (i.e., *adherence* or *compliance*). A recent review of interventions designed to enhance adherence to psychotropic medication regimens by patients with schizophrenia found that education alone often was the only strategy used. This is true despite evidence showing that the optimal strategy includes such approaches as concrete problem solving, motivational techniques, and practical assistant (reminders or cues for example). Although the psychiatrist must address technical, medical issues around diagnosis and treatment, effective pharmacotherapy largely depends on providing practical assistance. This approach includes helping patients manage the stresses and problems that might affect adherence. Such practical assistance might be direct, as in encounters with patients, or indirect, by working closely with nonpsychiatric mental health professionals and nondegreed care workers.

Team Leadership. The psychiatrist also often plays a leadership role as the project or program medical director—with the attendant responsibilities of monitoring the medical safety and well-being of all patients and establishing or supporting management and clinical procedures that support the quality of care and a cohesive treatment team. As the team leader or only as a team member, the psychiatrist serves as a role model for compassionate and professional behavior in relation not only to patients but also to all other team members. Formal or informal leadership is especially important when psychiatry residents and medical students work on a team as a training experience. The team psychiatrist serves not only as a mentor and a role

model for the core aspects of psychiatric practice but also to demonstrate the values and skills necessary to integrate psychiatry within the framework of multimodal community-based longitudinal psychosocial interventions.

Psychiatrists who work in these settings and desire a leadership role must go beyond their prescription pads to acquire more expertise. This expertise requires gaining the knowledge, attitudes, and skills relevant to the contemporary practice guidelines for psychiatric rehabilitation. It also includes respecting and supporting other team members and earning their respect and support in return. Also, the psychiatrist must cope with large caseloads, and collaborate with agencies and programs to ensure continuity, consistency, and coordination of care. If psychiatrists can incorporate these attitudes and skills, they can expect reciprocity and cohesion from other team members, and clients will benefit. Surveys of psychiatrists in the public sector indicate that those who embrace the rehabilitation perspective by expanding their roles to be consultants and teachers for patients, families, trainees, and colleagues from other mental health disciplines are more satisfied professionally than those who focus on diagnosis and treatment alone.

New Paradigms. Virtually all health care should be integrated and coordinated to deliver practical, rational, and cost-efficient care. The broader, contemporary definition of care must include public health. Linking public health models with acute care management, which, in turn, is coupled with chronic illness care management, rehabilitation, or recovery models, represents the continuum for an integrated system.

However, this continuum is insufficient without four other components: (1) the application of new research to improve care and the application of bench-to-bedside models to translational research, (2) meaningful involvement of patients and families in a shared decision-making paradigm, (3) integration with primary and specialty care systems, and (4) the development of the clinical system as a system of advocacy. Training preprofessionals in such a model is one approach to introduce meaningful and sustained change to health care and its delivery and is already operational in some systems.

New Models for Service Delivery and Treatment

Organized Systems of Care. The focus of reform has moved increasingly to coherent, efficient, and accountable delivery systems. The basic idea of the *system of care* for children with severe emotional disturbances can be described in two ways—in terms of interagency structures and clinical processes. Five categorical agencies in a given community form a *strong consortium* that targets a specific population of children (and their families) to whose needs none of the agencies can adequately respond on their own. The consortium agencies commit themselves to treat the child and family with a *common plan of care* and to find ways to pool their resources to do so appropriately. This care often requires that in the central bureaucracies at the state level, a parallel interagency commitment be in place that supports the local system of care initiative, resolves any regulatory conflicts that may arise, and gives permission to innovative aspects of the delivery system. The collaborative interagency structure provides the resources and flexibility for effective clinical work.

From the viewpoint of *clinical processes,* the system of care provides a full enactment of the traditional clinical practice that meets the requirements of medical quality assurance. What is different is that it is carried out in-home and community settings, and it involves participants from different disciplines—child welfare, special education, and juvenile justice—in one standardized treatment methodology. The center of the system of care is the *child and family team* that is made up of the child and family, clinicians and agency representatives involved in the case, and significant supportive individuals identified by the child and family. Current issues are reviewed—strengths, problems, and needs—diagnostic issues are considered, clinical goals are articulated, and appropriate treatment strategies are identified. The expected outcome of each intervention is specified, and progress toward it is systematically charted. The system of care requires a full array of flexible services. The essential *starters* include clinical diagnostic services, care coordination or case management, crisis intervention services, and a flexible essential supportive service—child care specialists who can be assigned to support the child and family in any situation. Particularly effective systems of care have relied on substantial community organization and collaboration or innovative funding models, or both, that blend or braid funding streams to focus on clear assignment of responsibility for a particular child and family,

as well as adequate resources.

The basic model for community support for adults was called *assertive community treatment* (ACT). ACT was implemented with multidisciplinary teams with psychiatrists, nurses, psychologists, social workers, psychiatric aides, and paraprofessionals. The ACT team would assume the care of a designated number of adult patients with severe and persistent mental illness and would be available around the clock, 7 days a week. The team would help find housing, manage money, organize household routines, find social contacts, find work, and support the individual's adjustment to workplace settings. Concurrently, medications would be managed and help provided to facilitate an individual adjusting to community living. At the heart of the program was the necessary clinical process that developed and maintained an individualized treatment plan, which was adjusted continuously to the changing needs of each client. The ACT model has been modified in various ways as it has been implemented in different states. Innovative funding models have been developed in several states by using bundled rates and case rates, which make it easier to implement and to sustain than traditional fee-for-service payment systems.

In contemporary managed care terms, ACT teams are *disease and disability management models* that assign accountability to provide systems that may not assume risk in managing community support of persons with disabling conditions. The National Alliance on Mental Illness (NAMI) has developed program models and protocols for the Program for Assertive Community Treatment (PACT) to encourage public agencies to contract for ACT services.

Effective Treatment Models. The previous discussions have outlined the various treatment models that have been introduced since the 1980s to establish an evidence base for the effectiveness of specific interventions and approaches to care. The attention to *evidence-based* treatment models has been a response to the call for quality and accountability for service outcomes demanded from health care services in general by purchasers and policymakers and part of an effort to cope with the difficulties of evaluating service delivery models or systems of care.

The movement to evidence-based services is necessary to break down components of the service delivery system to determine the relative

effectiveness of specific service interventions using the evaluative tools and methods that are available. Eventually, the case will be made to address the broader policy questions concerning the value of coherent and rationally organized service delivery in mitigating the effects of mental disability on the development of the child and enabling the recovery process for adults with severe and persistent mental illness.

Table 30-1 summarizes some of the evidence-based treatments used in adult psychiatric rehabilitation, and Table 30-2 summarizes treatment for children.

Table 30-1
Evidence-Based Manualized Interventions for Adult Psychiatric Rehabilitation

Modality	Goals and Targeted Areas	Results of Evaluation Research
Social and independent living skills	Teaches skills for managing symptoms and preventing relapse (mental illness and addictions), improving social communication with providers, peers, and family, and choosing and engaging in activities that match the person's abilities, limitations, and	Social and independent living skills evaluated in randomized, clinical trials show positive outcome, with increased successful community living and reduced rehospitalization

	interests	
Assertive community treatment (ACT)	Provides ongoing care coordination and case management to increase ability to live independently in the community and prevent/manage psychiatric crises	Randomized effectiveness trials with adults and adolescents with serious and persistent mental illness and co-occurring addictive disorders demonstrate increased psychiatric, residential, and vocational stability
Cognitive-behavior therapy (CBT)	Teaches skills for recognizing and modifying thoughts and beliefs that increase or prolong distress, and strengthening thoughts and beliefs that are self-affirming and interpersonally assertive	Meta-analyses support CBT's efficacy in reducing the severity of anxiety disorders, somatoform disorders, bulimia, anger control problems, and generalized stress reactions, and offer modest support for CBT as an adjunctive treatment with addictive disorders and serious mental illness
Dialectical behavior therapy	Teaches skills for regulating intense emotions, tolerating extreme	Evaluated in randomized clinical trials with parasuicidal adult patients with borderline personality disorder, resulting in reduced behavioral and

	emotional distress, achieving interpersonal effectiveness, and developing mindfulness	psychiatric crises greater than that achieved by expert psychiatrists' treatment
	Originally developed for adults with borderline personality disorder, but has been adapted for use with a wide range of Axis I disorders in which extreme dysregulation and poor impulse control are problematic	Randomized clinical trials and observational studies show positive psychosocial outcomes with adults with severe and persistent mental illness and chronic addictions and with adolescents who are suicidal or self-harming, including those who have substance abuse or posttraumatic stress disorders (PTSDs)
Acceptance and commitment therapy	Teaches skills for identifying and managing (rather than avoiding and feeling controlled by) the symptoms of psychosis, affective, anxiety, eating, traumatic stress, and addictive disorders.	Randomized clinical trials show evidence of increased awareness but reduced distress and impairment due to psychiatric symptoms across a variety of psychiatric disorders in outpatient and inpatient treatment settings

	Acceptance of symptoms facilitated by explanation that psychotic symptoms are extreme versions of normal perception and cognitive phenomena (private experiences)	
Relapse prevention therapy	Teaches skills for identifying the warning signs of potential or actual resumption of substance use or psychiatric symptoms Uses cognitive-behavioral skills for proactively modifying patterns of thought and behavior that are likely to escalate into a full relapse	Randomized clinical trials show efficacy in delaying, reducing the severity of, and preventing substance use relapse with adults with chronic addictions and co-occurring or comorbid psychiatric disorders
Interpersonal psychotherapy	Teaches skills for interacting and communicating	Randomized clinical trials show evidence of reduced severity and risk of relapse

	effectively in close relationships, with a particular focus on overcoming four core interpersonal problems: unresolved grief, role conflict (e.g., dissatisfaction with parenting), role transition (e.g., marital separation), and interpersonal deficits (e.g., isolation and anger management)	of moderate to severe depression, PTSD, anxiety disorders, and eating disorders
Behavioral therapy	Provides systematic reinforcement contingencies to increase adaptive behavior and to extinguish maladaptive behavior	Randomized effectiveness trials show evidence of reduced alcohol, drug, and other addictive behaviors
Motivational enhancement therapy	Teaches skills for recognizing and aligning choices and behavior	Randomized effectiveness trials show evidence of reduced alcohol, drug, and other addictive behaviors

	with personal motivations	
Trauma-focused CBT for PTSD	Teaches skills for safely recalling rather than avoiding troubling memories of traumatic events and for recognizing and managing PTSD symptoms, such as intrusive memories or flashbacks, emotional numbing, dissociation, and distress (e.g., guilt, grief), and problems with sleep or anger, or concentration problems due to hyperarousal or hypervigilance	Randomized clinical trials of seven approaches with adults (prolonged exposure therapy, cognitive processing therapy, eye movement desensitization and reprocessing, narrative exposure therapy, seeking safety, skills training for affect/interpersonal regulation with modified prolonged exposure, and emotion-focused trauma therapy) show evidence of safety and efficacy for adults with severe PTSD, co-occurring addictive disorders, problems with anger, dissociation, grief, and guilt, including one study with adults with chronic mental illness
Self-regulation focused CBT for PTSD	Teaches emotion regulation skills for recognizing and modulating traumatic stress symptoms without requiring	Randomized effectiveness trials of three approaches with adults (trauma affect regulation: guide for education and therapy, patient-centered therapy, and skills training in

	reworking of traumatic memories	affect/interpersonal regulation) show evidence of safety and efficacy for adults with severe PTSD, co-occurring addictive disorders, problems with anger, dissociation, grief, and guilt, including in individuals with comorbid serious mental illness, and incarcerated women

Table 30-2
Evidence-Based Manualized Intervention for Child Psychiatric Rehabilitation

Modality	Goals and Targeted Areas	Results of Evaluation
Problem-solving skills training (PSST)	Teaches children skills and supports parents in helping children with self-monitoring, prosocial goal setting, developing peer positive environments, setting limits with friends, and developing problem-solving and communication skills	Randomized, clinical trials show evidence of improved problem-solving and interpersonal skills and modest reductions in oppositional and inattentive behavior
Cognitive-behavior therapy	Teaches skills for recognizing and modifying thoughts and beliefs that increase or prolong	Meta-analyses demonstrate efficacy in reducing children's anxiety and depressive

	distress, and strengthening thoughts and beliefs that are self-affirming and interpersonally prosocial and assertive	symptoms
Parent behavior/Teacher classroom management training	Parent management training focuses on classroom strategies to help teachers and parents manage problematic child behavior and promote social, emotional, and academic competence	Randomized effectiveness studies with two approaches (Incredible Years; Oregon PMT) demonstrate reduced antisocial, oppositional, impulsive behavior, extending to adolescence for children with severe early antisocial problems
Brief strategic family therapy (BSFT)	A short-term, problem-focused intervention with an emphasis on modifying maladaptive patterns of interactions. It focuses on ways to help families interact more effectively	In a randomized, clinical trial with inner-city families whose children had a variety of behavior problems and varying degrees of juvenile justice involvement, BSFT was superior to usual community care services

Functional family therapy (FFT)	FFT teaches skills for problem solving and behavior management and delivers to parents and children together	Randomized and quasi-experimental studies show reduced juvenile recidivism for youths receiving FFT
Multidimensional family therapy (MDFT)	MDFT identifies family interaction patterns and restructures them to increase trust, cooperation, and emotional support among all members of the family; MDFT has evolved from a primarily clinic-based intervention to delivering services in the home and community settings to enhance youth engagement and the immediacy of services; MDFT is developing a variant for traumatized youth incorporating trauma affect regulation: guide for education and therapy (TARGET)	Randomized clinical trials of MDFT across a variety of ethnocultural and socioeconomic subpopulations have shown that it is associated with reduced youth substance abuse and legal problems and enhanced family functioning and school involvement
Multisystemic therapy (MST)	MST involves up to 6 mo of individualized, community-based	In randomized clinical trials, MST has been shown to

	contact by an M.A. or Ph.D. level therapist, supported by a 24-hr backup team; MST addresses all relevant environments by empowering parents with the skills and resources needed to independently prevent and manage crises and maintain family rules; variants of MST are under development for sexual offending youth, youth in psychiatric crisis, and youth who have experienced childhood maltreatment	reduce juvenile delinquent recidivism and crime severity, psychiatric symptoms, out-of-home placements, and drug use while improving family functioning and school attendance; large-scale dissemination studies in the United States, Canada, and Scandinavia show that MST is superior to usual services on some, but not all, psychosocial outcomes
Intensive in-home child and adolescent psychiatric services (IICAPS)	IICAPS provides assistance in the home for families who have children with serious emotional disorders using a clinical team consisting of clinicians and counselors who are supervised by a child and adolescent psychiatrist	One randomized effectiveness trial and observational studies with a system of community agencies treating psychiatrically impaired, socioeconomically disadvantaged children

		demonstrate reduced psychiatric morbidity
Trauma-informed affect regulation therapies for posttraumatic stress disorder (PTSD)	Dyadic therapies for young children and their primary caregivers, and group and individual therapies for adolescents, teach children and caregivers skills for affect regulation to reduce PTSD-related emotional and behavioral problems	Randomized controlled trials with young traumatized children (child–parent psychotherapy, parent–child interaction therapy) and youth (trauma affect regulation: guide for education and therapy; trauma and grief components therapy for adolescents) demonstrate improvements in parent–child relationships and child/youth emotional, behavioral, and interpersonal functioning
Multidimensional treatment foster care (MTFC)	MTFC provides training and ongoing support, parent education, family therapy, and youth mentoring to	Three randomized controlled trials showed that MTFC reduced adolescents’

	enable foster parents to maintain a structured therapeutic environment for teaching children skills, setting limits, and modeling communication and problem-solving strategies	psychiatric rehospitalization, arrests and incarceration, running away, and drug use while improving vocational and educational outcome
Cognitive-behavioral intervention for trauma in the schools (CBITS)	CBITS provides 10-session groups in school mental health or counseling settings for preadolescents or adolescents with PTSD due to family or community violence; CBITS includes education about traumatic stress, skills for anxiety management, and desensitization of trauma memories	Two randomized, controlled trials with inner-city children (one with Spanish-speaking youth) showed CBITS to be associated with reductions in PTSD and depression but not in teacher-reported behavioral or emotional problems
Trauma-focused cognitive–behavioral therapy (TF-CBT)	TF-CBT guides traumatized children and their parents in recognizing and managing PTSD symptoms and in desensitizing trauma memories	Randomized, controlled trials with sexually and physically abused children and children who experienced traumatic losses, disasters, or violence showed

	reductions in PTSD and depression and improvements in social functioning, but no improvement in disruptive or oppositional behavior

Chronic Illness Care Model: Psychiatry in the Context of Primary Care. Finally, the care of persons with long-term mental health problems is included in innovative developments in the provision of primary health care for persons with chronic illnesses (http://www.improvingchroniccare.org). The Health Resources Services Administration (HRSA), the federal agency responsible for the community health centers or Federally Qualified Health Centers (FQHCs), has adopted the chronic illness care model in its training and technical assistance efforts for community health centers. The model grows out of the current concern for the quality of care and accountability for health care delivery systems for effective outcomes. Depression management is one of the four chronic health conditions that the HRSA has selected for its training collaboratives.

The model begins with the assumption that the health care delivery system is part of a community context and must be responsive in its interactions with the community. Four areas of focus are essential in implementing the model in the health care delivery system: self-management support, delivery system design, decision support, and clinical tracking system. *Self-management support* gives patients a central role in determining their care, fostering a sense of responsibility for their health. Patients collaborate with the primary care team to establish goals, create treatment plans, and solve problems along the way. *Delivery system design* requires a reorganization of how the health system operates so that up-to-date information about a given patient is centralized, and follow-up responsibility is assigned as a standard procedure, and so on. *Decision support* requires that treatment decisions are based on explicit, proven practice guidelines supported by at least one defining study.

Guidelines are discussed with patients and providers, and treatment team members are trained continuously in the latest proven methods. Finally, *clinical tracking systems* track individual patients and populations of patients with similar problems. These systems must be practical and operational—able to check an individual's treatment at any point to confirm that the treatment conforms to recommended guidelines. The real integration of psychiatric care into primary care is an important innovation to consider that would improve physical health care for individuals with psychiatric disorders and eliminate the separation imposed by placing individuals with psychiatric problems into community mental health centers.

THE ROLE OF PUBLIC AND COMMUNITY PSYCHIATRY IN TWENTY-FIRST CENTURY HEALTH CARE

Public psychiatry emerged historically as an attempt to provide humane care for people with severe mental disabilities who did not have the resources to be protected from the stigma and approbation that shielded so-called "eccentrics" and "black sheep" fortunate enough to have been born into the wealthier social strata. Community psychiatry evolved as an answer to concerns that public psychiatric treatment was a de facto form of marginalization and oppression, if not inhumane exile and imprisonment, of economically disadvantaged persons with mental illness. The best ideas from community and public psychiatry are sometimes lost amidst the competition for scarce resources. The spirit and skills of advocacy that sparked the development and continue to characterize the best practices of public and community psychiatry, as well as the dedication to bring demonstrably effective services to the people who are most in need but are least served, have never been more needed by the entire mental health field.

31 Global and Cultural Issues in Psychiatry

Mental disorders are highly prevalent in all regions of the world and represent a significant source of disability and social burden worldwide. Treatments for all these disorders are available and are efficacious in both developed and developing countries. However, mental disorders are remarkably undertreated worldwide, especially in low-income countries. National mental health policies are lacking in several countries, especially low-income ones. Resources for mental health care are scarce and unequally distributed. World psychiatry focuses on these and other issues, such as the stigma attached to mental disorders, the relationships between mental and physical diseases, and the ethics of mental health care.

PREVALENCE AND BURDEN OF MENTAL DISORDERS WORLDWIDE

The World Health Organization (WHO) estimates that more than 25 percent of individuals worldwide develop one or more mental disorders during their lifetime. Among people seen by primary health care professionals, more than 20 percent have one or more current mental disorders. In a study carried out by the WHO at 14 sites in Africa, Asia, the Americas, and Europe, the average current prevalence of any mental disorder was 24 percent, without consistent differences between low- and high-income countries. The most common diagnoses were those of depression (average, 10.4 percent) and generalized anxiety disorder (average, 7.9 percent). Female rates were 1.89 times higher than male rates for depression, but male rates were higher for alcohol-related disorders so that there was no sex difference in the proportion

of people having at least one mental disorder. Physical ill-health and educational disadvantage were both significantly associated with a diagnosis of mental disorder.

To quantify the burden of the various diseases and injuries, the WHO, in collaboration with the Harvard School of Public Health and the World Bank, introduced the disability-adjusted life year (DALY). DALY for a given disease or injury is the sum of the years of life lost due to premature mortality plus the years lost due to disability for incident cases of that disease or injury in the general population. In the original estimates for the year 1990, mental and neurologic disorders accounted for 10.5 percent of the total DALYs lost due to all diseases and injuries. The estimate for the year 2000 was 12.3 percent, with two mental disorders (depression and alcohol use disorders) and suicide ranking in the top 20 causes of DALYs for all ages.

In the estimates for the year 2005, mental and neurologic disorders accounted for 13.5 percent of all DALYs in the world, and is the main contributor to burden among noncommunicable diseases (Table 31-1).

Table 31-2 summarizes the global burden of disease for mental and substance use disorders at various times in the last few decades.

By 2030, mental and neurologic disorders will likely account for 14.4 percent of all global DALYs and 25.4 percent of those due to noncommunicable diseases. Depression will rank number 2 in the percentage of total DALYs in that year (5.7 percent), following HIV/AIDS and preceding ischemic heart disease (Table 31-3). It will be number 1 in high-income countries (9.8 percent), number 2 in middle-income countries (6.7 percent), and number 3 in low-income countries (4.7 percent).

The WHO estimates that one of four families worldwide has at least one member with a mental disorder. The objective and subjective burden related to caring for people with severe mental disorders (in terms of disruption of family relationships; constraints in social, leisure, and work activities; financial difficulties; detrimental effects on physical health; feelings of loss, depression, and embarrassment in social situations; and the stress of coping with disturbing behaviors) is substantial and significantly higher than that related to caring for people with long-term physical diseases such as diabetes and heart, kidney, or lung diseases. Cross-cultural differences exist in some dimensions of family burden.

Suicide is among the 10 leading causes of death for all ages in most of the

countries for which information is available. In some countries (e.g., China), it is the leading cause of death for people between 15 and 34 years of age.

According to WHO estimates, about 849,000 people died from suicide worldwide in the year 2001. In that year, the number of suicide deaths overtook the number of deaths by violence (500,000) and war (230,000). In 2020, approximately 1.53 million people will die from suicide worldwide, based on current trends, and 10 to 20 times more people will attempt suicide. Reported suicide rates vary considerably across countries; for instance, in many Eastern and Central European countries, the annual suicide rates are between 48.0 and 79.3 per 100,000. In contrast, many Islamic and Latin American countries report rates of less than 4.0 per 100,000. More than 85 percent of suicides occur in low- or middle-income countries. However, this figure may represent an underestimate due to the low reliability of official statistics in those countries: for example, when epidemiologists used a verbal autopsy in South India, the observed rates for suicide exceeded official national estimates 10-fold. In the Asia-Pacific region, perhaps 300,000 cases of suicide per year occur by self-poisoning with pesticides.

Suicide rates are higher in men than in women (3.2:1 in 1950, 3.6:1 in 1995, and an estimated 3.9:1 in 2020). China is the only country where suicide rates in women are consistently higher than those in men, especially in rural areas. Over the past few decades, suicide rates are generally stable worldwide, but there is a rising trend among young men ages 15 to 19 years. A systematic review covering 15,629 cases in the general population worldwide estimated that 98 percent of those who committed suicide had a diagnosable mental disorder, with mood disorders accounting for 35.8 percent, substance-related disorders for 22.4 percent, personality disorders for 11.6 percent, and schizophrenia for 10.6 percent of cases.

TREATMENT GAP AND PROJECTED POPULATION-LEVEL TREATMENT EFFECTIVENESS WORLDWIDE

Clinical trials have convincingly proved the efficacy of pharmacologic and psychosocial treatments for mood, anxiety, psychotic, and substance-related disorders carried out in low- and middle-income, as well as in high-income countries. However, the treatment gap is substantial for all mental disorders worldwide, particularly in low-income countries.

Table 31-1
Disorder-Specific Global Sheehan Disability Scale Ratings for Commonly Occurring Mental and Chronic Physical Disorders in Developed and Developing WMH Countries

	Proportion Rated Severely Disabling			
	Developed		Developing	
	%	(SE)	%	(SE)
I. Physical Disorders				
Arthritis	23.3	(1.5)	22.8	(3.0)
Asthma	8.2	(1.4)	26.9	(5.4)
Back/Neck	34.6	(1.5)	22.7	(1.8)
Cancer	16.6	(3.2)	23.9	(10.3)
Chronic pain	40.9	(3.6)	24.8	(3.8)
Diabetes	13.6	(3.4)	23.7	(6.1)
Headaches	42.1	(1.9)	28.1	(2.1)
Heart disease	26.5	(3.9)	27.8	(5.2)
High blood pressure	5.3	(0.9)	23.8	(2.6)
Ulcer	15.3	(3.9)	18.3	(3.6)
II. Mental Disorders				
ADHD	37.6	(3.6)	24.3	(7.4)
Bipolar	68.3	(2.6)	52.1	(4.9)
Depression	65.8	(1.6)	52.0	(1.8)
GAD	56.3	(1.9)	42.0	(4.2)
IED	36.3	(2.8)	27.8	(3.6)
ODD	34.2	(6.0)	41.3	(10.3)
Panic disorder	48.4	(2.6)	38.8	(4.7)
PTSD	54.8	(2.8)	41.2	(7.3)
Social phobia	35.1	(1.4)	41.4	(3.6)
Specific phobia	18.6	(1.1)	16.2	(1.6)

35.8 percent, substance-related disorders for 22.4 percent, personality disorders for 11.6 percent, and schizophrenia for 10.6 percent of cases.

In the World Mental Health Surveys, failure and delays in treatment seeking were generally higher in low-income countries, older cohorts, men, and cases with earlier ages of onset. People with mood disorders had earlier treatment contact than other mental disorders, this is likely because many countries have targeted this disorder, with screening campaigns and public informational campaigns.

RESOURCES FOR MENTAL HEALTH CARE WORLDWIDE

According to the *Mental Health Atlas 2005,* only 62.1 percent of countries worldwide, accounting for 68.3 percent of the world population, have a mental health policy (i.e., a document of the government or ministry of health specifying the goals for improving the mental health situation of the country, the priorities among those goals, and the main directions for attaining them). Mental health policies are present in 58.8 percent of low-income and 70.5 percent of high-income countries. In Africa, only 50 percent of countries have a mental health policy. In Southeast Asia, only about half of countries have a mental health policy, and only about a quarter of the population are affected by these policies (Table 31-4).

Community care facilities exist in only 68.1 percent of the countries (51.7 percent of low-income and 93 percent of high-income countries). Only 60.9 percent of the countries report providing treatment facilities for severe mental disorders at the primary care level (55.2 percent of low-income and 79.5 percent of high-income countries). About one-fourth of low-income countries do not provide even rudimentary antidepressant medications in primary care settings. In many others, the supply does not cover all regions of the country or is very irregular. Because medicines are often not available in health care facilities, patients and families must pay for them out of pocket.

Whereas 61.5 percent of European countries spend more than 5 percent of their health budget on mental health care, 70 percent of countries in Africa and 50 percent of countries in Southeast Asia spend less than 1 percent. Out-of-pocket payment is the most important method of financing mental health care in 38.6 percent of countries in Africa and 30 percent of countries in Southeast Asia, but it is not the primary method of financing mental health

care in any European country (Table 31-5). All countries with out-of-pocket payment as the dominant method of financing mental health care belong to low-income or lower-middle-income categories, but almost all countries with social insurance as the dominant method of financing belong to high-income or upper-middle-income categories.

The median number of psychiatrists per 100,000 population ranges from 0.04 in Africa and 0.2 in Southeast Asia to 9.8 in Europe (Table 31-6). It is 0.1 in low-income countries compared with 9.2 in high-income countries. Two-thirds of low-income countries have less than one psychiatrist per 100,000 population. Chad, Eritrea, and Liberia (with populations of 9, 4.2, and 3.5 million, respectively) each have just one psychiatrist per 100,000 population. Afghanistan, Rwanda, and Togo (with populations of 25, 8.5, and 5 million respectively) each have just two psychiatrists per 100,000 population. Large-scale migration of psychiatrists from low- and middle-income to high-income countries, as part of the larger picture of migration of health professionals in general, has been consistently documented. India and some sub-Saharan African countries are the most important contributors to the mental health workforce in the United Kingdom, although the United Kingdom has 110 psychiatrists per million population. However, India has 2 per million and sub-Saharan Africa less than 1 per million. The median number of psychologists working in mental health care per 100,000 population ranges from 0.03 in Southeast Asia and 0.05 in Africa to 3.1 in Europe. Approximately 69 percent of low-income countries have less than one psychologist per 100,000 population. The median number of psychiatric nurses per 100,000 population ranges from 0.1 in Southeast Asia and 0.2 in Africa to 24.8 in Europe.

Table 31-2
Global Burden of Disease: Mental and Substance Use Disorders

	Mental Disorders	Substance Use Disorders	Before 1998	1998–2005	2006–2013	Total
All causes			100.0%	100.0%	100.0%	100.0%

Table 31-5
Countries in Which Out-of-Pocket Payment Is the Most Common Method of Financing Mental Health Care in Each Region of the World Health Organization (WHO)

WHO Region	Percent of Countries
Africa	38.6
Americas	12.9

Eastern Mediterranean	15.8
Europe	0
Southeast Asia	30.0
Western Pacific	18.5

From *World Health Organization: Mental Health Atlas 2005*. Geneva: World Health Organization; 2005.

From these figures, it is clear that resources for mental health care are grossly inadequate compared with the needs, and that inequalities across countries are substantial, especially between low- and high-income countries. Moreover, resources tend to be concentrated in urban areas, especially in low-income countries, leaving vast regions without any form of mental health care.

Even worse is the situation concerning child and adolescent mental health care. According to the WHO, only 7 percent of countries worldwide have a specific child and adolescent mental health policy. In less than one-third of all countries, is it possible to identify an institution or a governmental entity with overall responsibility for child mental health. School-based services are almost exclusively present in high-income countries; and even in Europe, only 17 percent of countries have a sufficient number of these services. There are no pediatric beds for mental health identified in low-income countries, but such beds exist in 50 percent of high-income countries. In all African countries outside South Africa, there are as little as 10 psychiatrists trained to work with children. In European countries, the number of child psychiatrists ranges from one per 5,300 to one per 51,800. In more than 70 percent of countries worldwide, there is no list of essential psychotropic medications for children. In 45 percent of countries worldwide, psychostimulants are either prohibited or unavailable for use in children with attention-deficit/hyperactivity disorder.

Table 31-6
Median Number of Mental Health Professionals per 100,000 Population in Each Region of the World Health Organization (WHO)

WHO Region	Psychiatrists	Psychiatric Nurses	Psychologists Working in Mental Health
Africa	0.04	0.20	0.05

Western Pacific	0.32	0.50	0.03

From *World Health Organization: Mental Health Atlas 2005*. Geneva: World Health Organization; 2005.

PRINCIPLES FOR MENTAL HEALTH PROGRAM DEVELOPMENT AND BARRIERS TO CHANGE WORLDWIDE

According to the WHO, the development of mental health programs worldwide should adhere to the following principles: (1) providing treatment in primary care; (2) making psychotropic medications available; (3) giving care in the community; (4) educating the public; (5) involving communities, families, and consumers; (6) establishing national policies and legislation; (7) developing human resources; (8) linking with other relevant sectors; (9) monitoring community mental health; and (10) supporting more research.

The guiding principles proposed for the prevention of suicide worldwide include (1) reducing access to means of suicide (e.g., pesticides, firearms), (2) treating people with mental disorders, (3) improving media portrayal of suicide, (4) training primary health care personnel, (5) implementing school-based programs, and (6) developing hotlines and crisis centers.

The most significant barriers to the implementation of the preceding principles worldwide, according to the WHO, include the following: (1) some stakeholders may be resistant to the changes; (2) health authorities may not believe in the effectiveness of mental health interventions; (3) there may be

no consensus among the country's stakeholders about how to formulate or implement the new policy; (4) financial and human resources may be scarce; (5) other essential health priorities may compete with mental health care for funding; (6) primary care teams may feel overburdened by their workload and refuse to accept the introduction of the new policy; and (7) many mental health specialists may not want to work in community facilities or with primary care teams, preferring to remain in hospitals. The suggested solutions include (1) adopting an "all-winners approach" that ensures countries take into account the needs of all stakeholders, (2) developing pilot projects and evaluating their effect on health and consumer satisfaction, (3) asking for technical reports from international experts, (4) focusing the implementation of the mental health policy on a demonstration area and performing cost-effectiveness studies, (5) linking mental health programs to other health priorities, and (6) showing primary care practitioners that people with mental disorders are already a hidden part of their burden and that the burden will decrease if they identify and treat these disorders.

STIGMATIZING ATTITUDES TOWARD PEOPLE WITH MENTAL DISORDERS

Stigmatizing attitudes toward people with mental disorders are widespread in the general public and even among mental health professionals. Although stigma may be less severe in some Asian and African countries, a study carried out in India within the Stigma Programme of the World Psychiatric Association (WPA), in which the investigators interviewed 463 persons with schizophrenia and 651 family members in four cities, reported that two-thirds of the respondents had experienced discrimination. Women and people living in urban areas were the most stigmatized. Whereas men experienced more significant discrimination in the job area, women experienced more problems in the family and social areas.

Unlike people with physical disabilities, those with mental disorders are often perceived by the public to be in control of their disabilities and responsible for causing them. The view that "weakness," "laziness," or "lack of willpower" contributes to the development of mental disorders still exists in many countries. The stigmatization of people with mental disorders may result in public avoidance, systematic discrimination, and reduced help-

seeking behavior. In a survey carried out in 1996 in a probability sample of 1,444 adults in the United States, more than half of the respondents were unwilling to spend an evening socializing with, work next to, or have a family member marry a person with mental illness. Although most countries have some provision for disability benefits, people with mental illness are often explicitly excluded from such entitlements. Moreover, mental disorders are frequently not considered in social and private insurance schemes for health care. Shame is one of the main barriers to seeking help for mental disorders in both developed and developing countries.

We can subdivide the strategies for addressing the stigmatization of people with mental disorders into three groups: protest, education, and contact. There is some evidence that protest campaigns may be useful in reducing stigmatizing behaviors against people with mental disorders. Education may promote a better understanding of mental illness, and educated people may be less likely to endorse stigma and discrimination. There is an inverse relationship between having contact with a person with mental illness and endorsing stigmatizing behavior.

RELATIONSHIPS BETWEEN MENTAL AND PHYSICAL DISEASES

People with severe mental disorders have higher mortality from physical illnesses compared with the general population. In a follow-up study carried out in the United Kingdom, the standardized mortality ratio (SMR) for natural causes in people with schizophrenia was 2.32 (i.e., death was more than twice higher than in the general population). The SMR for causes "avoidable by appropriate treatment" was 4.68. The highest SMRs were those for endocrine, nervous, respiratory, circulatory, and gastrointestinal diseases. There is also an increased nonsuicide all-cause mortality for bipolar disorder (SMR 1.9 for men and 2.1 for women) and dementia (relative risk [RR] 2.63; 95 percent confidence interval [CI] 2.17 to 3.21). A meta-analysis of 15 population-based studies of the effect of a diagnosis of depression on subsequent all-cause mortality yielded a pooled odds ratio of 1.7 (CI 1.5 to 2.0). Evidence from low-income countries is limited, but a large population study conducted in Ethiopia found high mortality rates for major depression (SMR 3.55, 95 percent CI 1.97 to 6.39) and schizophrenia (almost 5 percent

per year).

People with mental disorders also have a higher prevalence of several physical diseases compared with the general population. In a study carried out in the United States, people with psychotic disorders were more likely than other people to develop diabetes, hypertension, heart disease, asthma, gastrointestinal disorders, skin infections, malignant neoplasms, and acute respiratory disorders. This high rate remained true even when only considering patients without a concomitant substance use disorder. In a study conducted in Nigeria, 55.2 percent of persons with schizophrenia-spectrum disorders referred for the first time to a psychiatric clinic had at least one physical disease, but in persons with neurotic disorders, the rate was 11.8 percent. A strong prospective association exists between depression and coronary heart disease outcomes, including fatal myocardial infarction; on the other hand, the incidence of depression is increased after myocardial infarction, especially in the first month after the event. Depression also increases the risk of type II diabetes. In South Asia, there are reports of an association between maternal perinatal depression and infant malnutrition and stunting at 6 months.

People with severe mental disorders are at increased risk of contracting HIV infection, although prevalence rates vary substantially worldwide. A large multicenter study conducted in sub-Saharan Africa, Asia, Latin America, Europe, and the United States reported a higher prevalence of the depressive disorder among symptomatic HIV-seropositive people than in asymptomatic HIV-seropositive cases and seronegative control participants. Evidence from both developed and developing countries shows that adherence to highly active antiretroviral therapy (HAART) is negatively affected by depression, cognitive impairment, and substance abuse.

In a study carried out in the United Kingdom, people with severe mental illness were significantly more likely to be obese (body mass index higher than 30) and morbidly obese (body mass index higher than 40) than the general population; the respective figures were 35.0 versus 19.4 percent and 3.7 versus 1.3 percent. When these figures were broken down by age and sex, 28.7 percent of men with severe mental illness between 18 and 44 years of age were obese compared with 13.6 percent in the general population, and 3.7 versus 0.4 percent were morbidly obese. Even more striking were the figures concerning women of the same age; 50.6 versus 16.6 percent and 7.4 versus

2.0 percent, respectively.

A meta-analysis of worldwide studies confirmed that there is a highly significant association between schizophrenia and current smoking. The weighted average odds ratio was 5.9; it was 7.2 in men and 3.3 in women. The association remained significant when controls with severe mental illness were used (odds ratio, 1.9). Heavy smoking and high nicotine dependence were also more frequent in people with schizophrenia than in the general population.

The quality of physical health care received by patients with severe mental illness is often worse than the general population. A study conducted in the United States found that adverse events during medical and surgical hospitalizations were significantly more frequent in patients with schizophrenia than in the other people, including infections due to medical care, postoperative respiratory failure, postoperative deep venous thrombosis or pulmonary embolism, and postoperative sepsis. All of these adverse events were associated with a significantly increased odds of admission to an intensive care unit and of death.

The decreased access of people with mental disorders to medical services relates to several factors concerning the health care system. There is a well-documented effect of lack of insurance and the cost of care. In a study carried out in the United States, people with mental disorders were twice as likely as those without mental disorders to have been denied insurance because of a preexisting condition (odds ratio, 2.18). Having a mental disorder conferred a higher risk of having delayed seeking care because of cost (odds ratio, 1.76) and of having been unable to obtain needed medical care (odds ratio, 2.30).

Even when a doctor sees people with mental illness, their physical diseases often remain undiagnosed. Primary care providers may misperceive the medical complaints of people with mental disorders as “psychosomatic” or be unskilled or feel uncomfortable in dealing with this population. Underlying stigmatization may be involved. Moreover, during hospitalizations in medical and surgical wards, health care professionals may not be experienced in dealing with the unique needs of patients with schizophrenia, may minimize or misinterpret their somatic symptoms, and may make inappropriate use of restraints or sedative drugs or fail to consider possible interactions of psychotropic drugs with other medications. On the other hand, many psychiatrists are unable or unwilling to perform physical and even neurologic

examinations or are not up to date on the management of even common physical diseases.

The first step is raising awareness of the problem among mental health care professionals, primary care providers, and patients with schizophrenia and their families. Education and training of mental health professionals and primary care providers is a further essential step. We should train mental health professionals to perform at least basic medical tasks. They should understand the importance of recognizing physical illness in people with severe mental disorders and become familiar with the most common reasons for underdiagnosis or misdiagnosis of physical illness in these patients. On the other hand, primary care providers should overcome their reluctance to treat people with severe mental illness and learn practical ways to interact and communicate with them; it is not only an issue of knowledge and skills but also most of all one of attitudes.

A well-identified professional should be responsible for physical health care in each person with a severe mental disorder. Mental health services should be able to provide at least a standard routine assessment of their patients to identify or at least suspect the presence of physical health problems. Guidelines about the management of patients receiving antipsychotic drugs should be known and applied by all mental health services. Patients should be involved as much as possible; for instance, mental health professionals should encourage patients to monitor and chart their weight. Mental health services should routinely provide dietary and exercise programs. Flexible smoking cessation programs, which have shown some degree of success, could be considered in some settings.

ETHICAL ISSUES IN MENTAL HEALTH CARE

The protection and promotion of the human rights of people with mental disorders are emerging as a priority worldwide. In 1991, the United Nations (UN) issued Resolution 46/119 for the Protection of Persons with Mental Illness and the Improvement of Mental Health Care. In that resolution, the UN codified the human rights of people with mental disorders, and their right to treatment. The 25 principles covered the following areas: definition of mental illness; protection of confidentiality; standards of care and treatment, including involuntary admission and consent to treatment; rights of persons

with mental disorders in mental health facilities; protection of minors; provision of resources for mental health facilities; the role of community and culture; review mechanisms providing for the protection of the rights of offenders with mental disorders; and procedural safeguards protecting rights of persons with mental disorders. The UN encouraged national governments to promote the principles of the resolution by appropriate legislative, juridical, administrative, educational, and other provisions. However, violations of the human rights of people with mental disorders still exist in many countries, and in a substantial number of low- and middle-income countries, patients in mental hospitals are physically restrained or secluded for long periods.

In Latin America, an influential document has been the Declaration of Caracas, adopted in 1990 by the Regional Conference on Restructuring Psychiatric Care in Latin America, which states that resources, care, and treatment for people with mental disorders should safeguard their dignity and human and civil rights and strive to maintain them in their communities. The Declaration also states that mental health legislation should safeguard the human rights of people with mental disorders and that countries should organize services so that they can enforce these rights.

In Africa, the Banjul Charter on Human and Peoples' Rights, a legally binding document supervised by the African Commission on Human and Peoples' Rights, in Article 5 addresses the right to respect for the dignity inherent in human beings and the prohibition of all forms of degradation, including cruel, inhuman, or degrading treatment.

According to the WHO, mental health legislation should cover the following issues: access to fundamental mental health care, least restrictive care, informed consent to treatment, voluntary and involuntary admission to treatment, competence issues, periodical review mechanism, confidentiality, rehabilitation, accreditation of professionals and facilities, and rights of families and caregivers. Specific legislation in the field of mental health is present in 74 percent of low-income countries versus 92.7 percent of high-income countries.

In 1996, the WPA released the Madrid Declaration, which contains the ethical principles by which all national psychiatric societies should abide. The declaration includes seven general guidelines focusing on the aims of psychiatry: (1) psychiatrists must serve patients by providing the best therapy

available, consistent with accepted scientific knowledge and ethical principles, and should devise therapeutic interventions that are the least restrictive to the freedom of the patient; (2) it is the duty of psychiatrists to keep abreast of scientific developments of their specialty and to convey updated knowledge to others; (3) the patient should be accepted as a partner by right in the therapeutic process, and the therapist–patient relationship must be based on mutual trust and respect, to allow the patient to make free and informed decisions; (4) treatment must always be in the best interest of the patient, and no treatment should be provided against the patient's will, unless withholding treatment would endanger life of the patient or those who surround him or her; (5) when psychiatrists are requested to assess a person, it is their duty to inform the person being assessed about the purpose of the intervention; (6) information contained in the therapeutic relationship should be kept in confidence and used exclusively for the purpose of improving the mental health of the patient; and (7) because psychiatric patients are particularly vulnerable research subjects, extra caution should be taken to safeguard their autonomy, as well as their mental and physical integrity.

INTERNATIONAL ORGANIZATIONS ACTIVE IN THE MENTAL HEALTH FIELD

Many international organizations are active in the mental health field. They include the WHO, which is the world's leading public health agency; some professional associations, among which the largest is the WPA, representing the psychiatric profession worldwide; and several organizations with a membership of users and families (such as the World Fellowship for Schizophrenia and Allied Disorders and the Global Alliance of Mental Illness Advocacy Networks [GAMIAN]) or both mental health professionals and users and families (such as the World Federation for Mental Health [WFMH]).

The WHO is a UN agency that is funded by 192 member states. It has six regional groupings: Africa, the Americas, Eastern Mediterranean, Europe, Southeast Asia, and Western Pacific. The Department of Mental Health and Substance Abuse is in Geneva, and it has advisors for mental health in each of its regional offices. Its main functions are direction and coordination of international health work and technical cooperation with countries. Among

the numerous recent WHO activities in the mental health field, of particular interest, are the release of the *World Health Report 2001* and the development of the report *Mental Health: New Understanding, New Hope*, which was devoted entirely to mental health. It provided a summary of the current and projected impact of mental disorders and the principles of mental health policy and service provision, as well as a set of recommendations for future action that countries can adapt to their various needs and resources. Project Atlas aims to collect information on mental health resources across the world. Global and regional analyses of those resources were first published in 2001 and updated in 2005. Reports from the project focus, for example, on resources for child and adolescent mental health and psychiatric education and training worldwide (the latter in collaboration with the WPA).

The WPA is an association of national psychiatric societies aimed at increasing the knowledge and skills necessary for work in the field of mental health and the care for the mentally ill. Its member societies number 134, and it spans 122 countries and represents more than 200,000 psychiatrists. The WPA organizes the World Congress of Psychiatry every 3 years. It also organizes international and regional congresses and meetings and thematic conferences. It has 65 scientific sections, which disseminate information and promoting collaborative work in specific domains of psychiatry. It has produced several educational programs, books, and consensus statements (including the Declaration of Madrid on ethical principles for psychiatric practice). It has an official journal, *World Psychiatry*, which is in English, Spanish, and Chinese and is indexed in PubMed and Current Contents and reaches more than 33,000 psychiatrists worldwide.

The WFMH is a multidisciplinary advocacy and education organization aimed at promoting the advancement of mental health awareness, prevention, advocacy, and best-practice recovery-focused interventions worldwide. Among its activities is the organization of the World Mental Health Day, observed every year on October 10, each time with a different theme.

FUTURE PERSPECTIVES

There are several statements from various groups and organizations about the priorities for future action in the mental health field at the international level. Of particular interest is a document produced by 39 leaders comprising the

Lancet Commission on global mental health and sustainable development, or the Global Mental Health Commission. This document identifies five main goals: (1) placing mental health on the public health priority agenda, (2) improving the organization of mental health services, (3) integrating the availability of mental health into general health care, (4) developing human resources for mental health, and (5) strengthening public mental health leadership.

Among the strategies proposed to place mental health on the public health priority agenda are the development and use of uniform and understandable messages for mental health advocacy and the education of decision-makers within governments and donor agencies on the evidence concerning the public health significance of mental disorders and the cost-effectiveness of mental health care. Strategies suggested to improve the organization of mental health services include, among others, the provision of incentive arrangements to overcome vested interests blocking change and the organization of international technical support to learn from countries that have experienced successful mental health reforms. The authors proposed that mental health professionals be appointed and trained specially to support and supervise primary health care staff, to help integrate mental and general health care. It is also crucial that we increase and diversify the professional and specialist workforce is increased and diversified and improve the quality of mental health training to ensure that it is practical and widely practiced in community or primary care settings.

Normal Development and Aging

32.1 Infant, Child, and Adolescent Development

The transactional nature of development in infancy, childhood, and adolescence, consisting of a continuous interplay between biologic predisposition and environmental experiences, forms the basis of current conceptualizations of development. There is much evidence that observed developmental outcomes evolve from interactions between particular biologic substrates and specific environmental events. For example, the serotonin transporter gene sensitizes a child with early adverse experiences of abuse or neglect to increased risk for later development of a depressive disorder. Also, the degree of resilience and adaptation, that is, the ability to withstand adversity without damaging effects, is likely to be mediated by endogenous glucocorticoids, cytokines, and neurotrophins. Thus, allostasis, the process of achieving stability in the face of adverse environmental events, results from interactions between specific environmental challenges and particular genetic backgrounds that combine to result in a response. Adverse childhood experiences (ACEs) are likely to alter the trajectory of development in a given individual and that during early development, the brain is especially vulnerable to injury. Future studies may uncover windows of plasticity in older children and adolescents that affect vulnerability as well. Acquiring subtle social skills, for example, relates to changes in the adolescent brain. Adolescents' keen abilities, competencies, and interests in a host of technologic advances—including the Internet, social media sites, and

smartphones, to name a few—shed some light on their potential to adapt to new and challenging demands.

PRENATAL, INFANT, AND CHILD

The phases of development described in this section are defined as follows: prenatal is the time frame from conception to 8 weeks; the fetus, from 8 weeks to birth; infancy, from birth to 15 months; the toddler period, from 15 months to 2½ years; the preschool period, from 2½ years to 6 years; and the middle years, from 6 to 12 years.

PRENATAL

Historically, the analysis of human development began with birth. The influence of endogenous and exogenous in utero factors, however, now requires that developmental schemes consider intrauterine events. The infant is not a tabula rasa, a smooth slate upon which outside influences etch patterns. On the contrary, myriad factors within the womb have already influenced the newborn. For example, the studies of Stella Chess and Alexander Thomas (described later) have demonstrated a wide range of temperamental differences among newborns. Maternal stress, through the production of adrenal hormones, also influences the behavioral characteristics of newborns.

The time frame in which the development of the embryo and fetus occurs is known as the prenatal period. After implantation, the egg begins to divide and is known as an embryo. Growth and development occur at a rapid pace; by the end of 8 weeks, the shape is recognizably human, and the embryo has become a fetus. Figure 32-1 illustrates a sonogram of a 9-week and 15-week fetus in utero.

The fetus maintains an internal equilibrium that, with variable effects, interacts continuously with the intrauterine environment. In general, most disorders that occur are multifactorial—the result of a combination of effects, some of which can be cumulative. Damage at the fetal stage usually has a more global impact than damage after birth, because rapidly growing organs are the most vulnerable. Boys are more vulnerable to developmental damage than girls are; geneticists recognize that in humans and animals, female

fetuses show a propensity for greater biologic vigor than male fetuses, possibly because of the second X chromosome in the female.

Prenatal Life

Much biologic activity occurs in utero. A fetus is involved in a variety of behaviors that are necessary for adaptation outside the womb. For example, a fetus sucks on thumb and fingers; folds and unfolds its body, and eventually assumes a position in which its occiput is in an anterior vertex position, which is the position in which fetuses usually exit the uterus.

Behavior. Pregnant women are extraordinarily sensitive to fetal movements. They describe their unborn babies as active or passive, as kicking vigorously or rolling around, as quiet when the mothers are active, but as kicking as soon as the mothers try to rest.

Women usually detect fetal movements 16 to 20 weeks into the pregnancy; the fetus can be artificially set into total body motion by in utero stimulation of its ventral skin surfaces by the 14th week. The fetus may be able to hear by the 18th week, and it responds to loud noises with muscle contractions, movements, and an increased heart rate. A bright light flashed on the abdominal wall of the 20-week pregnant woman causes changes in fetal heart rate and position. The retinal structures begin to function at that time. Eyelids open at 7 months. Smell and taste develop then, and the fetus can respond to substances injected into the amniotic sac, such as contrast medium. Some reflexes present at birth exist in utero: the grasp reflex, which appears at 17 weeks; the Moro (startle) reflex, which appears at 25 weeks; and the sucking reflex, which appears at about 28 weeks.

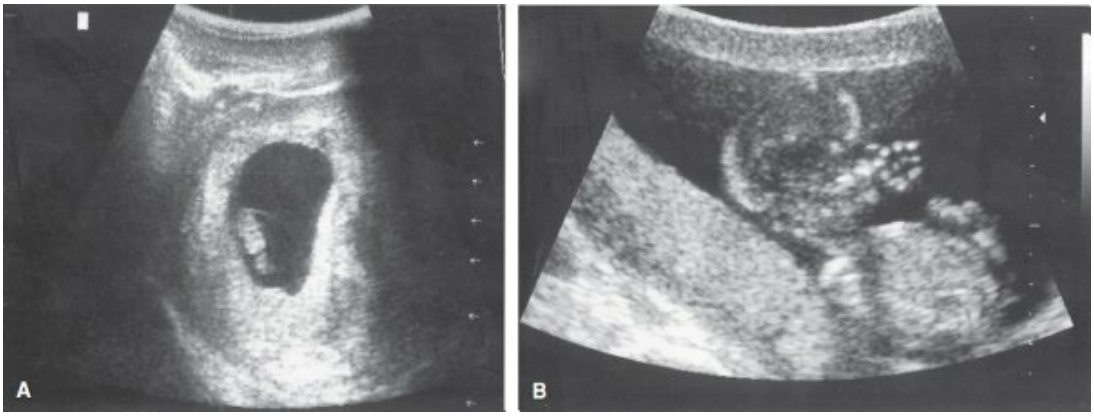

FIGURE 32-1
A: Sonogram of fetus at 9 weeks. **B:** Same fetus at 15 weeks. (Courtesy K.C. Attwell, M.D.)

Nervous System. The nervous system arises from the neural plate, which is a dorsal ectodermal thickening that appears on about day 16 of gestation. By the sixth week, part of the neural tube becomes the cerebral vesicle, which later becomes the cerebral hemispheres (Fig. 32-2).

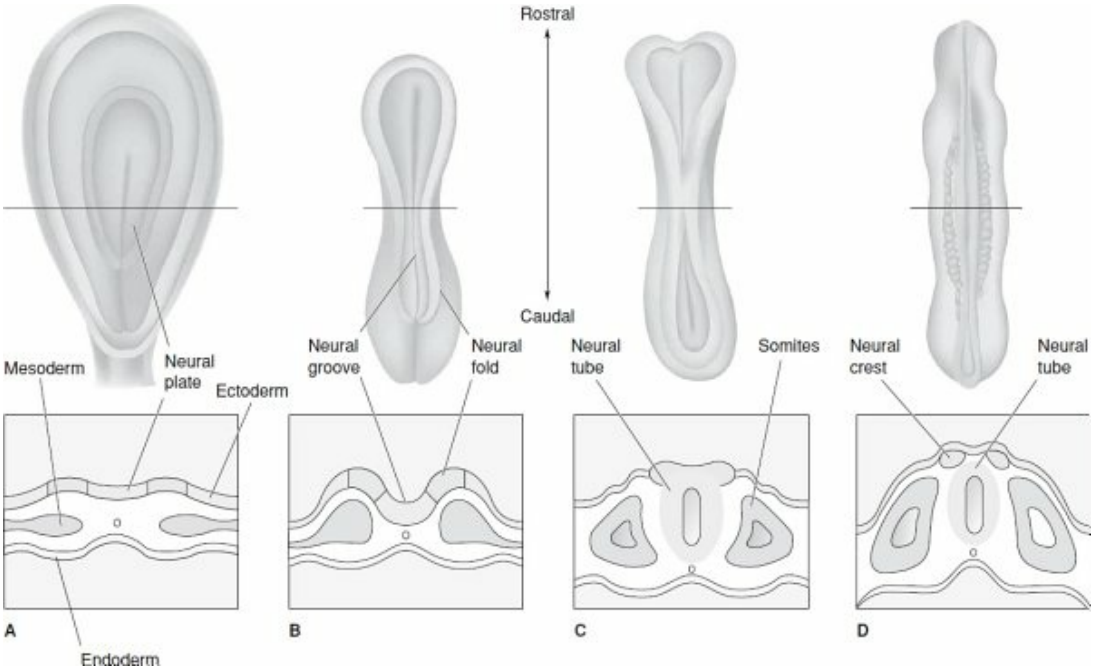

FIGURE 32-2
Formation of the neural tube and neural crest. These schematic illustrations follow the early development of the nervous system in the embryo. The drawings above are dorsal views of the embryo; those below are cross sections. **A:** The primitive embryonic central nervous system (CNS) begins as a thin sheet of ectoderm. **B:** The first important step in the development of the nervous system is the formation of the neural groove. **C:** The walls of the groove, called neural folds, come together and fuse, forming the neural tube. **D:** The bits of neural ectoderm that are pinched off when the tube rolls up are called the neural crest, from which the peripheral nervous system (PNS) will develop. The somites are mesoderm that will give rise to much of the skeletal system and the muscles. (Reprinted from Bear MF, Conners BW, Paradiso MA, eds. *Neuroscience: Exploring the Brain*. 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2001:179, with permission.)

The cerebral cortex begins to develop by the 10th week, but layers do not appear until the sixth month of pregnancy; the sensory cortex and the motor cortex form before the association cortex. Some brain function has been

detected in utero by fetal encephalographic responses to sound. The human brain weighs about 350 g at birth and 1,450 g at full adult development, a fourfold increase, mainly in the neocortex. This increase is almost entirely because of the growth in the number and branching of dendrites establishing new connections. After birth, the number of new neurons is negligible. Uterine contractions can contribute to fetal neural development by causing the developing neural network to receive and transmit sensory impulses.

Pruning. Pruning refers to the programmed elimination during the development of neurons, synapses, axons, and other brain structures from the original number, present at birth, to a lesser number. Thus, the developing brain contains structures and cellular elements that are absent in the older brain. The fetal brain generates more neurons than it will need for adult life. For example, in the visual cortex, neurons increase in number from birth to 3 years of age, at which point they diminish in number. The adult brain contains fewer neural connections than were present during the early and middle years of childhood. About twice as many synapses are present in certain parts of the cerebral cortex during early postnatal life than during adulthood.

Pruning occurs to rid the nervous system of cells that have served their function in the development of the brain. Some neurons, for example, exist to produce neurotrophic or growth factors and are programmed to die once they complete their task, a process called *apoptosis.*

These observations imply that the immature brain can be vulnerable in locations that lack sensitivity to injury later on. The developing white matter of the human brain before 32 weeks of gestation is especially sensitive to damage from hypoxic and ischemic injury and metabolic insults. Neurotransmitter receptors located on synaptic terminals are subject to injury from excessive stimulation by excitatory amino acids, (e.g., glutamate, aspartate), a process referred to as excitotoxicity. This process may be relevant to the etiology of disorders such as schizophrenia.

Maternal Stress

Maternal stress correlates with high levels of stress hormones (epinephrine, norepinephrine, and adrenocorticotropic hormone) in the fetal bloodstream,

which act directly on the fetal neuronal network to increase blood pressure, heart rate, and activity level. Mothers with high levels of anxiety are more likely to have babies who are hyperactive, irritable, and of low birth weight, and who have problems feeding and sleeping than are mothers with low anxiety levels. Fever in the mother causes the fetus's temperature to rise.

Genetic Disorders

In many cases, genetic counseling depends on prenatal diagnosis. The diagnostic techniques used include amniocentesis (transabdominal aspiration of fluid from the amniotic sac), ultrasound examinations, x-ray studies, fetoscopy (direct visualization of the fetus), fetal blood and skin sampling, chorionic villus sampling, and α-fetoprotein screening. In about 2 percent of women tested, the results are positive for some abnormality, including X-linked disorders, neural tube defects (detected by high levels of α-fetoprotein), chromosomal disorders (e.g., trisomy 21), and various inborn errors of metabolism (e.g., Tay–Sachs disease and the lipoidoses). Figure 32-3 illustrates hypertelorism of the eyes.

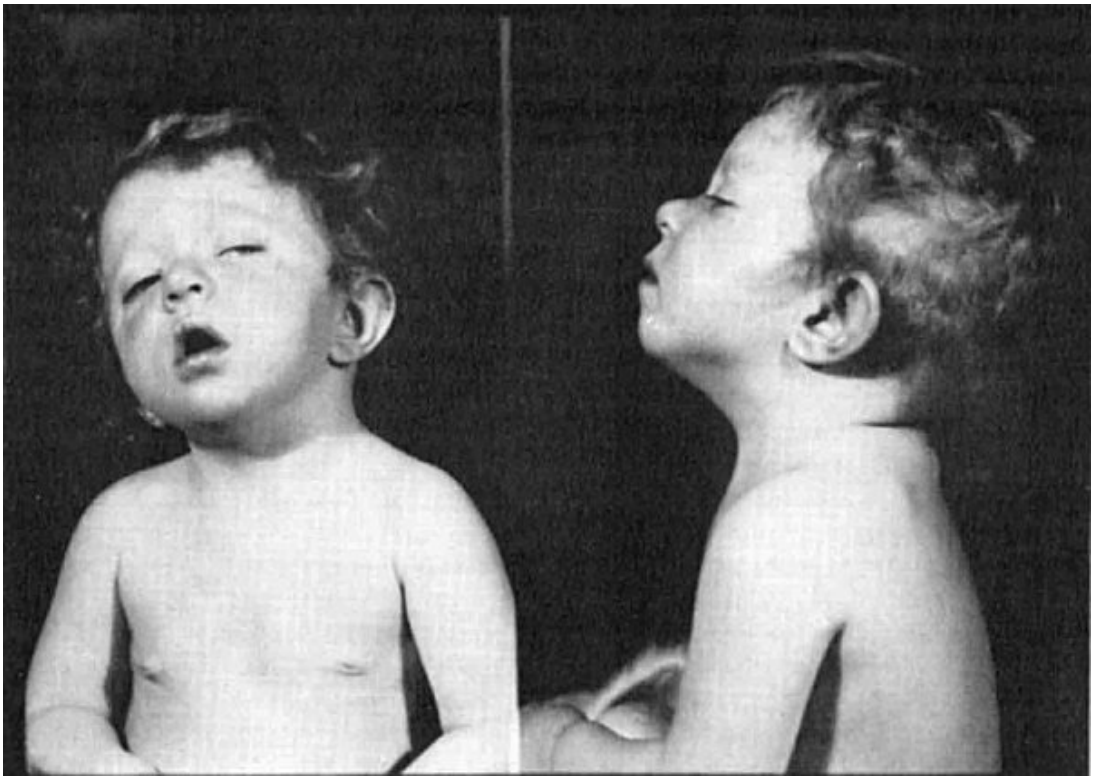

FIGURE 32-3
Hypertelorism. Note the wide distance between the eyes, flat nasal bridge, and

external strabismus. (Courtesy of Michael Malone, M.D. Children's Hospital, Washington, DC.)

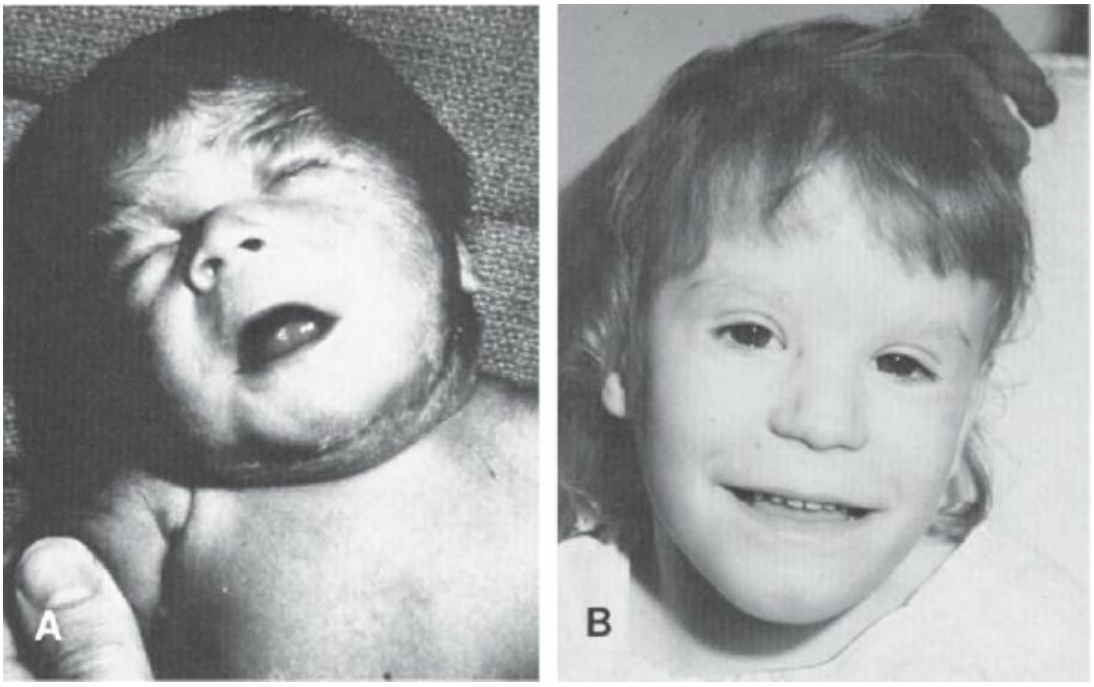

FIGURE 32-4
Photographs of children with "fetal-alcohol syndrome." **A:** Severe case. **B:** Slightly affected child. Note in both children the short palpebral fissures and hypoplasia of the maxilla. Usually, the defect includes other craniofacial abnormalities. Cardiovascular defects and limb deformities are also common symptoms of the fetal alcohol syndrome. (From Langman J. *Medical Embryology*. 7th ed. Philadelphia, PA: Williams & Wilkins; 1995:108, with permission.)

Some diagnostic tests carry a risk; for instance, about 5 percent of women who undergo fetoscopy miscarry. Amniocentesis, usually performed between the 14th and 16th weeks of pregnancy, causes fetal damage or miscarriage in less than 1 percent of women tested. Fully 98 percent of all prenatal tests in pregnant women reveal no abnormality in the fetus. Women older than 35 years of age and those with a family history of a congenital disability should have prenatal testing.

Parental reactions to congenital disabilities can include feelings of guilt, anxiety, or anger. The loss of the fantasized perfect child may cause depression. Some women may choose to terminate a pregnancy because of a known or suspected congenital malformation.

Maternal Drug Use

Alcohol. Alcohol use in pregnancy is a significant cause of severe physical and mental congenital disabilities in children. Each year, up to 40,000 babies are born with some degree of alcohol-related damage. The National Institute on Drug Abuse (NIDA) reports that 19 percent of pregnant women used alcohol during their pregnancy, the highest rate being among white women.

Fetal alcohol syndrome (Fig. 32-4) affects about one-third of all infants born to alcoholic women. Table 32-1 lists the characteristics of the disorder. The incidence of infants born with fetal alcohol syndrome is about 0.5 per 1,000 live births.

Some studies suggest that alcohol use during pregnancy may also contribute to attention-deficit/hyperactivity disorder (ADHD).

Smoking. Smoking during pregnancy may cause both premature births and below-average infant birth weight. Some reports have associated sudden infant death syndrome (SIDS) with mothers who smoke.

Table 32-1
Characteristics of Fetal Alcohol Syndrome

Growth retardation of prenatal origin (height, weight)
Facial Dysmorphism
Microcephaly (head circumference below the third percentile)
Hypertelorism (large distance between eyes)
Microphthalmia (small eyeballs)
Short palpebral fissures
Inner epicanthal folds
Midface hypoplasia (underdevelopment)
Smooth or short philtrum
Thin upper lip
Short, turned up nose
Cardiac Defects
Central nervous system (CNS) manifestations
Delayed development
Hyperactivity
Attention deficits
Learning disabilities

Intellectual deficits Seizures	

Other Substances. Chronic marijuana use is associated with low infant birth weight, prematurity, and withdrawal-like symptoms, including excessive crying, tremors, and hyperemesis (severe and chronic vomiting). Crack cocaine use by women during pregnancy may cause behavioral abnormalities such as increased irritability and crying and decreased desire for human contact. Infants born to mothers dependent on narcotics go through a withdrawal syndrome at birth.

Table 32-2
Causes of Human Malformations Observed During the First Year of Life

Suspected Cause	% of Total
Genetic	
Autosomal genetic disease	15–20
Cytogenic (chromosomal abnormalities)	5
Unknown	
Polygenic	
Multifactorial (genetic–environmental interactions)	
Spontaneous error of development	
Synergistic interactions of teratogens	
Environmental	
Maternal conditions: diabetes; endocrinopathies; nutritional deficiencies, starvation; drug and substance addictions	4
Maternal infections: rubella, toxoplasmosis, syphilis, herpes, cytomegalic inclusion disease, varicella,	3

Venezuelan equine encephalitis, parvovirus B19	
Mechanical problems (deformations): abnormal cord constrictions, disparity in uterine size and uterine contents	1–2
Chemicals, drugs, radiation, hyperthermia	<1
Preconception exposures (excluding mutagens and infectious agents)	<1

Reprinted from Brent RL, Beckman DA. Environmental teratogens. *Bull NY Acad Med*. 1990;66(2):123–163, with permission.

Prenatal exposure to various prescribed medications can also result in abnormalities. Common drugs with teratogenic effects include antibiotics (tetracyclines), anticonvulsants (valproate, carbamazepine, phenytoin), progesterone-estrogens, lithium, and warfarin. Table 32-2 outlines the etiologies of malformations that may emerge during the first year of life.

INFANCY

The average newborn weighs about 3,400 g (7.5 lb). Small fetuses (birth weight below the 10th percentile for their gestational age) occur in about 7 percent of all pregnancies. From the 26th to the 28th week of gestation, the prematurely born fetus has a good chance of survival. Arnold Gesell described developmental landmarks that are widely used in both pediatrics and child psychiatry. These landmarks outline the sequence of children's motor, adaptive, and personal–social behavior from birth to 6 years (Table 32-3).

Premature infants are born before 34 weeks or weigh less than 2,500 g (5.5 lb). Such infants are at increased risk for learning disabilities, such as dyslexia, emotional and behavioral problems, mental retardation, and child abuse. With each 100 g increment of weight, beginning at about 1,000 g (2.2 lb), infants have a progressively better chance of survival. A 36-week-old fetus has less chance of survival than a 3,000 g (6.6 lb) fetus born close to term. Figure 32-5 gives examples of some differences between full-term and premature infants.

FIGURE 32-5
Premature baby at breast during a gavage feed. (Photo courtesy of Mike McCarter, Connecticut Children's Medical Center.)

Postmature infants are born 2 weeks or more beyond the expected date of birth. The incidence of postmaturity is high if based on menstrual history alone. The postmature baby typically has long nails, scanty lanugo, more scalp hair than usual, and increased alertness.

Developmental Milestones in Infants

Reflexes and Survival Systems at Birth. Primitive reflexes are present at birth. They include the rooting reflex (puckering of the lips in response to perioral stimulation), the grasp reflex, the plantar (Babinski) reflex, the knee reflex, the abdominal reflexes, the startle (Moro) reflex (Fig. 32-6), and the tonic neck reflex. In healthy children, the grasp reflex, the startle reflex, and the tonic neck reflex disappear by the fourth month. The Babinski reflex usually disappears by the 12th month.

FIGURE 32-6
The Moro reflex. The head is allowed to fall backward. The arms abduct and extend.

Survival systems—breathing, sucking, swallowing, and circulatory and temperature homeostasis—are relatively functional at birth, but the sensory organs are still developing. Further differentiation of neurophysiologic functions depends on an active process of stimulatory reinforcement from the external environment, such as persons touching and stroking the infant. The newborn infant is awake for only a short period each day; rapid eye movement (REM) and non-REM sleep are present at birth. Other spontaneous behaviors include crying, smiling, and penile erection in males. Infants 1 day old can detect the smell of their mother's milk, and those 3 days old distinguish their mother's voice.

Table 32-3
Landmarks of Normal Behavioral Development

Age	Motor and Sensory	Adaptive	Personal and

	Behavior	Behavior	Social Behavior
Birth to 4 wk	Hand-to-mouth reflex, grasping reflex Rooting reflex (puckering lips in response to perioral stimulation), Moro reflex (digital extension when startled), sucking reflex, Babinski reflex (toes spread when sole of foot is touched) Differentiates sounds (orients to human voice) and sweet and sour tastes Visual tracking Fixed focal distance of 8 in Makes alternating crawling movements Moves head laterally when placed in prone position	Anticipatory feeding-approach behavior at 4 days Responds to sound of rattle and bell Regards moving objects momentarily	Responsiveness to mother's face, eyes, and voice within first few hours of life Endogenous smile Independent play (until 2 yr) Quiets when picked up Impassive face
4 wk	Tonic neck reflex positions predominate Hands fisted Head sags but can hold head erect for a	Follows moving objects to the midline Shows no interest and drops object	Regards face and diminishes activity Responds to speech Smiles

	few seconds Visual fixation, stereoscopic vision (12 wk)	immediately	preferentially to mother
16 wk	Symmetrical postures predominate Holds head balanced Head lifted 90 degrees when prone on forearm Visual accommodation	Follows a slowly moving object well Arms activate on sight of dangling object	Spontaneous social smile (exogenous) Aware of strange situations
28 wk	Sits steadily, leaning forward on hands Bounces actively when placed in standing position	One-hand approach and grasp of toy Bangs and shakes rattle Transfers toys	Takes feet to mouth Pats mirror image Starts to imitate mother’s sounds and actions
40 wk	Sits alone with good coordination Creeps Pulls self to standing position Points with index finger	Matches two objects at midline Attempts to imitate scribble	Separation anxiety manifest when taken away from mother Responds to social play, such as pat-a-cake and peek-a-boo Feeds self cracker and holds own bottle
52 wk	Walks with one hand held Stands alone briefly	Seeks novelty	Cooperates in dressing
15 mo	Toddles		Points or vocalizes

	Creeps up stairs		wants Throws objects in play or refusal
18 mo	Coordinated walking, seldom falls Hurls ball Walks up stairs with one hand held	Builds a tower of three or four cubes Scribbles spontaneously and imitates a writing stroke	Feeds self in part, spills Pulls toy on string Carries or hugs a special toy, such as a doll Imitates some behavioral patterns with slight delay
2 yr	Runs well, no falling Kicks large ball Goes up and down stairs alone Fine motor skills increase	Builds a tower of six or seven cubes Aligns cubes, imitating train Imitates vertical and circular strokes Develops original behaviors	Pulls on simple garment Domestic mimicry Refers to self by name Says “no” to mother Separation anxiety begins to diminish Organized demonstrations of love and protest Parallel play (plays side by side but does not interact with other children)

3 yr	Rides tricycle Jumps from bottom steps Alternates feet going up stairs	Builds tower of 9 or 10 cubes Imitates a three-cube bridge Copies a circle and a cross	Puts on shoes Unbuttons buttons Feeds self well Understands taking turns
4 yr	Walks down stairs one step to a tread Stands on one foot for 5–8 s	Copies a cross Repeats four digits Counts three objects with correct pointing	Washes and dries own face Brushes teeth Associative or joint play (plays cooperatively with other children)
5 yr	Skips, using feet alternately Usually has complete sphincter control Fine coordination improves	Copies a square Draws a recognizable person with a head, a body, and limbs Counts 10 objects accurately	Dresses and undresses self Prints a few letters Plays competitive exercise games
6 yr	Rides two-wheel bicycle	Prints name Copies triangle	Ties shoelaces

Adapted from Arnold Gessell, M.D., Ph.D. and Stella Chess, M.D.

Table 32-4
Language Development

Age and Stage of Development	Mastery of Comprehension	Mastery of Expression
0–6 mo	Shows startle	Has vocalizations other

	response to loud or sudden sounds; Attempts to localize sounds, turning eyes or head; Appears to listen to speakers, may respond with smile; Recognizes warning, angry, and friendly voices; Responds to hearing own name	than crying; Has differential cries for hunger, pain; Makes vocalizations to show pleasure; Plays at making sounds Babbles (a repeated series of sounds)
7–11 mo Attending-to-Language	Shows listening selectivity (voluntary control over responses to sounds); Listens to music or singing with interest; Recognizes “no,” “hot,” own name; Looks at pictures being named for up to 1 min; Listens to speech without being distracted by other sounds	Responds to own name with vocalizations; Imitates the melody of utterances; Uses jargon (own language); Has gestures (shakes head for no); Has exclamation (“oh-oh”); Plays language games (pat-a-cake, peekaboo)
12–18 mo Single-Word	Shows gross discriminations between dissimilar sounds (bells vs. dog vs. horn vs.	Uses single words (mean age of first word is 11 mo; by age 18 mo, child is using up to 20 words); “Talks” to toys, self, or

	mother’s or father’s voice); Understands basic body parts, names of common objects; Acquires understanding of some new words each week; Can identify simple objects (baby, ball, etc.) from a group of objects or pictures; Understands up to 150 words by age 18 mo	others using long patterns of jargon and occasional words; Approximately 25% of utterances are intelligible; All vowels articulated correctly; Initial and final consonants often omitted
12–24 mo Two-Word Messages	Responds to simple directions (“Give me the ball”) Responds to action commands (“Come here,” “Sit down”) Understands pronouns (me, him, her, you) Begins to understand complex sentences (“When we go to the store, I’ll buy you some candy”)	Uses two-word utterances (“Mommy sock,” “all gone,” “ball here”); Imitates environmental sounds in play (“moo,” “mmm, mmm,” etc.); Refers to self by name, begins to use pronouns; Echoes two or more last words of sentences; Begins to use three-word telegraphic utterances (“all gone ball,” “me go now”); Utterances 26–50% intelligible; Uses language to ask for needs
24–36 mo	Understands small	Uses real sentences with

Grammar Formation	body parts (elbow, chin, eyebrow); Understands family name categories (grandma, baby) Understands size (little one, big one) Understands most adjectives Understands functions (why do we eat, why do we sleep)	grammatical function words (can, will, the, a); Usually announces intentions before acting “Conversations” with other children, usually just monologues Jargon and echolalia gradually drop from speech Increased vocabulary (up to 270 words at 2 yr, 895 words at 3 yr); Speech 50–80% intelligible P, b, m articulated correctly; Speech may show rhythmic disturbances
36–54 mo Grammar Development	Understands prepositions (under, behind, between) Understands many words (up to 3,500 at 3 yr, 5,500 at 4 yr) Understands cause and effect (What do you do when you’re hungry? cold?) Understands analogies (Food is to eat, milk is to ____)	Correct articulation of *n, w, ng, h, t, d, k, g*; Uses language to relate incidents from the past; Uses wide range of grammatical forms: plurals, past tense, negatives, questions; Plays with language: rhymes, exaggerates; Speech 90% intelligible, occasional errors in the ordering of sounds within words; Able to define words; Egocentric use of language rare; Can repeat a 12-syllable sentence correctly;

		Some grammatical errors still occur
55 mo on True Communication	Understands concepts of number, speed, time, space; Understands left and right; Understands abstract terms; Is able to categorize items into semantic classes	Uses language to tell stories, share ideas, and discuss alternatives; Increasing use of varied grammar; spontaneous self-correction of grammatical errors; Stabilizing of articulation f, v, s, z, l, r, th, and consonant clusters; Speech 100% intelligible

Language and Cognitive Development. At birth, infants can make noises, such as crying, but they do not vocalize until about 8 weeks. At that time, guttural or babbling sounds occur spontaneously, especially in response to the mother. The persistence and further evolution of children's vocalizations depend on parental reinforcement. Language development occurs in well-delineated stages, as outlined in Table 32-4.

By the end of infancy (about 2 years), infants have transformed reflexes into voluntary actions that are the building blocks of cognition. They begin to interact with the environment, to experience feedback from their bodies, and to become intentional in their actions. By the end of the second year of life, children begin to use symbolic play and language.

Table 32-5
Piaget's Stages of Cognitive Development

Period of Development	Cognitive Spatial Stages and Associated Concepts	Cognitive Achievements
Gestational		Fetus can "learn"

		sounds and respond differentially to them after birth
Infancy: Birth–2 yr	**Sensorimotor**	Infants “think” with their eyes, ears, and senses
Birth–1 mo	Reflective; egocentric (newer research refutes this)	Newborns can learn to associate stroking with sucking
4–8 mo	Secondary circular: looks for objects partially hidden	Newborns can learn to suck to produce certain visual displays or music
8–12 mo	Secondary circulation coordinated: peek-a-boo, finds hidden objects	Can remember for 1-mo periods Can play with parent by looking for partially hidden objects
12–18 mo	Tertiary circular: explores properties and drops objects	Memory improves
18 mo–2 yr	Mental representation, make-believe play; memory of objects	Body parts used as objects Can stack one object within another Remembers hidden objects Drops objects over crib Knows animal sounds;

		names objects Knows body parts and familiar pictures Can understand causes not visible
Early Childhood: 2–7 yr	**Preoperational**	
2–7 yr	Egocentrism: “I want you to eat this too.” Animistic: “I’m afraid of the moon.” Lack of hierarchy: “Where do these blocks go?” Centration: “I want it now, not after dinner.” Irreversibility: “I don’t know how to go back to that room.”	Preschoolers use symbols Development of language and make-believe No sign of logic 3-yr-olds can count 2–3 objects; know colors and age 4-yr-olds can fantasize without concrete props
2–5 yr	Transductive reasoning: “We have to go this way because that’s the way Daddy goes.”	5–6-yr-olds get humor; understand good and bad; can do some chores 7–11-yr-olds have good memory; recall; can solve problems
Middle Childhood: 7–11 yr	**Concrete operational**	
	Hierarchical classification—arranges cars by types Reversibility—can play	Children begin to think logically Understand

	games backward and forward (e.g., checkers, triple kings) Conservation—lose two dimes and look for same Decentration—worry about small details, obsessive Spatial operations—likes models for directions Horizontal decalage—conservation of weight, logic Transitive inference—syllogisms; compare everything, brand names important	conservation of matter Frozen milk same amount as melted Can organize objects into hierarchies Children seem rational and organized
Adolescence: 11–19 yr	**Formal operational**	
11 yr onward	Hypothetical-deductive reasoning; adolescent quick thinking or excuses Imaginary audience—everyone is looking at them Personal fable—inflated opinion of themselves Propositional thinking—logic	Abstraction and reason Can think of all possibilities

Jean Piaget (1896–1980), a Swiss psychologist, observed the growing capacity of young children (including his own) to think and to reason. Table

32-5 outlines Piaget's stages of cognitive development.

Emotional and Social Development. By the age of 3 weeks, infants imitate the facial movements of adult caregivers. They open their mouths and thrust out their tongues in response to adults who do the same. By the third and fourth months of life, we can easily elicit these behaviors. These imitative behaviors are likely the precursors of the infant's emotional life. The smiling response occurs in two phases: the first phase is endogenous smiling, which occurs spontaneously within the first 2 months and is unrelated to external stimulation; the second phase is exogenous smiling, usually stimulated by the mother, and occurs by the 16th week.

The stages of emotional development parallel those of cognitive development. The caregiving person provides the primary stimulus for both aspects of mental growth. Human infants depend totally on adults for survival. Through warm and predictable interactions, an infant's social and emotional repertoire expands with the interplay of caregivers' social responses (Table 32-6).

Table 32-6
Emotional Development

Stages First Seen	Emotional Skills	Emotional Behavior
Gestational–Infancy: 0–2 yr		
0–2 mo onward	Love, evoked by touching	Social smile and joy shown
	Fear, evoked by loud noise	Responds to emotions of others
	Rage, evoked by body restrictions	All emotions there
	Brain pathways for emotion forming	

3–4 mo onward	Self-regulation of emotions starts; brain pathways of emotion growing	Laughter possible and more control over smiles; anger shown
7–12 mo	Self-regulation of emotion grows	Able to elicit more responsiveness
	Increased intensity of basic three	Denies to cope with stress
1–2 yr	Shame and pride appear; envy, embarrassment appear Displaces onto other children	Some indications of empathy starting; expressions of feeling: “I like you, Daddy” “I’m sorry” Likes attention and approval; enjoys play alone or next to peers
Early Childhood: 2–5 yr		
3–6 yr	Can understand causes of many emotions Can begin to find ways for regulating emotions and for expressing them Identifies with adult to cope	Empathy increases with understanding More response and less reaction; self-regulation: “Use your words to say that you are angry with him” Aggression becomes competition By age 5, shows sensitivity to criticism and cares about feelings of others

Middle Childhood: 5–11 yr		Ego rules until age 6
7–11 yr	Can react to the feelings of others More aware of other's feelings	Empathy becomes altruism: "I feel so bad about their fire, I'm going to give them some of my things" Superego dominates

In the first year, infants' moods are highly variable and intimately related to internal states such as hunger. Toward the second two-thirds of the first year, infants' moods grow increasingly related to external social cues; a parent can get even a hungry infant to smile. When the infant is internally comfortable, a sense of interest and pleasure in the world and its primary caregivers should prevail. Prolonged separation from the mother (or other primary caregivers) during the second 6 months of life can lead to depression that may persist into adulthood as part of an individual's character.

Temperamental Differences

Infants vary in their autonomic reactivity and temperament. Chess and Thomas identified nine behavioral dimensions in which reliable differences among infants can be observed (Table 32-7).

In studies of temperament, most temperamental dimensions of individual children remain stable through adulthood, but some do not persist. This is likely due to genetic and environmental effects on personality. A complex interplay exists among the initial characteristics of infants, the mode of parental interactions, and children's subsequent behavior. Observations of the stability and plasticity of certain temperamental traits support the importance of interactions between genetic endowment (nature) and environmental experience (nurture) in behavior.

Attachment

Bonding is the term used to describe the intense emotional and psychological

relationship a mother develops for her baby. Attachment is the relationship the baby develops with its caregivers. Infants in the first months after birth become attuned to social and interpersonal interaction. They show a rapidly increasing responsivity to the external environment and an ability to form a special relationship with significant primary caregivers—that is, to form an attachment. Table 32-8 lists the commonly observed attachment styles.

Harry Harlow. Harry Harlow studied social learning and the effects of social isolation on monkeys. Harlow placed newborn rhesus monkeys with two types of surrogate mothers—one a wire-mesh surrogate with a feeding bottle and the other a wire-mesh surrogate covered with terry cloth. The monkeys preferred the terry-cloth surrogates, which provided contact and comfort, to the feeding surrogate. (When hungry, the infant monkeys would go to the feeding bottle but then would quickly return to the terry-cloth surrogate.) When frightened, monkeys raised with terry-cloth surrogates showed intense clinging behavior and appeared to be comforted, whereas those raised with wire-mesh surrogates gained no comfort and appeared to be disorganized. The results of Harlow's experiments suggest that infant attachment is not merely the result of feeding.

Table 32-7
Temperament—Newborn to 6 Years

Dimension	Description
Activity level	Percent of time spent in activities
Distractibility	Degree to which stimuli are allowed to alter behavior
Adaptability	Ease moving into change
Attention span	Amount of time spent on attending
Intensity	Energy level
Threshold of responsiveness	Intensity required for response

Quality of mood	Amount positive compared to amount negative behavior
Rhythmicity	Regulation of functions
Approach/withdrawal	Response to new situations

Table 32-8
Types of Attachment

Secure Attachment	Children show fewer adjustment problems; however, these children have typically received more consistent and developmentally appropriate parenting for most of their life. The parents of securely attached children are likely better able to maintain these aspects of parenting through a divorce. Given that the family factors that lead to divorce also impact the children, there could be fewer securely attached children in divorcing families
Insecure/Avoidant Attachment	Children become anxious, clinging, and angry with the parent. These children typically come from families with adults who were also insecurely attached to their families and, thus, were unable to provide the kind of consistency, emotional responsiveness, and care that securely attached parents could offer. Such parents have a more difficult time with divorce, and are more likely to become rejecting.
Insecure/Ambivalent Attachment	Children generally are raised with disorganized, neglecting, and inattentive parenting. The parents are even less able to provide stability and psychological

strength for them after a divorce and, as a result, the children are even more likely to become clinging but inconsolable in their distress, as well as to act out, suffer mood swings, and become oversensitive to stress.

Both types of surrogate-reared monkeys were subsequently unable to adjust to life in a monkey colony and had extraordinary difficulty learning to mate. When impregnated, the female monkeys failed to mother their young.

John Bowlby. John Bowlby studied the attachment of infants to mothers and concluded that early separation of infants from their mothers had severe adverse effects on children's emotional and intellectual development. He described attachment behavior, which develops during the first year of life, as the maintenance of physical contact between the mother and child when the child is hungry, frightened, or in distress.

Mary Ainsworth. Mary Ainsworth expanded on Bowlby's observations and found that the interaction between mother and baby during the attachment period influences the baby's current and future behavior significantly. Many observers believe that patterns of infant attachment affect future adult emotional relationships. Patterns of attachment vary among babies; for example, some babies signal or cry less than others. Sensitive responsiveness to infant signals, such as cuddling the baby when it cries, causes infants to cry less in later months. Close bodily contact with the mother when the baby signals for her fosters self-reliance, rather than clinging dependence. Unresponsive mothers produce anxious babies.

Ainsworth also confirmed that attachment serves to reduce anxiety. What she called the secured base effect enables a child to move away from the attachment figure and explore the environment. Inanimate objects, such as a teddy bear or a blanket (called the transitional object by Donald Winnicott), also serve as a secure base, one that often accompanies children as they investigate the world. A growing body of literature derived from direct observation of mother–infant interactions and longitudinal studies has expanded on and refined Ainsworth's original descriptions. Maternal

sensitivity and responsiveness are the main determinants of secure attachment. However, when the attachment is insecure, the type of insecurity (avoidant, anxious, or ambivalent) is determined by infant temperament. Overall, male infants are less likely to have secure attachments and are more vulnerable to changes in maternal sensitivity than are female infants.

The birth of a second child decreases the attachment of the firstborn child. This decrease is most notable when the firstborn is 2 to 5 years of age as opposed to younger. Not surprisingly, the extent of the decrease also depends on the mother's sense of security, confidence, and mental health.

Social Deprivation Syndromes and Maternal Neglect. Investigators, especially René Spitz, have long documented the severe developmental retardation that accompanies maternal rejection and neglect. Infants in institutions characterized by low staff-to-infant ratios and frequent turnover of personnel tend to display marked developmental retardation, even with adequate physical care and freedom from infection. The same infants, placed in adequate foster or adoptive care, exhibit marked acceleration in development.

Fathers and Attachment. Babies become attached to fathers as well as to mothers, but the attachment is different. Generally, mothers hold babies for caregiving, and fathers hold babies for purposes of play. Given a choice of either parent after separation, infants usually go to the mother, but if the mother is unavailable, they turn to the father for comfort. Babies raised in extended families or with multiple caregivers can establish many attachments.

Stranger Anxiety. A developmentally expected fear of strangers first appears in infants at about 26 weeks of age and is more fully developed by 32 weeks. At the approach of a stranger, infants cry and cling to their mothers. Babies exposed to only one caregiver are more likely to have stranger anxiety than babies exposed to a variety of caregivers. Stranger anxiety likely results from a baby's growing ability to distinguish caregivers from all other persons.

Separation anxiety, which occurs between 10 and 18 months of age, is related to stranger anxiety but is not identical to it. Separation from the

person to whom the infant is attached precipitates separation anxiety. Stranger anxiety, however, occurs even when the infant is in the mother's arms. The infant learns to separate as it starts to crawl and move away from the mother, but the infant continually looks back and frequently returns to the mother for reassurance.

Margaret Mahler (1897–1985) proposed a theory to describe how young children acquire a sense of identity separate from that of their mothers'. Her observations of children and their mothers lead to her theory of separation-individuation. Table 32-9 lists Mahler's stages of separation-individuation.

Table 32-9
Stages of Separation-Individuation Proposed by Mahler

1. Normal autism (birth–2 mo)
   Periods of sleep outweigh periods of arousal in a state reminiscent of intrauterine life.
2. Symbiosis (2–5 mo)
   Developing perceptual abilities gradually enable infants to distinguish the inner from the outer world; mother–infant is perceived as a single fused entity.
3. Differentiation (5–10 mo)
   Progressive neurologic development and increased alertness draw infants' attention away from self to the outer world. Physical and psychological distinctiveness from the mother is gradually appreciated.
4. Practicing (10–18 mo)
   The ability to move autonomously increases children's exploration of the outer world.
5. Rapprochement (18–24 mo)
   As children slowly realize their helplessness and dependence, the need for independence alternates with the need for closeness. Children move away from their mothers and come back for reassurance.
6. Object constancy (2–5 yr)
   Children gradually comprehend and are reassured by the permanence of mother and other important people, even

when not in their presence.

Infant Care

Clinicians are now beginning to view infants as important actors in the family drama, ones who partly determine its course. Infants' behavior controls mothers' behavior, just as mothers' behavior modulates infants' behavior. A calm, smiling, predictable infant is a powerful reward for tender maternal care. A jittery, irregular, irritable infant tries a mother's patience. When a mother's capacity for giving is marginal, such infant traits may cause her to turn away from her child and thus complicate the child's already-troubled beginnings.

Parental Fit

Parental fit describes how well the mother or father relates to the newborn or developing infant; the idea takes into account the temperamental characteristics of both parent and child. Each newborn has innate psychophysiological characteristics, which are known collectively as temperament. Chess and Thomas identified a range of standard temperamental patterns, from the difficult child at one end of the spectrum to the easy child at the other end.

Difficult children, who make up 10 percent of all children, have a hyperalert physiologic makeup. They overreact to stimuli (cry easily at loud noises), sleep poorly, eat at unpredictable times, and are difficult to comfort. Easy children, who make up 40 percent of all children, are regular in eating, eliminating, and sleeping; they are flexible, can adapt to change and new stimuli with a minimum of distress, and are easily comforted when they cry. The other 50 percent of children are mixtures of these two types. The difficult child is harder to raise and places higher demands on the parent than the easy child. Chess and Thomas used the term *goodness of fit* to characterize the harmonious and consonant interaction between a mother and a child in their motivations, capacities, and styles of behavior. Poor fit is likely to lead to distorted development and maladaptive functioning. A difficult child must be recognized because parents of such infants often have feelings of inadequacy and believe that they are doing something wrong to account for the child's difficulty in sleeping and eating and their problems comforting the child.

Also, most difficult children have emotional disturbances later in life.

Good-Enough Mothering. Winnicott believed that infants begin life in a state of nonintegration, with unconnected and diffuse experiences, and that mothers provide the relationship that enables infants' incipient selves to emerge. Mothers supply a holding environment in which infants are contained and experienced. During the last trimester of pregnancy and for the first few months of a baby's life, the mother is in a state of primary maternal preoccupation, absorbed in fantasies about, and experiences with, her baby. The mother need not be perfect, but she must provide good-enough mothering. She plays a vital role in bringing the world to the child and offering empathic anticipation of the infant's needs. If the mother can resonate with the infant's needs, the baby can become attuned to its bodily functions and drives that are the basis for the gradually evolving sense of self.

TODDLER PERIOD

Accelerated motor and intellectual development occur in the second year. The ability to walk gives toddlers some control over their actions; this mobility enables children to determine when to approach and when to withdraw. The acquisition of speech profoundly extends their horizons. Typically, children learn to say "no" before they learn to say "yes." Toddlers' negativism is vital to the development of independence, but if it persists, oppositional behavior connotes a problem.

Learning language is a crucial task in the toddler period. Vocalizations become distinct, and toddlers can name a few objects and make needs known in one or two words. Near the end of the second year and into the third year, toddlers sometimes use short sentences. The pace of language development varies considerably from child to child, and although a small number of children are genuinely late developers, most child experts recommend a hearing test if the child is not making two-word sentences by age 2.

Developmental Milestones in Toddlers

Language and Cognitive Development. Toddlers begin to listen to explanations that can help them tolerate delay. They create new behaviors

from old ones (originality) and engage in symbolic activities, for instance, using words and playing with dolls when the dolls represent something, such as a feeding sequence. Toddlers have varied capacities for concentration and self-regulation.

Emotional and Social Development. In the second year, pleasure and displeasure become further differentiated. Social referencing is often apparent at this age; the child looks to parents and others for emotional cues about how to respond to novel events. Toddlers show exploratory excitement, assertive pleasure, and pleasure in discovery and in developing new behavior (e.g., new games), including teasing and surprising or fooling the parent (e.g., hiding). The toddler has capacities for an organized demonstration of love, as when the toddler runs up and hugs, smiles, and kisses the parent at the same time, and of protest when the toddler turns away, cries, bangs, bites, hits, yells, and kicks. Comfort with family and apprehension with strangers may increase. Anxiety appears to be related to disapproval and the loss of a loved caregiver and can be disorganizing.

Sexual Development. Sexual differentiation is evident from birth when parents start dressing and treating infants differently because of the expectations evoked by sex typing. Through imitation, reward, and coercion, children assume the behaviors that their cultures define as appropriate for their sexual roles. Children exhibit curiosity about anatomical sex. When their curiosity is recognized as healthy and elicits age-appropriate replies, children acquire a sense of the wonder of life and are comfortable with their roles. If the subject of sex is taboo and parents rebuff children’s questions, shame and discomfort may result.

Gender identity, the conviction of being male or female, begins to manifest at 18 months of age and is often fixed by 24 to 30 months. It was once widely believed that gender identity was primarily a function of social learning. John Money reported on children with ambiguous or damaged external genitalia who were raised as the sex opposite to their chromosomal sex. Long-term follow-up of those individuals suggests that the major part of gender identity is innate and that rearing may not affect the genetic diathesis.

Gender role describes the behavior that society deems appropriate for one sex or another, and it is not surprising that significant cultural differences

exist. There may be different expectations for boys and girls in what and with whom they play, their tone of voice, the expression of emotions, and how they dress. Nevertheless, some generalizations are possible. Boys are more likely than girls to engage in rough and tumble play. Mothers talk more to girls than to boys, and by the time the child is 2 years of age, fathers generally pay more attention to boys. Many educated, middle-class parents determined to raise nonsexist children are startled to see their children's determined preference for sex-stereotyped toys: girls want to play with dolls and boys with guns.

Toilet Training. The second year of life is a period of increasing social demands on children. Toilet training serves as a paradigm of the family's general training practices; that is, the parent who is overly severe in the area of toilet training is likely to be punitive and restrictive in other areas also. Control of daytime urination is usually complete by the age of 2½, and control of nighttime urination is usually complete by the age of 4 years. Since 1900, the pendulum has swung between extremes of permissiveness and control in toilet training. The trend in the United States has been toward delayed training, but in the last few years, this trend appears to be shifting back to early training.

Toddlers may have sleep difficulties related to fear of the dark, which may be helped with a nightlight. Most toddlers generally sleep about 12 hours a day, including a 2-hour nap. Parents must be aware that children of this age may need reassurance before going to bed and that the average 2-year-old takes about 30 minutes to fall asleep.

Parenting Challenges. In infancy, the primary responsibility for parents is to meet the infant's needs sensitively and consistently. The parental task in the toddler stage requires firmness about the boundaries of acceptable behavior and encouragement of the child's progressive emancipation. Parents must be careful not to be too authoritarian at this stage; children must be allowed to operate for themselves and to learn from their mistakes and must be protected and assisted when challenges are beyond their abilities.

During the toddler period, children are likely to struggle for the exclusive affection and attention of their parents. They may compete with siblings or one or another parent for the starring role in the family. Although children are

beginning to be able to share, they do so reluctantly. When the demands for exclusive possession are not resolved effectively, the result is likely to be jealous competitiveness in relationships with peers and lovers. The fantasies aroused by the struggle lead to fear of retaliation and displacement of fear onto external objects. In an equitable, loving family, a child elaborates on a moral system of ethical rights. Parents need to balance between punishment and permissiveness and set realistic limits on a toddler's behavior.

PRESCHOOL PERIOD

Marked physical and emotional growth occurs during the preschool period. Generally, between 2 and 3 years of age, children reach half their adult height. The 20 baby teeth are in place at the beginning of the stage, and by the end, they begin to fall out. Children are ready to enter school by the time the stage ends at age 5 or 6. They have mastered the tasks of primary socialization—to control their bowels and urine, to dress and feed themselves, and to control their tears and temper outbursts, at least most of the time.

The term preschool for the age group of 2½ to 6 years may be a misnomer; many children are already in school-like settings, such as preschool nurseries and daycare centers, where working mothers must often place their children. Preschool education can be valuable, but stressing academic advancement too far beyond a child's capabilities can be counterproductive.

Developmental Milestones in Preschoolers

Language and Cognitive Development. In the preschool period, children's use of language expands, and they use sentences. Individual words have regular and consistent meanings at the beginning of the period, and children begin to think symbolically. In general, however, their thinking is egocentric; they cannot place themselves in the position of another child and are incapable of empathy. Children think intuitively and prelogically and do not understand causal relations.

Emotional and Social Behavior. At the start of the preschool period, children can express such complex emotions as love, unhappiness, jealousy,

and envy, both preverbally and verbally. Their emotions are still easily influenced by somatic events, such as tiredness and hunger. Although they still think mostly egocentrically, children's capacity for cooperation and sharing is emerging. Various losses, such as of a loved person or approval, may cause anxiety. Although still potentially disorganizing, preschool children can tolerate anxiety better than when they were younger. Four-year-olds are learning to share and to have concern for others and may express feelings of tenderness.

By the end of the preschool period, children have many relatively stable emotions. The child balances expansiveness, curiosity, pride, and gleeful excitement related to the self and the family with coyness, shyness, fearfulness, jealousy, and envy. Shame and humiliation are evident. Capacities for empathy and love are developed but are fragile and quickly lost if competitive or jealous strivings intervene. Anxiety and fears are related to bodily injury and loss of respect, love, and emerging self-esteem. Guilt feelings are possible.

Children between the ages of 3 and 6 years are aware of their bodies and differences between the sexes. Their physical awareness extends beyond genitalia. Children may be preoccupied with illness or injury, and some call this the "the Band-Aid phase." Every injury must be examined and taken care of by a parent.

Children develop a division between what they want and what others tell them to do. The division increases until a gap grows between their set of expanded desires, their exuberance at unlimited growth, and their parents' restrictions; they gradually turn parental values into self-obedience, self-guidance, and self-punishment.

At the end of the preschool stage, the child's conscience is evolving. The development of a conscience sets the tone for the moral sense of "right and wrong." Until about 7 years of age, children typically experience rules as "absolute" and as existing for their own sake. They do not understand that more than one point of view on a moral issue may exist; a violation of the rules calls for absolute retribution—that is, children have the notion of immanent justice.

SIBLING RIVALRY. In the preschool period, children relate to others in new ways. The birth of a sibling (a common occurrence during this time) tests a

preschool child's capacity for further cooperation and sharing but may also evoke sibling rivalry, which is most likely to occur at this time. Sibling rivalry depends on child-rearing practice. Favoritism, for any reason, commonly aggravates such rivalry. Children who get special treatment because they are gifted, are defective in some way, or have a preferred gender are likely to receive angry feelings from their siblings. Experiences with siblings can influence growing children's relationships with peers and authority; for example, a problem may result if the needs of a new baby prevent the mother from attending to a firstborn child's needs. If not handled properly, the displacement of the firstborn can be a traumatic event.

PLAY. In the preschool years, children begin to distinguish reality from fantasy, and play reflects this growing awareness. Pretend games are popular and playfully help test real-life situations. Dramatic play in which children act out a role is typical. One-to-one play relationships advance to complicated patterns with rivalries, secrets, and two-against-one intrigues. Children's play behavior reflects their level of social development.

Between 2½ and 3 years, children commonly engage in parallel play, solitary play alongside another child with no interaction between them. By age 3, play is often associative, that is, playing with the same toys in pairs or small groups, but still with no real interaction among them. By age 4, children are usually able to share and engage in cooperative play. Real interactions and taking turns become possible.

Between 3 and 6 years of age, drawings may trace growth. A child's first drawing of a human being is a circular line with marks for the mouth, nose, and eyes; they add ears and hair later; arms and stick-like fingers appear next, and then legs appear. Last to appear is a torso in proportion to the rest of the body. Intelligent children can deal with details in their art. Drawings express creativity throughout a child's development: They are representational and formal in early childhood, make use of perspective in middle childhood, and become abstract and affect-laden in adolescence. Drawings also reflect children's body image concepts and sexual and aggressive impulses.

IMAGINARY COMPANIONS. Imaginary companions most often appear during preschool years, usually in children with above-average intelligence and usually in the form of persons. Imaginary companions may also be things,

such as anthropomorphized toys. Some studies suggest that up to 50 percent of children between the ages of 3 and 10 years have imaginary companions at one time or another. Their significance is not clear, but these figures are usually friendly, relieve loneliness, and reduce anxiety. In most instances, imaginary companions disappear by age 12, but they can occasionally persist into adulthood.

MIDDLE YEARS

The period between age 6 and puberty is the middle years. During this time, children enter elementary school. The formal demands for academic learning and accomplishment become significant determinants of further personality development.

Developmental Milestones in School-Age Children

Language and Cognitive Development. In the middle years, language expresses complex ideas with relations among several elements. Logical exploration tends to dominate fantasy, and children show an increased interest in rules and orderliness and an increased capacity for self-regulation. During this period, children's conceptual skills develop, and thinking becomes organized and logical. The ability to concentrate is well established by age 9 or 10, and by the end of the period, children begin to think in abstract terms. Improved gross motor coordination and muscle strength enable children to write fluently and draw artistically. They are also capable of complex motor tasks and activities, such as tennis, gymnastics, golf, baseball, and skateboarding.

Recent evidence has shown that changes in thinking and reasoning during the middle years result from maturational changes in the brain. Children are now capable of increased independence, learning, and socialization. Theorists consider moral development a gradual, stepwise process spanning childhood, adolescence, and young adulthood.

In the middle years, both girls and boys make new identifications with other adults, such as teachers and counselors. These identifications may so influence girls that their goals of wanting to marry and have babies, as their mothers did, may be combined with a desire for a career or may be postponed

or abandoned entirely.

Girls who cannot identify with their mothers or whose fathers are overly attached may become fixated at about a 6-year-old level; as a result, they may fear men or women or both or become seductively close to them. A similar situation can occur in boys who have been unable to identify successfully with fathers who were aloof, brutal, or absent. As a result, boys may enter this period with a variety of problems. They may be fearful of men, unsure of their sense of masculinity, or unwilling to leave their mothers (sometimes manifested by a school phobia); they may lack initiative and be unable to master school tasks, thus incurring academic problems.

The school-age period is a time when peer interaction assumes significant importance. Interest in relationships outside the family takes precedence over those within the family. Nevertheless, a special relationship exists with the same-sex parent, with whom children identify and who is now an ideal and a role model.

Empathy and concern for others begin to emerge early in the middle years; by the time children are 9 or 10, they have well-developed capacities for love, compassion, and sharing. They have a capacity for long-term, stable relationships with family, peers, and friends, including best friends. Emotions about sexual differences begin to emerge as either excitement or shyness with the opposite sex. School-age children prefer to interact with children of the same sex. Although the middle years have sometimes been referred to as a latency period—a moratorium on psychosexual exploration and play until the eruption of sexual impulses with puberty—it is now recognized that a considerable amount of sexual interest continues through these years. Sex play and curiosity are typical, especially among boys, but also among girls. Boys compare genitals and sometimes engage in group or mutual masturbation. Interest in anal humor and toilet jokes is also typical. Children this age often start using sexual and excretory words as expletives.

BEST FRIEND. Harry Stack Sullivan postulated that a buddy, or best friend, is an influential phenomenon during the school years. By about 10 years of age, children develop a close same-sex relationship, which Sullivan believed is necessary for further healthy psychological growth. Moreover, Sullivan believed that the absence of a close friend during the middle years of childhood is an early harbinger of schizophrenia.

SCHOOL REFUSAL. Some children refuse to go to school at this time, generally because of separation anxiety. A fearful mother may transmit her fear of separation to a child, or a child who has not resolved dependence needs panics at the idea of separation. School refusal is usually not an isolated problem; children with the problem typically avoid many other social situations.

Sex Role Development

Persons' sex roles are similar to their gender identity; persons see themselves as male or female. The sex-role also involves identification with culturally acceptable masculine or feminine ways of behaving, but changing expectations in society (particularly in the United States) of what constitutes masculine and feminine behavior can create ambiguity.

Parents react differently to their male and female children. Independence, physical play, and aggressiveness are encouraged in boys; dependence, verbalization, and physical intimacy are encouraged in girls. Nowadays, however, boys are encouraged to verbalize their feelings and to pursue interests traditionally associated with girls, whereas girls are encouraged to pursue careers traditionally dominated by men and to participate in competitive sports. As society grows more tolerant in its expectations of the sexes, roles become less rigid, and opportunities for boys and girls enlarge and broaden.

Biologically, boys are more physically aggressive than girls; and parental expectations, particularly the expectations of fathers, reinforce this trait. Differences also exist between boys and girls in the influence of persons outside the family. Girls tend to respond to the expectations and opinions of girls and teachers of either sex but to ignore boys. Boys, on the other hand, tend to respond to other boys but to ignore girls and teachers.

Dreams and Sleep

Children's dreams can have a profound effect on behavior. During the first year of life, when reality and fantasy are not yet fully differentiated, dreams may be experienced as if they were, or could be, real. At age 3, many children believe dreams are shared directly by more than one person, but most 4-year-olds understand that dreams are unique to each person. Children

view dreams either with pleasure or, as is most often reported, with fear. The dream content depends on the children's life experience, developmental stage, mechanisms used during dreaming, and sex.

Disturbing dreams are most common when children are 3, 6, and 10 years of age. Two-year-old children may dream about being bitten or chased; at the age of 4, they may have many animal dreams and also dream of persons who either protect or destroy. At age 5 or 6, dreams of being killed or injured, of flying and being in cars, and of ghosts become prominent; the role of conscience, moral values, and increasing conflicts are concerned with these themes. In early childhood, aggressive dreams rarely seem to occur; instead, dreamers are in danger, a state that perhaps reflects children's dependent position. By about the age of 5, children realize that their dreams are not real; before then, they believed them to be real events. By age 7, children know that they create their dreams themselves.

Between the ages of 3 and 6 years, children usually want to keep their bedroom door open or to have a nightlight, so that they can either maintain contact with their parents or view the room in a realistic, nonfearful way. At times, children resist going to sleep to avoid dreaming. Disorders associated with falling asleep, therefore, are often connected with dreaming. Children often create rituals to protect themselves in the withdrawal from the world of reality into the world of sleep. Parasomnias, such as sleepwalking, sleep talking, enuresis (bed-wetting), and night terrors, are common at this age. They usually occur during stage 4 sleep when dreaming is minimal, and they do not indicate emotional trouble or underlying psychopathology. Most children grow out of parasomnias by adolescence.

Periods of REM occur about 60 percent of the time during the first few weeks of life, a period when infants sleep two-thirds of the time. Premature babies sleep even longer than full-term babies, and a higher proportion of their sleep is REM sleep. The sleep-wake cycle of newborns is about 3 hours long. Adults spend about 20 percent of sleep dreaming. Even newborns have brain activity similar to that of the dreaming state.

Birth Spacing

For women in the United States, 10 percent of conceptions that lead to live births are considered unwanted, and 20 percent are wanted but considered ill-

timed.

Children born close together have higher rates of premature or underweight births and malnutrition; they develop more slowly and are at increased risk of contracting and dying from childhood infectious diseases. Studies have shown that a mother and child's health risks are reduced when the child is born 3 to 5 years after a previous birth. Compared with 24- to 29-month intervals, children born in 36- to 41-month intervals have a 28 percent reduction in stunting and a 29 percent reduction of low birth weight. Women who have children at 27- to 32-month intervals are 1.3 times more likely to avoid anemia, 1.7 times more likely to avoid third-trimester bleeding, and 2.5 times more likely to survive childbirth.

Birth Order

The effects of birth order vary. Firstborn children may be more highly valued or given more attention than subsequent children. Firstborn children appear to be more achievement-oriented and motivated to please their parents than subsequent children born to the same parents. Some studies show that people in certain competitive occupational areas, such as architecture, accounting, and engineering, tend to be firstborn children.

Second and third children have the advantage of their parents' previous experience. Younger children also learn from their older siblings. For example, they may show a more sophisticated use of pronouns at an earlier age than firstborns did. When spacing children too tightly, however, there may not be enough time for each child. The arrival of new children in the family affects not only the parents but also the siblings. Firstborn children may resent the birth of a new sibling, who threatens their sole claim on parental attention. In some cases, regressive behavior, such as enuresis or thumb-sucking, occurs.

Some researchers have suggested that there is a relationship between birth order and personality. However, extensive multicohort analyses have not supported this.

Children and Divorce

Many children live in homes in which divorce has occurred. Approximately 30 to 50 percent of all children in the United States live in homes in which

one parent (usually the mother) is the sole head of the household, and 61 percent of all children born in any given year can expect to live with only one parent before they reach the age of 18 years. A child's age at the time of the parents' divorce affects the child's reaction to the divorce. Immediately after a divorce, an increase in behavioral and emotional disorders appears in all age groups. Infants do not understand anything about separation or divorce; however, they do notice changes in their parents' responses to them and may experience changes in their eating or sleeping patterns; have bowel problems; and seem more fretful, fearful, or anxious. Children 3 to 6 years of age may not understand what is happening, and those who do understand often assume that they are somehow responsible for the divorce. Older children, especially adolescents, comprehend the situation and may believe that they could have prevented the divorce had they intervened in some way, but they are still hurt, angry, and critical of their parents' behavior.

Some children harbor the fantasy that their parents will reunite. Such children may show animosity toward a parent's real or potential new mate. Adaptation to the effects of divorce in children typically takes several years; however, up to about one-third of children from divorced homes may have lasting psychological trauma. Among boys, physical aggression is a common sign of distress. Adolescents tend to spend more time away from the parental home after the divorce. Children who adapt best to divorce are typically in a situation in which both parents make genuine efforts to spend time and relate to the child despite the child's potential anger about the divorce. The pre-divorce stability of the household is another influence, as are economic factors. To facilitate adaptation in children, a divorced couple who are amicable and avoid arguing with one another is most likely to succeed. Table 32-10 lists the potential psychological effects of divorce on children.

Table 32-10
Effects of Divorce on Children

- Children in homes with absent fathers are more likely to suffer from antisocial personality disorder, child conduct disorder, and attention-deficit hyperactivity disorder.
- The divorce rate of children of divorced parents doubles that of children from stable families.

- Children of divorce are far more likely to be delinquent, engage in premarital sex, and bear children out of wedlock during adolescence and young adulthood.
- Children from divorced homes function more poorly than children from continuously married parents across a variety of domains, including academic achievement, social relations, and conduct problems.
- Children from divorced homes have more psychological problems than those from homes disrupted by the death of a parent.
- Children from disrupted marriages experience greater risk of injury, asthma, headaches, and speech defects than children from intact families.
- Children of divorce tend to be impulsive, irritable, socially withdrawn, lonely, unhappy, anxious, and insecure.
- Children of divorce, especially boys, are more aggressive than children whose parents stayed married.
- Suicide rates for children of divorce are much higher than for children from intact families.
- Twenty to 25% have significant adjustment problems as teenagers

Data adapted from Americans for Divorce Reform, Arlington, Virginia. Table by Nitza Jones.

Table 32-11
Types of Step-Families

Neo-Traditional Families	• Resembles “traditional” families • Absent biologic parent is included at times. • Discipline, boundaries and limits, and expectations are discussed openly. • Family coalitions and “side-taking” are better avoided.
Romantic Families	• Expect to be a “traditional family” immediately • The absent biologic parent is expected to disappear and is often criticized. • Stepparent/stepchild difficulties are common.

	• Stress is unbearable. • Few open and frank discussions about problems
Matriarchal Families	• Run by a highly competent mom and her companion follows • Companion is a “buddy” to the children, not to the parent. • Birth of a step-sibling causes problems.

Stepparents. Although many possible scenarios that may occur after a divorce and remarriage, several potential scenarios have been outlined in Table 32-11. These include (1) Neo-traditional, (2) Romantic, and (3) Matriarchal. When remarriage occurs, children must learn to adapt to the stepparent and the “blended” family. Adaptation is often challenging, especially when a child feels that a stepparent is nonsupportive, resents the stepchild, or favors his or her natural children. Of step-families, 25 percent tend to dissolve within the first 2 years, whereas 75 percent grow to find a new balance in their blended family. A biologic child born to a new couple with a stepchild already in the home may receive more attention than the stepchild, leading to sibling rivalry. After 5 years, about 20 percent of adolescents in step-families suggest that they move out and try living with their other biologic parent.

Family Factors in Child Development

Family Stability. Parents and children living under the same roof in harmonious interaction is the expected cultural norm in Western society. Within this framework, childhood development presumably proceeds most expeditiously. Deviations from the norm, such as divorced- and single-parent families, are associated with a broad range of problems in children, including low self-esteem, increased risk of child abuse, and increased incidence of divorce when they eventually marry, and increased incidence of mental disorders, particularly depressive disorders and antisocial personality disorder as adults. Why some children from unstable homes are less affected than others (or even immune to these deleterious effects) is of great interest. Michael Rutter postulates that sex (boys are more affected than girls), age

(older children are less vulnerable than younger ones), and inborn personality characteristics influence vulnerability. For example, children who have a placid temperament are less likely to be victims of abuse within a family than are hyperactive children; they may be less affected by the emotional turmoil surrounding them.

Adverse Events. It is now well known that significant adverse events, especially in early childhood, such as sexual and physical abuse, neglect, or loss of a parent, interact with genetic background in a given child and influences the trajectory of development. For example, as mentioned earlier, early severe maltreatment such as sexual abuse increases the risk of multiple psychosocial difficulties and the emergence of many psychiatric disorders. Among young maltreated children, those with particular genetics, that is, who have the "short" variant of the serotonin transporter gene (short 5-HTTLPR polymorphism), may be more vulnerable to chronic depression in adulthood. This example of specific gene–environment interaction plays a vital role in a child's development as well as in the risk for future psychopathology. Current investigations are also seeking insight into what factors lead to resilience in youth exposed to adverse events, yet maintain allostasis, that is, stability in the face of stressful events. Hormones of the adrenal glands, thyroid, gonads, as well as metabolic hormones, play a role in the brain's ability to maintain stability upon exposure to stress, and the prefrontal cortex, hippocampus, and amygdala play critical roles in regulating emotionality, aggression, and resilience.

Daycare Centers. The role of daycare centers for children is under continuous investigation, and various studies have produced different results. One study found that children placed in daycare centers before the age of 5 are less assertive and less adequately toilet trained than home-reared children. Another study found that children in daycare to be more advanced in social and cognitive development than children who were not in daycare. The National Institute of Child Health and Human Development reported that 4½-year-olds who had spent more than 30 hours a week in child care were more demanding, more aggressive, and more noncompliant than those raised at home and showed higher cognitive skills, particularly in math and reading. These same children continued to score higher in math and reading skills but

had more poor work habits and social skills in third grade. The researchers were careful to note that this behavior was within the normal range, however.

All studies of daycare must take into account the quality of both the daycare center and the homes from which children come. For example, a child from a disadvantaged home may be better off at a daycare center than a child from an advantaged home. Similarly, a woman who wishes to leave home to work for financial or other reasons and cannot do so may resent remaining in the home in a child-rearing role, which may adversely affect the child.

Parenting Styles. How children are raised, vary considerably between and within cultures. Rutter has clustered this diversity into four general styles. Subsequent research has confirmed that certain styles tend to correlate with particular behavior in the children, although the outcomes are by no means absolute. The authoritarian style, characterized by strict, inflexible rules, can lead to low self-esteem, unhappiness, and social withdrawal. The indulgent-permissive style, which includes little or no limit setting coupled with unpredictable parental harshness, can lead to low self-reliance, poor impulse control, and aggression. The indulgent-neglectful style, one of noninvolvement in the child's life and rearing, puts the child at risk for low self-esteem, impaired self-control, and increased aggression. The authoritative-reciprocal style, marked by firm rules and shared decision-making in a warm, loving environment, is believed to be the style most likely to result in self-reliance, self-esteem, and a sense of social responsibility.

Development and Expression of Psychopathology

The expression of psychopathology in children can be related to both age and developmental level. Specific developmental disorders, particularly developmental language disorders, often are diagnosed in the preschool years. Delayed development of language is a common parental concern. Children who do not use words by 18 months or phrases by 2½ to 3 years may need assessment, particularly if they do not appear to understand typical verbal cues or much language at all. Mild mental retardation or specific learning problems often are not diagnosed until after the child begins elementary school. Disruptive behavior disorder will become apparent at that

time as the child begins to interact with peers. Similarly, attention-deficit disorders may only be apparent in school with its need for sustained attention. Other conditions, particularly schizophrenia and bipolar disorder, are rare in preschool and school-aged children.

ADOLESCENCE

Adolescence, marked by the physiologic signs and surging sexual hormones of puberty, is the period of maturation between childhood and adulthood. Adolescence is a transitional period in which peer relationships deepen, autonomy in decision-making grows, and they seek intellectual pursuits and social belonging. Adolescence is mostly a time of exploration and making choices, a gradual process of working toward an integrated concept of self. Adolescents are "works in progress," characterized by increasing ability for mastery over complex challenges of academic, interpersonal, and emotional tasks while searching for new interests, talents, and social identities. A body of growing literature of the specific mechanisms of brain development in adolescence has increased our understanding of broadening social skills in adolescents, in addition to the three expected developmental changes in adolescence: increased risk-taking, increased sexual behavior, and a move toward peer affiliation rather than a primary family attachment. The total cortical gray matter is at its peak at about age 11 years in girls and 13 years in boys, which enhances the ability to understand subtle social situations, control impulses, make long-range plans, and think ahead. White matter volume increases throughout childhood and adolescence, which may allow for increased "connectivity," thereby enhancing the abilities of adolescents to acquire new competencies, such as those needed to master today's technology.

What Is Normal Adolescence?

The concept of normality in adolescent development refers to the degree of psychological adaptation an adolescent achieves while navigating the hurdles and meeting the milestones characteristic of this period of growth. For up to approximately 75 percent of youth, adolescence is a period of successful adaptation to physical, cognitive, and emotional changes, mostly continuous with their previous functioning. Psychological maladjustment, self-loathing,

disturbance of conduct, substance abuse, affective disorders, and other impairing psychiatric disorders emerge in approximately 20 percent of the adolescent population.

Adolescent adjustment is continuous with previous psychological function; thus, psychologically disturbed children are at higher risk for psychiatric disorders during adolescence. Adolescents with psychiatric disorders are at increased risk for more significant conflicts with families and for feeling alienated from their families. Although up to 60 percent of adolescents endorse occasional distress or a psychiatric symptom, this group of adolescents functions well academically and with peers and describes themselves as generally satisfied with their lives.

The developmentalist Erik Erikson characterizes the normative task of adolescence as identity versus role confusion. The integration of past experiences with current changes takes place in what Erikson calls *ego identity*. Adolescents explore various aspects of their psychological selves by becoming fans of heroes or other well-known musical or political idols. Some adolescents appear consumed by their identification with a particular idol, whereas others are more moderate in their expression. Adolescents who feel accepted by a peer group and are involved in a variety of activities are less likely to become consumed by adoration of an idol. Socially isolated adolescents, feel socially rejected and become overly identified with an idol to the exclusion of all other activities, are at higher risk for serious emotional problems, and require psychiatric intervention.

Erickson uses the term moratorium to describe the interim period between the concrete thinking of childhood and a more evolved complex ethical development. Erikson defines identity crisis as a normative part of adolescence in which adolescents pursue alternative behaviors and styles and, then, successfully mold these different experiences into a stable identity. A failure to do so would result in identity diffusion, or role confusion, in which the adolescent lacks a cohesive or confident sense of identity. Adolescence is the time to bond with peers, experiment with new beliefs and styles, fall in love for the first time, and explore creative ideas for future endeavors.

Most adolescents go through this developmental process with optimism, develop good self-esteem, maintain good peer relationships, and sustain harmonious relationships with their families.

Stages of Adolescence

Early Adolescence. Early adolescence, from 12 to 14 years of age, is the period in which the most striking initial changes occur—physically, attitudinally, and behaviorally. Growth spurts often begin in these years for boys, whereas girls may have already had rapid growth for 1 to 2 years. At this stage, boys and girls begin to criticize usual family habits, insist on spending time with peers with less supervision, have a greater awareness of style and appearance, and may question previously accepted family values. A new awareness of sexuality may be displayed by increased modesty and embarrassment with their current physical development or may exhibit itself in an increased interest in the opposite sex.

Early adolescents engage in subtle or overt displays of their growing desire for autonomy, sometimes with challenging behaviors toward authority figures, including teachers and school administrators, and exhibit disdain for rules themselves. At this age, some adolescents begin to experiment with cigarettes, alcohol, and marijuana.

During early adolescence, there is a normal variation in when new defining behaviors are acquired. Overall, although many early adolescents make new friends and modify their public image, most maintain positive connections to family members, old friends, and their family's values. However, for some, early adolescence can a time of overwhelming turmoil, during which there is a dramatic rejection of family, friends, and lifestyle, resulting in a powerful alienation of the adolescent.

Jake, a 13-year-old adolescent, had just started the 8th grade. In the past, he has been a jovial, fun-loving, and cooperative student, but this year he found the school rules increasingly irritating and felt that his teachers were too strict. He had always been a good student while putting in a minimum of work. His older brother Sean, now in 11th grade, had established himself as a compliant, well-liked, and well-behaved student who always put maximal effort into school projects in the same school, so Jake was compared with his brother regularly by many teachers. Jake resented these comparisons because, unlike his brother, whom Jake felt was a "nerd," Jake was more rebellious, took more risks, and made

friends with more popular peers. To distinguish himself from his older brother in school and at home, Jake began to challenge the rules at school, stating that they were “stupid” and “meaningless.” Jake began to cut classes, to stay out late, and to experiment with alcohol and marijuana. He rejected his best friends from sixth and seventh grade and began to hang out with more daring peers. When Jake was at home, he was able to relate to his older brother Sean only when they played basketball and video games.

Jake’s grades began to deteriorate only slightly, but his parents noticed that on his report cards, his teachers rated his effort and behavior as unsatisfactory. During the second month of school, Jake’s parents received a phone call that Jake was going to be suspended due to possession of a small amount of marijuana on the school grounds during recess. During a subsequent meeting with the assistant principal and school counselor, Jake argued that the suspension was unfair because his grades were still good, and did not understand why his marijuana possession had triggered a suspension. When confronted with the fact that he had broken not only the school rules, but also violated the law, and that he was fortunate because the school did not involve the police, Jake became angry and continued to insist that they were mistreating him. He also blurted out that all of his teachers and his parents favored his older brother Sean and treated him like a second-class citizen. The school suspended Jake for 5 days but indicated that they would report the incident to the police unless Jake and his family initiated immediate counseling.

Jake begrudgingly began psychotherapy and entered into a weekly therapy group specializing in substance use for teens. Jake’s parents also sought therapy to work on becoming more unified in their parenting. Jake remained in psychotherapy for the next 1½ years, during which time his attitude and reasoning style changed and evolved considerably. At age 15, Jake was able to understand why his school had suspended him for possession of marijuana and came to appreciate their willingness to give him the chance to seek counseling, rather than be turned over to the police. Over time, Jake was able to admit the dangers of using drugs and took responsibility for his ill-advised behaviors. Alcohol and drug use continued to be a focus of his therapy and, by 15, Jake had virtually lost

interest in alcohol, and admitted to smoking marijuana rarely at parties. Jake became more open to making friends with a variety of peers, and he disclosed that he liked himself better now than when he was 13. He now treated his brother respectfully when alone or with friends, and he felt that his parents appreciated him for "who he was." (Courtesy of Caroly S. Pataki, M.D.)

Middle Adolescence. During the middle phase of adolescence (roughly between the ages of 14 and 16), adolescents' lifestyles may reflect their efforts to pursue their own stated goals of being independent. Their abilities to combine abstract reasoning with realistic decision-making and judgment are put to the test. In this phase, sexual behavior intensifies, making romantic relationships more complicated, and self-esteem becomes a pivotal influence on positive and negative risk-taking behaviors.

In this phase of development, adolescents tend to identify with a group of peers who become highly influential in their choices of activities, styles, music, idols, and role models. Adolescents' underestimation of the risks associated with a variety of recreational behaviors and their sense of "omnipotence," mixed with their drive to be autonomous, frequently cause some conflict with parental requests and expectations. Most teens can achieve the challenge of defining themselves as unique and different from their families while still connected with family members.

Jenna, a 16-year-old junior in high school, had just gotten her driver's license. She realized that she was lucky to have been given a brand new car at 16 because many of her friends did not yet have cars. Jenna was upset that her parents disapproved of her agreement to drive all of her friends to places that she did not even want to go. Jenna was an attractive and well-liked adolescent who had always been an "A" and "B" student, and never had school conflicts. She played the flute in the school's orchestra and was not involved in any team sports. Jenna started "going out" with a boy in her grade at school, Brett, who was also 16 years old, shortly after getting her license, and even though they did not know each other that well, Jenna felt that they had a close relationship. Since he did not yet have a car, she was the "identified driver" whenever they went out

or to parties. Jenna was glad about this because she did not like alcohol and was relieved that Brett would not be driving, given that he drank quite a bit at parties. Jenna got along reasonably well with her parents, who were considered very “easy-going” by her friends, and she felt that she and her parents had similar values and ideas.

Things were going well until Brett began to pressure her to go further in their sexual relationship. When Jenna told him that she was not ready, Brett hounded her more. When the subject of sex had come up with her parents “hypothetically” in the past, they had dismissed the subject, indicating that when it was the right time for her, Jenna would know. Jenna knew that she was not ready to have sex, although many of her classmates were sexually active. Jenna was not an impulsive person and liked to plan things carefully so that they would feel right to her. Jenna realized that she could not agree with Brett’s request, but she was confident that she could make him understand. One of Jenna’s friends suggested that Brett might break up with her as a result, but Jenna was willing to take that risk. Jenna carefully told Brett that she loved him, but she was not yet ready for sex. Jenna was slightly surprised that instead of pressuring her more or breaking up with her, Brett accepted her decision. He seemed a little relieved.

Jenna and Brett continued their relationship into their senior year of high school, and, toward the end of her senior year, Jenna desired to be sexually active with him. They decided to go to a community clinic known for its positive attitude toward adolescents, to learn about birth control methods, and pick one without including their parents. Jenna and Brett took the time to learn about a variety of birth control methods and chose to use condoms. When they left the clinic, Jenna and Brett felt closer than they had before and realized how they had both grown in their relationship. Jenna and Brett both felt that they were doing the right thing. (Courtesy of Caroly S. Pataki, M.D.)

Late Adolescence. Late adolescence (between the ages of 17 and 19) is a time when continued exploration of academic pursuits, musical and artistic tastes, athletic participation, and social bonds lead a teen toward a greater definition of self and a sense of belonging to specific groups or subcultures

within mainstream society. Well-adjusted adolescents can be comfortable with current choices of activities, tastes, hobbies, and friendships, yet remain aware that they will continue to refine their “identities” during young adulthood.

Joey was a second-semester freshman in college, living away from home, and had just turned 18 years of age. He reflected on the fact that he was no longer a “minor” and could make almost any decision for himself without involving his parents.

Joey felt liberated, but at the same time, he was confused and a little lost. Since 10th grade, Joey had planned to pursue a career in medicine like his father, so he had taken a heavy load of science courses in the first semester, all of which he had despised. This semester, however, Joey signed up for liberal arts classes. He did not mention this to his father. He then added classes that ranged from art history to architectural drafting to sociology, philosophy, and music. He had been influenced, he believed, by his roommate Tony, who was in the architecture program, and by his girlfriend, Lisa, who was majoring in studio art.

As the semester progressed, Joey found that his favorite course was the drafting class. Joey could not help but wonder whether he liked the drafting class so much because of how much he idolized Tony, or because he enjoyed the class. Joey talked this over with Lisa, who suggested that he chill out and not figure out the rest of his life right now. She recommended that he take at least two more semesters of varied classes, including those in the architecture curriculum, before making a final decision about a career. Joey realized that Lisa’s approach to college and life was so relaxed, the opposite of his approach, following his parents’ pressure to plan, make commitments early, and see them through, regardless of how it felt. Lisa’s approach left more room for reflecting on experiences and then making a choice, rather than jumping into what he was “supposed” to do. Joey took her advice and allowed himself another year to try out majors and then decide on a career. After experiencing courses in many varied subjects, Joey decided that he did truly enjoy architecture and was able to switch his focus from premed to architecture. (Courtesy of Caroly S. Pataki M.D.)

Components of Adolescence

Physical Development. Puberty is the process by which adolescents develop physical and sexual maturity, along with reproductive ability. The first signs of the pubertal process are an increased rate of growth in both height and weight. This process begins in girls by approximately 10 years of age. By the age of 11 or 12, many girls noticeably tower over their male classmates, who do not experience a growth spurt, on average, until they reach 13 years of age. By age 13, many girls have experienced menarche, and most have developed breasts and pubic hair.

Wide variation exists in the normal range of onset and timing of pubertal development and its components. A set sequence occurs, however, in the order in which pubertal development proceeds. Thus, secondary sexual characteristics in boys, such as increased length and width of the penis, for example, will occur after the release of androgens from developed enlarged testes.

Sexual maturity ratings (SMRs), also referred to as Tanner Stages, range from SMR 1 (prepuberty) to SMR 5 (adult). The SMR ratings include stages of genital maturity in boys and breast development in girls, as well as pubic hair development. Table 32-12 outlines SMRs for boys and girls.

The primary female sex characteristic is ovulation, the release of eggs from ovarian follicles, approximately once every 28 days. When adolescent girls reach SMR 3 to 4, ovarian follicles are producing enough estrogen to result in menarche, the onset of menstruation. When adolescent girls reach SMR 4 to 5, an ovarian follicle matures monthly, and ovulation occurs. Estrogen and progesterone promote sexual maturation, including further development of fallopian tubes and breasts.

For adolescent boys, the primary sex characteristic is the development of sperm by the testes. In boys, sperm development occurs in response to follicle-stimulating hormone acting on the seminiferous tubules within the testes. The pubertal process in boys consists of the growth of the testes stimulated by luteinizing hormone. An adolescent boy’s ability to ejaculate generally emerges within 1 year of reaching SMR 2. Secondary sexual characteristics in boys include thickening of the skin, broadening of the

shoulders, and the development of facial hair.

Cognitive Maturation. Cognitive maturation in adolescence encompasses a wide range of expanded abilities that fall within the global category of executive functions of the brain. These include the transition from concrete thinking to more abstract thinking, an increased ability to draw logical conclusions in scientific pursuits, with peer interactions, and in social situations; and new abilities for self-observation and self-regulation. Adolescents acquire increased awareness of their intellectual, artistic, and athletic gifts and talents, yet it often takes many more years into young adulthood to establish a practical application for these abilities.

Table 32-12
Sexual Maturity Ratings for Male and Female Adolescents

Sexual Maturity Rating	Girls	Boys
Stage 1	Preadolescent, papilla elevated No pubic hair	Penis, testes, scrotum preadolescent No pubic hair
Stage 2	Breast bud, small mound; areola diameter increased Sparse long pubic hair, mainly along labia	Penis size same, testes and scrotum enlarged, with scrotal skin reddened Sparse long pubic hair, mainly at the base of penis
Stage 3	Breast and areola larger; no separation of contours Pubic hair darker and coarser; spread over pubic area	Penis elongated, with increased size of testes and scrotum Pubic hair darker and coarser; spread over pubic area
Stage 4	Breast size increased	Penis increased in length

		and width
	Areola and papilla raised	Testes and scrotum larger
	Pubic hair coarse and thickened; covers less area than in adults, does not extend to thighs	Pubic hair coarse and thickened; covers less area than in adults, does not extend to thighs
Stage 5	Breasts resemble adult female breast; areola has recessed to breast contour Pubic hair increased in density; area extends to thighs	Penis, testes, scrotum appear mature Pubic hair increased in density; area extends to thighs

The central cognitive change that occurs gradually during adolescence is the shift from concrete thinking (concrete operational thinking, according to Jean Piaget) to the ability to think abstractly (formal operational thinking, in Piaget's terminology). This evolution occurs as an adaptation to stimuli that demand an adolescent to produce hypothetical responses, as well as in response to the adolescent's expanded abilities to provide generalizations from specific situations. The development of abstract thinking is not a sudden epiphany but, rather, a gradual process of expanding logical deductions beyond concrete experiences and achieving the capacity for idealistic and hypothetical thinking based on everyday life.

Adolescents often use an omnipotent belief system that reinforces their sense of immunity from danger, even when confronted with logical risks. Some degree of child-like magical thinking continues to coexist with more mature abstract thinking in many adolescents. Despite the persistence of magical thinking into adolescence, adolescent cognition departs from that of younger children insofar as the increased ability for self-observation and development of strategies to promote strengths and compensate for weaknesses.

One of the essential cognitive tasks in adolescence is to identify and gravitate toward those pursuits that seem to match the adolescent's cognitive strengths, in academic courses, and in thinking about future aspirations.

Piaget believed that cognitive adaptation in adolescence is profoundly influenced by social relationships and the dialogue between adolescents and peers, making social cognition an integral part of cognitive development in adolescence.

Socialization. Socialization in adolescence encompasses the ability to find acceptance in peer relationships, as well as the development of more mature social cognition. The skills to develop a sense of belonging to a peer group are of central importance to a sense of well-being. Being viewed as socially competent by peers is a critical component in building good self-esteem for most early adolescents. Peer influences are powerful and can foster positive social interactions, as well as apply pressure in less socially accepted behaviors or even high-risk behavior. Belonging to a peer group is, in general, a sign of adaptation and a developmentally appropriate step in separating from parents and turning the focus of loyalty toward friends. Children between the ages of 6 and 12 can engage in exchanges of ideas and opinions and acknowledge feelings of peers, but the relationships often wax and wane in a discontinuous way based on altercations and good times. Friendships deepen with repeated good times, but, for some school-aged children, a variety of peers are often interchangeable—that is, a child may seek a companion when that child has free time, rather than out of a desire to spend time with a specific friend. As adolescence ensues, friendships become more individualized, and adolescents may share personal secrets with a friend rather than a family member. The adolescent may achieve a comfort level with one or several early adolescent peers, and the group may "stick together," spending most of their free time together. In early adolescence, a blend of the above two social modes may emerge, small "cliques" arise, and, even within the cliques, competition and jealousies regarding which dyads are "preferred" or higher ranked within the clique may result in some discontinuities in the relationships. In later adolescence, the peer group solidifies, leading to increased stability in the friendships and a greater mutuality in the quality of the interactions.

Moral Development. Morality is a set of values and beliefs about codes of behavior that conform to those shared by others in society. Adolescents, as do younger children, tend to develop patterns of behaviors characteristic of their

family and educational environments and by imitation of specific peers and adults whom they admire. Moral development does not strictly follow chronologic age but, instead, is an outgrowth from cognitive development.

Piaget described moral development as a gradual process parallel to cognitive development, with expanded abilities in differentiating the best interests for society from those of individuals occurring during late adolescence. Preschool children simply follow the rules set forth by the parents; in the middle years, children accept rules but show an inability to allow for exceptions; and during adolescence, young persons recognize rules in terms of what is good for the society at large.

Lawrence Kohlberg integrated Piaget's concepts and described multiple stages of moral development within three significant levels of morality. The first level is preconventional morality, in which punishment and obedience to the parent are the determining factors. The second level is the morality of conventional role-conformity, in which children try to conform to gain approval and to maintain good relationships with others. The third and highest level is the morality of self-accepted moral principles, in which children voluntarily comply with rules based on a concept of ethical principles and make exceptions to rules in certain circumstances.

Although Kohlberg's and Piaget's notions of moral development focus on a unified theory of cognitive maturation for both sexes, Carol Gilligan emphasizes the social context of moral development leading to divergent patterns in moral development. Gilligan points out that, in women, compassion and the ethics of caring are dominant features of moral decision-making, whereas, for men, predominant features of moral judgments are related more to a perception of justice, rationality, and a sense of fairness. Although influential, many psychologists and scholars criticize Gilligan's work as primarily observational and lacking scientific rigor. Feminist scholars note that Gilligan rarely considers the role of societal expectations in influencing gender-based behavior.

Modern psychologists have incorporated insights from cognitive psychology and suggest that moral development goes beyond the rationality of Piaget and Kolberg. Psychologists such as Jonathan Haidt emphasize the role of intuition and preconceived beliefs based on the fundamental moral foundations found in a society. He suggests that the logical explanations one gives to justify one's actions are post hoc rationalizations meant to justify

one's emotional (i.e., irrational) reactions to the moral dilemmas we face in society.

Self-Esteem. Self-esteem is a measure of one's sense of self-worth based on perceived success and achievements, as well as a perception of how much one is valued by peers, family members, teachers, and society in general. The most important correlates of good self-esteem are one's perception of attractive physical appearance and high value to peers and family. Secondary features of self-esteem relate to academic achievement, athletic abilities, and unique talents. Adolescent self-esteem is mediated, to a significant degree, by the positive feedback received from a peer group and family members, and adolescents often seek out a peer group that offers acceptance, regardless of negative behaviors associated with that group. Adolescent girls have more of a problem maintaining self-esteem than do boys. Girls continued to rate themselves with generally lower self-esteem into adulthood.

Current Environmental Influences and Adolescence

Adolescent Sexual Behavior. Sexual experimentation in adolescents often begins with fantasy and masturbation in early adolescence, followed by noncoital genital touching with the opposite sex or, in some cases, same-sex partners, oral sex with partners, and initiation of sexual intercourse at a later point in development. By high school, most male adolescents report experience with masturbation, and more than half of adolescent girls report masturbation. The balance between healthy adolescent sexual experimentation and emotionally and physically safe sexual practices is one of the significant challenges for society.

Estimates vary, but about 50 percent of 9th- to 12th-grade students reported having had sexual intercourse. The median age at first intercourse is about 16 years for boys and 17 years for girls. Boys generally have more sexual partners than do girls, and boys are less likely than girls to seek emotional attachments with their sexual partners.

FACTORS INFLUENCING ADOLESCENT SEXUAL BEHAVIOR. Factors that affect sexual behavior in adolescents include personality traits, gender, cultural and religious background, racial factors, family attitudes, and sexual education

and prevention programs.

Personality factors are associated with sexual behavior, as well as sexual risk-taking. Higher levels of impulsivity are associated with a younger age at the first experience of sexual intercourse; a higher number of sexual partners; sexual intercourse without the use of contraception, including condoms; and a history of a sexually transmitted disease (STD, chlamydia).

Historically, male adolescents have initiated sexual intercourse at a younger age than female adolescents. The younger a teenage girl is when she has sex for the first time, the more likely she is to have had unwanted sexual activity. Close to four of ten girls who had first intercourse at 13 or 14 years of age report it was either not voluntary or unwanted. Three of four girls and over half of boys report that girls who have sex do so because their boyfriends want them to. In general, adolescents who initiate sexual intercourse at younger ages are also more likely to have a higher number of sexual partners.

The additive effects of more highly educated families, social and religious youth groups, and school-based educational programs can decrease high-risk sexual behavior among adolescents. Female empowerment strategies can play an essential role in decreasing unwanted sexual behavior and teenage pregnancies. The primary reason that teenage girls who have never had intercourse give for abstaining from sex is that having sex would be against their religious or moral values. Other reasons include the desire to avoid pregnancy, fear of contracting a STD, and not having met the appropriate partner.

CONTRACEPTIVES. Currently, 98 percent of teenagers 15 to 19 years are using at least one method of birth control. The two most common methods are condoms and birth control pills. STDs, despite the use of condoms, are still at high levels in teens—approximately one in four sexually active teens contracts an STD every year. Approximately half of all new human immunodeficiency virus (HIV) infections occur in people younger than age 25.

PREGNANCY. Each year 750,000 to 850,000 teenage girls younger than age 19 become pregnant. Of this number, 432,000 give birth, a 19 percent decline from 532,000 in 1991; the rest (418,000) obtain abortions. The largest decline

in teen pregnancy by race is for black women. Hispanic teen births have declined 20 percent, but continue to have the highest teen birth rates compared with other races.

Teenage pregnancy creates a plethora of health risks for both mother and child. Children born to teenage mothers have a higher chance of dying before the age of 5 years. Those who survive are more likely to perform poorly in school and are at higher risk of abuse and neglect. Teenage mothers are less likely to gain adequate weight during pregnancy, increasing the risk of premature births and low–birth-weight infants. Low–birth-weight babies are more likely to have organs that are not fully developed, resulting in bleeding in the brain, respiratory distress syndrome, and intestinal problems. Teenage mothers are also less likely to seek regular prenatal care and to take recommended daily multivitamins, and they are more likely to smoke, drink, or use drugs during pregnancy. Only one-third of teenage mothers obtain high school diplomas, and only 1.5 percent have a college degree by the age of 30.

The average adolescent mother who cannot care for her child has the child either placed in foster care or raised by the teenager's already overburdened parents or other relatives. Few teenage mothers marry the fathers of their children; the fathers, usually teenagers, cannot care for themselves, much less the mothers of their children. If the two do marry, they usually divorce. Many are more likely to end up on welfare.

ABORTION. Nearly four of ten teen pregnancies end in abortion. Almost all the girls are unwed mothers from low socioeconomic groups; their pregnancies result from sex with boys to whom they felt emotionally attached. Most (61 percent) teenagers elect to have abortions with their parents' consent, but laws of mandatory parental consent put two rights into a competition: a girl's claim to privacy and a parent's need to know. Most adults believe that teenagers should have parental permission for an abortion, but when parents refuse to give their consent, most states prohibit parents from vetoing the teenager's decision.

The abortion rate in many European countries tends to be far lower than that in the United States. The Control and Prevention (CDC) reports that the abortion rate in the United States for girls between the ages of 15 and 19 is about 30 per 1,000. In France, about 10.5 of every 1,000 girls under the age

of 20 had an abortion, according to World Health Organization statistics. The rate of abortion in Germany was 6.8; in Italy, 6.3; and in Spain, 4.5. Britain has a higher rate, 18.5. Family planning experts believe that more sex education and the availability of contraceptive devices help keep the number of abortions down. In Holland, where contraceptives are freely available in schools, the teenage pregnancy rate is among the lowest in the world.

Risk-Taking Behavior. Reasonable risk-taking is a necessary endeavor in adolescence, leading to confidence both in forming new relationships and in sports and social situations. High-risk behaviors among adolescents are associated with severe negative consequences, however, and can take many forms, including drug and alcohol use, unsafe sexual practices, self-injurious behaviors, and reckless driving.

Drug Use

ALCOHOL. About 30 percent of 12th graders report having five or more drinks in a row within 2 weeks. The average age when youths first try alcohol is 11 years for boys and 13 years for girls. The national average age at which Americans begin regular drinking is 15.9 years of age. People ages 18 to 25 show the highest prevalence of binge and heavy drinking. Drunk driving has declined since 2002. Alcohol dependence, along with other drugs, is associated with depression, anxiety, oppositional defiant disorder, antisocial personality disorder, and an increased rate of suicide.

NICOTINE. The number of young American smokers has declined since 1990. However, the rate of smoking among teenagers is still as high as or higher than that of adults. According to the American Cancer Society, on average more than one of five students have smoked cigarettes. Each day, more than 4,000 teenagers try their first cigarette, and another 2,000 become regular, daily smokers. Cigarette smokers are more likely to get into fights, carry weapons, attempt suicide, suffer from mental health problems such as depression, and engage in high-risk sexual behaviors. One of three will eventually die from smoking-related diseases. Cigarettes are the most common type of tobacco used among middle-school students, followed by cigars, smokeless tobacco, and pipes.

CANNABIS. Marijuana is the most popular illicit drug, with 14.6 million people using it (6.2 percent of the population), two-thirds being under the age of 18. Its use, however, is slowly declining. About 6 percent of 12th graders report daily use of marijuana.

One of the primary reasons for such prevalence of marijuana use among teenagers is because many find that marijuana is easier to get than alcohol or cigarettes. This belief has declined in recent years. Once teenagers are dependent on marijuana, they often tumble into truancy, crime, and depression.

COCAINE. About 13 percent of high school seniors use cocaine, exceeding the national average of 3.6 percent. Also, about 1 percent of 12th graders admit to using phencyclidine (PCP). Crystal methamphetamine (ice) has an annual prevalence in 12th graders of about 2 percent.

OPIOIDS. In recent years, the number of teens using prescription pain relievers for nonmedical reasons has increased. Prescription drug abuse by people ages 18 to 25 has increased by 15 percent. Drugs of specific concern are the pain relievers oxycodone and hydrocodone. Oxycodone has gained ground among high school students since its emergence in 2001, with 5 percent of 12th graders, 3.5 percent of 10th graders, and 1.7 percent of 8th graders reporting use. About 9 percent of 12th graders use hydrocodone, 6 percent of 10th graders, and 2.5 percent of 8th graders.

HEROIN. Heroin use is prevalent among adolescents, although less so than cocaine. The average age of use is 19, but almost 2 percent of 12th graders use it. The nasal route (snorting) is the most common method of use.

Violence. Although rates of violent crime have decreased throughout the United States in recent years, violent crimes by young offenders are on the increase. Homicides are the second leading cause of death among people aged 15 to 25. (Accidents are first; suicides are third.) Black male teenagers are far more likely to be murder victims than are boys from any other racial or ethnic group or girls of any race. The factor most strongly associated with violence among adolescent boys is growing up in a household without a father or father surrogate; this factor aside, race, socioeconomic status, and

education show no effect on the propensity toward violence.

BULLYING. *Bullying* is the use of one's strength or status to intimidate, injure, or humiliate another person of lesser strength or status. It can be physical, verbal, or social. Physical bullying involves physical injury or threat of injury to someone. Verbal bullying refers to teasing or insulting someone. Social bullying refers to the use of peer rejection or exclusion to humiliate or isolate a victim.

About 30 percent of 6th- through 10th-grade students experience moderate-to-frequent bullying, as a bully, a target, or both. Approximately 1.7 million children within this age group bully other children. Boys are more likely to be involved in bullying and violent behavior than girls. Girls tend to use verbal bullying rather than physical.

An estimated 160,000 students miss school each day because of fear of attack or intimidation from peers; some may drop out. Stresses of "victimization" can interfere with student's engagement and learning in school. Children who bully other children are at risk for engaging in more violent severe behaviors, such as frequent fighting and carrying a weapon.

Cyberbullying. During the last decade, electronic or internet bullying has become of great concern to adolescents. Cyberbullying is defined broadly to convey the use of electronic means to intimidate or harm someone intentionally. The reported prevalence of cyberbullying is variable, reports ranging from 1 to 62 percent of youth reporting that they were victims of cyber victimization. A study of about 700 Australian students, recruited at age 10 years, and followed until ages 14 to 15 years, found that 15 percent had engaged in cyberbullying, 21 percent had engaged in traditional bullying, and 7 percent had engaged in both. Another study of self-reported information collected from 399 teens in the 8th to 10th grades found that involvement in cyberbullying, either as a victim or a bully, specifically contributed to the prediction of depressive symptoms and suicidal ideation. This correlation between cyberbullying and depressive symptomatology is more reliable than the association of traditional bullying and affective disorder.

Gangs. Gang violence is a problem throughout the United States. There are

2,000 different youth gangs around the country, with more than 200,000 teens and young adults as members. Most members are between the ages of 12 and 24 years, with an average of 17 to 18 years. Gang membership is a brief phase for many teenagers; one-half to two-thirds leave the gang by the 1-year mark. Boys are more likely to join gangs than girls; however, female gang membership may be underrepresented. Female gang members are more likely to be found in small cities and rural areas and tend to be younger than male gang members. Female gang members are also involved in less delinquent or criminal activity than males and commit fewer violent crimes.

WEAPONS. Each day, on average, nearly 10 American children younger than the age of 18 years are killed in handgun suicides, homicides, and accidents. Many more are wounded. One in five youths in grades 9 to 12 carries a weapon: knife, gun, or club.

By law, anyone younger than 18 years cannot purchase a firearm. Two-thirds of students in grades 6 to 12 say that they can get a firearm within 24 hours, however. More than 22 million children live in a home with a firearm. In 40 percent of these homes, at least one gun is not locked, and 13 percent are unlocked and loaded. Two of three students involved in school shootings acquired their guns from their own home or that of a relative. At least 60 percent of suicide deaths in teens involve the use of a handgun.

SCHOOL VIOLENCE. According to the CDC, of all youth homicides in 2010, about 2 percent occurred in schools. Approximately 7 percent of teachers report they have been threatened with injury or physically attacked by a student from their school. Also, among students in grades 9 through 12, about 6 percent reported carrying a weapon on school property on one or more days in the 30 days before the survey.

Many factors can lead to violent acts in teenagers. Some inherited traits include impulsivity, learning difficulties, low IQ, or fearlessness. A correlation also exists between witnessing violent acts and involvement in violence. Children who witness violent acts are more aggressive and grow up more likely to become involved in violence—either as a victimizer or as a victim. Table 32-13 lists some of the early and imminent warning signs of school violence.

On April 20, 1999, two teenage boys, ages 17 and 18 years, went on a shooting rampage through Columbine High School of Littleton, Colorado. Armed with shotguns, a semiautomatic rifle, and a pistol, they laughed and shouted as they shot classmates and teachers at point-blank range while hurling homemade explosives. Fifteen were killed, including the 2 gunmen, who also injured 25 people.

The gunmen were members of the "trench coat mafia" at the high school, a clique of social misfits who stood out at the school for their gothic style of dress and nihilistic attitude. The two gunmen were obsessed with violent video games and intrigued with Nazi culture, even though one was part Jewish. They chose the date of the attack to coincide with Adolf Hitler's birthday.

On March 21, 2005, a 16-year-old boy went on a shooting rampage at Red Lake High School on the Red Lake Indian Reservation in far northern Minnesota. He began his shooting spree by killing his grandfather and the grandfather's companion. He then donned his grandfather's police-issue gun belt and bulletproof vest before heading to the school, where he killed a security guard, a teacher, five students, and then himself. About 15 others were injured.

The gunman had a troubled childhood; his father committed suicide in 1997, and his mother suffered head injuries in an auto accident. He expressed admiration for Adolf Hitler on a neo-Nazi website, using the handle "Todesengel," which is German for "Angel of Death." He had bouts of depression, suicide ideation and was taking fluoxetine. He was a member of a clique of about five students known as "The Darkers," who wore black clothes and chains, spiked or dyed their hair, and loved heavy-metal music. The gunman usually wore a long black trench coat, eyeliner, and combat boots. Peers described him as a quiet teenager.

Table 32-13
Warning Signs of School Violence

Early Warning Signs
Social withdrawal
Excessive feelings of isolation and being alone

- Excessive feelings of rejection
- Being a victim of violence
- Feelings of being picked on and persecuted
- Expression of violence in writings and drawings
- Uncontrolled anger
- Patterns of impulsive and chronic hitting, intimidating, and bullying behaviors
- History of discipline problems
- History of violent and aggressive behavior
- Intolerance for differences and prejudicial attitudes
- Drug and alcohol use
- Affiliation with gangs
- Inappropriate access to, possession of, and use of firearms
- Serious threats of violence

Imminent Warning Signs

- Serious physical fighting with peers or family members
- Severe destruction of property
- Severe rage for seemingly minor reasons
- Detailed threats of lethal violence
- Possession and/or use of firearms and other weapons
- Other self-injurious behaviors or threats of suicide

SEXUAL OFFENSE. Adolescents younger than age 18 years account for 20 percent of arrests for all sexual offenses (excluding prostitution), 20 to 30 percent of rape cases, 14 percent of aggravated sexual assault offenses, and 27 percent of child sexual homicides. These adolescent offenders account for the victimization of approximately one-half of boys and one-fourth of girls who are molested or sexually abused. Most instances have involved adolescent male perpetrators.

Table 32-14
Juvenile Sex Offender Subtypes

Juvenile Offenders Who Sexually Offend against Peers or Adults

- Predominantly assault females and strangers or casual

- acquaintances
- Sexual assaults occur in association with other types of criminal activity (e.g., burglary)
- Have histories of nonsexual criminal offenses, and appear more generally delinquent and conduct disordered
- Commit their offenses in public areas
- Display higher levels of aggression and violence in the commission of their sexual crimes
- More likely to use weapons and to cause injuries to their victims

Juvenile Offenders Who Sexually Offend against Children

- Most victims are male and are related to them, either siblings or other relatives
- Almost half of the offenders have had at least one male victim
- The sexual crimes tend to reflect a greater reliance on opportunity and guile than injurious force. This appears to be particularly true when their victim is related to them. These youths may “trick” the child into complying with the molestation, use bribes, or threaten the child with loss of the relationship
- Within the overall population of juveniles who sexually assault children are certain youths who display high levels of aggression and violence. Generally, these are youths who display more severe levels of personality and/or psychosexual disturbances, such as psychopathy, sexual sadism, and so on
- Suffer from deficits in self-esteem and social competency
- Many show evidence of depression

Characteristics Common to Both Groups

- High rates of learning disabilities and academic dysfunction (30–60%)
- The presence of other behavioral health problems, including substance abuse, and disorders of conduct (up to 80% have some diagnosable psychiatric disorder)
- Observed difficulties with impulse control and judgment

There appear to be two types of juvenile sex offenders: those who target children and those who offend against peers or adults. The age difference between the victim and the offender is the main difference between the two groups. Table 32-14 lists the differences and similarities between these two groups.

Etiologic factors of juvenile sex offending include maltreatment experiences, exposure to pornography, substance abuse, and exposure to aggressive role models. A significant number of offending adolescents have a childhood history of physical abuse (25 to 50 percent) or sexual abuse (10 to 80 percent). Half of the adolescent offenders lived with both parents and one other juvenile at the time of their offending. Evidence also suggests that most juvenile sex offenders are likely to become adult sex offenders. The most common psychosocial deficits of adolescent sexual offenders include low self-esteem, few social skills, minimal assertive skills, and poor academic performance. The most common psychiatric diagnoses are conduct disorder, substance abuse disorder, adjustment disorder, ADHD, specific phobia, and mood disorders. Male offenders are more often diagnosed with paraphilias and antisocial behavior, whereas female offenders are more likely to be diagnosed with mood disorders and engage in self-mutilation.

Prostitution. Teenagers constitute a large portion of all prostitutes, with estimates ranging up to 1 million teenagers involved in prostitution. The average age of a recruit is 13 years; however, some are young as 9 years of age. Most adolescent prostitutes are girls, but boys may become same-sex prostitutes. Most teenagers who enter a life of prostitution come from broken homes; however, a growing number of teenage prostitutes come from middle- to upper-middle-class homes. Many have been victims of rape or abuse as children. Most teenagers ran away from home and were taken in by pimps and substance abusers; the adolescents themselves then became substance abusers. Twenty-seven percent of teenage prostitution occurs in large cities, and incidents usually take place at an outside location, such as highways, roads, alleys, fields, woods, or parking lots. Teenage prostitutes are at high risk for acquired immunodeficiency syndrome (AIDS), and many (up to 70 percent in some studies) have HIV.

As many as 17,500 individuals are smuggled into the United States each year as “sex slaves.” They arrive under the pretenses of a better life and job

opportunities, but once they are in the United States, they are forced into prostitution, making little money while traffickers make thousands of dollars from their services. Many times they are raped and abused.

Tattoos and Body Piercing. Body piercing and tattoos have become more prevalent among adolescents since the 1980s. In the general population, approximately 10 to 13 percent of adolescents have tattoos. Of the more than 500 adolescents surveyed in a study, 13.2 percent report at least one tattoo, and 26.9 percent report at least one body piercing, other than in their ear lobe, at some point in their lives. Both tattoos and body piercing are more common in girls than in boys. Adolescents who endorsed possession of at least one tattoo or body piercing are more likely to endorse the use of gateway drugs (cigarettes, alcohol, marijuana), as well as experience with hard drugs (cocaine, crystal methamphetamine, and ecstasy).

32.2 Adulthood

INTRODUCTION

For most of the history of developmental psychology, the predominant theory held that development ended with childhood and adolescence. Adults were considered to be finished products in whom the ultimate developmental states had been reached. Beyond adolescence, the developmental point of view was relevant only insofar as success or failure to reach adult levels or to maintain them determined the maturity or immaturity of the adult personality.

In contradistinction were the long-recognized ideas that adult experiences, such as pregnancy, marriage, parenthood, and aging, had an obvious and significant impact on mental processes and experience in the adult years. This view of adulthood suggests that the patient, of any age, is still in the process of ongoing development, as opposed to merely having a past that influences mental processes and is the primary determinant of current behavior. Although the debate continues, the idea that development continues throughout life is increasingly accepted.

Development in adulthood, as in childhood, is always the result of the

interaction among body, mind, and environment, never exclusively the result of any one of the three variables. Most adults are forced to confront and adapt to similar circumstances: establishing an independent identity, forming a marriage or other partnership, raising children, building and maintaining careers, and accepting the disability and death of one's parents.

In modern Western societies, adulthood is the most prolonged phase of human life. Although the exact age of consent varies from person to person, adulthood can be divided into three main parts: young or early adulthood (ages 20 to 40), middle adulthood (ages 40 to 65), and late adulthood or old age.

YOUNG ADULTHOOD (20 TO 40 YEARS OF AGE)

Usually considered to begin at the end of adolescence (about age 20) and to end at age 40, early adulthood is characterized by peaking biologic development, the assumption of major social roles, and the evolution of an adult self and life structure. The successful passage into adulthood depends on the satisfactory resolution of childhood and adolescent crises.

During late adolescence, young persons generally leave home and begin to function independently. Sexual relationships become serious, and the quest for intimacy begins. The 20s are spent, for the most part, exploring options for occupation and marriage or alternative relationships and making commitments in various areas.

Early adulthood requires choosing new roles (e.g., husband, father) and establishing an identity congruent with those new roles. It involves asking and answering the questions "Who am I?" and "Where am I going?" The choices made during this time may be tentative; young adults may make several false starts.

Transition from Adolescence to Young Adulthood

The transition from adolescence to young adulthood is characterized by real and intrapsychic separation from the family of origin and the engagement of new, phase-specific tasks (Table 32-15). It involves many important events, such as graduating from high school, starting a job or entering college, and living independently. During these years, the individual resolves the issue of childhood dependency sufficiently to establish self-reliance and begins to

formulate new, young-adult goals that eventually result in the creation of new life structures that promote stability and continuity.

Developmental Tasks

Establishing a self that is separate from parents is a significant task of young adulthood. For most individuals, the emotional detachment from parents that takes place in adolescence and young adulthood is followed by a new inner definition of themselves as comfortably alone and competent, able to care for themselves in the real world. This shift away from the parents continues long after marriage, and parenthood results in the formation of new relationships that replace the progenitors as the most influential individuals in the young adult's life.

Psychological separation from the parents is followed by the synthesis of mental representations from the childhood past and the young-adult present. The psychological separation from parents in adolescence has been called the *second individuation*, and the continued elaboration of these themes in young adulthood has been called the *third individuation.* The continuous process of elaboration of self and differentiation from others that occurs in the developmental phases of young and middle age continues to influence our meaningful adult relationships.

Table 32-15
Development Tasks of Young Adulthood

To develop a young-adult sense of self and other: the third individuation
To develop adult friendships
To develop the capacity for intimacy; to become a spouse
To become a biologic and psychological parent
To develop a relationship of mutuality and equality with parents while facilitating their midlife development
To establish an adult work identity
To develop adult forms of play
To integrate new attitudes toward time

Table 32-16
Psychological Development Concepts

Concept	Definition	Example
Transition	The bridge between two successive stages	Late adolescence
Normative crisis	A period of rapid change or turmoil that strains a person's adaptive capacities	Midlife crisis
Stage	Period of consolidation of skills and capacities	Mature adulthood
Plateau	Period of developmental stability	Adulthood up to midlife
Rite of passage	Social ritual that facilitates a transition	Graduation; marriage

Adapted from Wolman T, Thompson T. Adult and later-life development. In: Stoudemire A, ed. *Human Behavior*. Philadelphia, PA: Lippincott-Raven; 1998, with permission.

Several different models have been proposed for understanding adult development. They are all theoretical and somewhat idealized. They all use metaphors to describe complex social, psychological, and interpersonal interactions. The models are heuristic: They provide a conceptual framework for thinking about important common experiences. They are descriptive rather than prescriptive; that is, they offer a useful way of looking at what many persons do, not a formula for what all persons should do. Some of the terms and concepts commonly used are explained in Table 32-16. These periods involve individuation, that is, leaving the family of origin and becoming one's own man or woman, passing through midlife, and preparing in middle adulthood for the transition into late adulthood.

Work Identity. The transition from learning and play to work may be gradual or abrupt. Socioeconomic group, gender, and race affect the pursuit and development of particular occupational choices. Blue-collar workers generally enter the workforce directly after high school; white-collar workers

and professionals usually enter the workforce after college or professional school. Depending on the choice of career and opportunity, work may become a source of ongoing frustration or activity that enhances self-esteem. Symptoms of job dissatisfaction are a high rate of job changes, absenteeism, mistakes at work, accident proneness, and even sabotage.

UNEMPLOYMENT. The effects of unemployment transcend those of loss of income; the psychological and physical tolls are enormous. The incidence of alcohol dependence, homicide, violence, suicide, and mental illness rises with unemployment. One's core identity, which is often tied to occupation and work, is seriously damaged when a job is lost, whether through firing, attrition, or early or sometimes even regular retirement.

A young adult female patient had much enjoyed her 5 years in college, and only reluctantly accepted a job with a large real estate firm. During college, she had limited interest in her appearance, and she began work in clothing borrowed from family and friends. She scoffed when her boss began to criticize her dress and gave her an advance to buy an upscale wardrobe, but she then began to enjoy the fine clothing and the respect engendered by her appearance and position. As her income began to rise, work became a source of pleasure and self-esteem and the way to acquire some of the trappings of adulthood. (Courtesy of Calvin Colarusso, M.D.)

Developing Adult Friendships. In late adolescence and young adulthood, before marriage and parenthood, friendships are often the primary source of emotional sustenance. Roommates, apartment-mates, sorority sisters, and fraternity brothers, as indicated by the names used to describe them, are substitutes for parents and siblings, temporary stand-ins until more permanent replacements are found.

Friendships mostly meet the emotional needs of closeness and confidentiality. All major developmental issues are discussed with friends, particularly those in similar circumstances. As marriages occur and children are born, the central emotional importance of friendships diminishes. Some friendships are abandoned at this point because the spouse objects to the friend, recognizing at some level that they are competitors. Gradually, there is

a movement toward a new form of friendship, couples friendships. They reflect the newly committed status but are more difficult to form and to maintain because four individuals must be compatible, not just two.

As children begin to move out of the family into the community, parents follow. Dance classes and Little League games provide the progenitors with a new focus and the opportunity to make friends with others who are at the same point developmentally and who are receptive to the formation of relationships that help explain and cushion the pressures of young adult life.

Sexuality and Marriage. The developmental shift from sexual experimentation to the desire for intimacy is experienced in young adulthood as intense loneliness, resulting from the awareness of an absence of committed love similar to that experienced in childhood with their parents. Brief sexual encounters in short-lived relationships no longer significantly boost self-esteem. Increasingly, the desire is for emotional involvement in a sexual context. The young adult who fails to develop the capacity for intimate relationships runs the risk of living in isolation and self-absorption in midlife.

For most individuals in Western culture, the experience of intimacy increases the desire for marriage. Most persons in the United States marry for the first time in their mid-to-late 20s. The median age of first marriage has been rising steadily since 1950 for both men and women, and the number of persons who never marry has been increasing. Today, approximately 50 percent of all adults ages 18 and older are not married, compared with only 28 percent in 1960. The proportion of 30- to 34-year-olds who never married has almost tripled, and the ratio of never-married 35- to 39-year-olds doubled.

INTERRACIAL MARRIAGE. Mixed-race marriages were banned in 19 states until a U.S. Supreme Court decision in 1967. In 1970, such marriages accounted for only 2 percent of all marriages. The trend has been steadily upward. Currently, interracial marriages account for about 1.5 million marriages in the United States.

Despite the trend toward more interracial marriages, they remain a small proportion of all marriages. Most persons are more likely to marry someone from the same racial and ethnic background. Marriages between Hispanic whites and non-Hispanic whites and between Asians and whites are more

common than those between blacks and whites.

SAME-SEX MARRIAGE. Same-sex marriage is recognized as legal by many states in the United States and by the U.S. Supreme Court, as well as in several countries around the world (e.g., France and Denmark). It differs from same-sex civil unions granted by states, which do not provide the same federal protections or benefits as marriage. No reliable estimates are available for the number of same-sex marriages in the United States; however, in 2013, it was estimated to be about 80,000. There is growing consensus in the United States and around the world that gay and lesbian persons should be allowed the same marital rights and privileges as straight adults. Same-sex marriage can be subject to more stress than heterosexual marriage because of continued prejudice toward such unions among certain conservative political or religious groups who oppose such unions.

MARITAL PROBLEMS. Although marriage tends to be regarded as a permanent tie, unsuccessful unions can be terminated, as indeed they are in most societies. Nevertheless, many marriages that do not end in separation or divorce are disturbed. In considering marital problems, clinicians are concerned with both the persons involved and with the marital unit itself. How any marriage works relates to the partner selected, the personality organization or disorganization of each, the interaction between them, and the original reasons for the union. Persons marry for a variety of reasons—emotional, social, economic, and political, among others. One person may look to the spouse to meet unfulfilled childhood needs for good parenting. Another may see the spouse as someone to be saved from an otherwise unhappy life. Irrational expectations between spouses increase the risk of marital problems.

MARRIAGE AND COUPLES THERAPY. When families consist of grandparents, parents, children, and other relatives living under the same roof, assistance for marital problems can sometimes be obtained from a member of the extended family with whom one or both partners have rapport. With the contraction of the extended family in recent times, however, this source of informal help is no longer as accessible as it once was. Similarly, religion once played a more important role than it does now in the maintenance of

family stability. Wise religious leaders are available to provide counseling. Still, they are not sought out to the extent they once were, which reflects the decline in religious influence among large segments of the population. Traditionally, a couple's extended family and their religion guided them during distressing times. In addition to these supports, social pressure helped to prevent the dissolution of marriages. As family, religious, and societal pressures have been relaxed, legal procedures for relatively easy separation and divorce have expanded. Concurrently, the need for formalized marriage counseling services has developed.

Marital therapy is a form of psychotherapy for married persons in conflict with each other. A trained person establishes a professional contract with the patient-couple and, through definite types of communication, attempts to alleviate the disturbance, to reverse or change maladaptive patterns of behavior, and to encourage personality growth and development.

In *marriage counseling*, only a particular conflict related to the immediate concerns of the family is discussed; marriage counseling is conducted much more superficially by persons with less psychotherapeutic training than is marital therapy. *Marital therapy* places greater emphasis on restructuring the interaction between the couple, including, at times, exploration of the psychodynamics of each partner. Both therapy and counseling emphasize helping marital partners cope effectively with their problems.

Parenthood. Parenthood intensifies the relationship between new parents. Through their physical and emotional union, the couple has produced a fragile, dependent being that needs them in the interlocking roles of father and mother. This recognition expands their internal images of each other to include thoughts and feelings emanating from the role of parent. As they live together as a family, the lovers' relationship with each other changes. They become parents relating to one another and their children.

Parent–child problems do arise, however. In addition to the economic burden of raising a child (estimated to be $250,000 for a middle-class family whose child goes to college), there are emotional costs. Children may reawaken conflicts that parents themselves had as children, or children may have chronic illnesses that challenge families' resources. In general, men have been more concerned with their work and occupational advancement than with child-rearing, and women have been more concerned about their

role as mothers than with advancement in their occupation. However, this emphasis is changing dramatically for both sexes. A small but growing number of couples are choosing to split a job (or work at two part-time jobs) and share child-rearing duties.

Parenting has been described as a continuing process of letting go. Children must be allowed to separate from parents and, in some cases, must be encouraged to do so. Letting go involves separation from children who are starting school. School phobias and school refusal syndromes that are accompanied by extreme separation anxiety may have to be handled. Often, a parent who cannot let go of a child accounts for this situation; some parents want their children to remain tightly bound to them emotionally. Family therapy that explores these dynamics may be needed to resolve such problems.

As children get older and enter adolescence, the process of establishing identity assumes great importance. Peer relationships become crucial to a child's development, and overprotective parents who keep a child from developing friendships or having the freedom to experiment with friends that the parents disapprove of can interfere with the child's passage through adolescence. Parents need not refrain from exerting influence over their children; guidance and involvement are crucial. But they must recognize that adolescents especially require parental approval. However, rebellious on the surface, adolescents are much more tractable than they appear, provided parents are not overbearing or generally punitive.

SINGLE-PARENT FAMILIES. More than 10 million single-parent families exist with one or more children under the age of 18; of these families, 20 percent are single-parent homes in which a woman is the sole head of the household. The increase in the number of single-parent families has risen by almost 200 percent since 1980.

ALTERNATIVE LIFESTYLE PARENTING. Single, partnered, and married gay men and women are choosing to raise children. In most cases, such children are obtained through adoption. Some, however, may be born to a lesbian through artificial insemination or obtained from a willing mother surrogate. The number of such family units is increasing. The data about the development of children in these homes indicate that they are at no greater risk for emotional

problems (or for a gay orientation) than children raised in conventional households.

ADOPTION. Since the turn of the century, adoption or foster placement has replaced institutional care as the preferred way to raise children who are neglected, unwanted, or abandoned. Many couples who are unable to conceive (and some couples who already have children) turn to adoption.

In addition to the full range of typical parent–child developmental issues, adoptive parents face particular problems. They must decide how and when to tell the child about the adoption. They must deal with the child's possible desire for information about his or her biologic parents. Adopted children are more likely to develop conduct disorders, problems with drug abuse, and antisocial personality traits. It is unclear whether these problems result from the process of adoption or whether parents who give up children for adoption are more likely to pass along a genetic predisposition for these behaviors.

With the widespread use of birth control and access to safe abortions, the number of infants available for adoption has declined steeply. Wealthy parents may prefer to arrange for private adoption rather than wait many uncertain years for institutional adoption. (In private adoptions, a biologic mother is paid for her legal and medical expenses but not for the baby. Baby selling is a felony in all states.) International adoptions (especially from Bosnia, Latin America, Eastern Europe, and China) have also become more common. Questionable regulation in these countries has raised concerns that some infants put up for adoption in developing countries may not be orphans but are being sold by impoverished mothers.

MIDDLE ADULTHOOD (40 TO 65 YEARS OF AGE)

Middle adulthood is the golden age of adulthood, similar to the latency years in childhood, but much longer. Physical health, emotional maturity, competence, and power in the work situation, and gratifying relationships with spouse, children, parents, friends, and colleagues all contribute to a normative sense of satisfaction and well-being. Concerning occupation, many persons begin to experience the gap between early aspirations and current achievements. They may wonder whether the lifestyle and the commitments they chose in early adulthood are worth continuing; they may feel that they

would like to live their remaining years in a different, more satisfying way, without knowing exactly how. As children grow up and leave home, parental roles change, and persons redefine their roles as husbands and wives.

Significant gender-specific changes occur in middle adulthood. Many women who no longer need to nurture young children can release their energy into independent pursuits that require assertiveness and a competitive spirit, traits that were traditionally considered masculine. Alternatively, men in middle adulthood may develop qualities that enable them to express their emotions and recognize their dependency needs, traits that were usually considered feminine. With the new balance of the masculine and the feminine, a person may now be able to relate more effectively to someone of the other sex than in the past.

Transition from Young to Middle Adulthood

The transition from young adulthood to middle adulthood is slow and gradual, with no sharp physical or psychological demarcation. The aging process picks up speed and becomes a powerful organizing influence on intrapsychic life, but the change is gradual, unlike during adolescence. Mental change is experienced similarly, slow and imperceptible, without a sense of disruption.

Development in young adulthood is embedded in close relationships. Intimacy, love, and commitment are related to the mastery of the relationships most immediate to personal experience. The transition from young adulthood to middle age includes widening concern for the more extensive social system and differentiation of one's own social, political, and historical system from others. Authors have described middle adulthood in terms of generativity, self-actualization, and wisdom.

Table 32-17
Features Salient to Middle Adulthood

Issues	Positive Features	Negative Features
Prime of life	Responsible use of power; maturity; productivity	Winner–loser view; competitiveness
Stock taking:	Possibility; alternatives;	Closure; fatalism

what to do with the rest of one's life	organization of commitments; redirection	
Fidelity and commitments	Commitment to self, others, career, society; filial maturity	Hypocrisy; self-deception
Growth-death (to grow is to die); juvenescence and rejuvenation fantasies	Naturality regarding body, time	Obscene or frenetic efforts (e.g., to be youthful); hostility and envy of youth and progeny; longing
Communication and socialization	Matters understood; continuity; picking up where left off; large social network; rootedness of relationships, places, and ideas	Repetitiveness; boredom; impatience; isolation; conservatism; confusion; rigidity

Adapted from Robert N. Butler, M.D.

Developmental Theorists

Robert Butler described several underlying themes in middle adulthood that appear to be present regardless of marital and family status, gender, or economic level (Table 32-17). These themes include aging (as changes in bodily functions are noticed in middle adulthood); taking stock of accomplishments and setting goals for the future; reassessing commitments to family, work, and marriage; dealing with parental illness and death, and attending to all the developmental tasks without losing the capacity to experience pleasure or to engage in playful activities.

Erik Erikson. Erikson described middle adulthood as characterized either by generativity or by stagnation. Erikson defined *generativity* as the process by which persons guide the oncoming generation or improve society. This

stage includes having and raising children, but wanting or having children does not ensure generativity. A childless person can be generative by (1) helping others, (2) being creative, and (3) contributing to society. Parents must be secure in their own identities to raise children successfully: They cannot be preoccupied with themselves and act as if they were, or wished to be, the child in the family.

To be *stagnant* means that a person stops developing. For Erikson, stagnation was anathema, and he referred to adults without any impulses to guide the new generation or to those who produce children but don't care for them as being "within a cocoon of self-concern and isolation." Such persons are in great danger. Because they are unable to negotiate the developmental tasks of middle adulthood, they are unprepared for the next stage of the life cycle, old age, which places more demands on the psychological and physical capacities than all the preceding stages.

George Vaillant. In his longitudinal study of 173 men who were interviewed at 5-year intervals after they graduated from Harvard, Vaillant found a strong correlation between physical and emotional health in middle age. Also, those with the most deficient psychological adjustment during college years had a high incidence of physical illness in middle age. No single factor in childhood accounted for adult mental health, but an overall sense of stability in the parental home predicted well-adjusted adulthood. A close sibling relationship during college years was correlated with emotional and physical well-being in middle age. In another study, Vaillant found that childhood and adult work habits were related and that adult mental health and good interpersonal relationships were associated with the capacity to work in childhood. Vaillant's studies are ongoing and represent the most extended continuous study of adulthood ever performed.

Calvin Colarusso and Robert Nemiroff. Based on their experience as clinicians and psychoanalysts, Calvin Colarusso and Robert Nemiroff propose a broad theoretical foundation for adult development by suggesting that the developmental process is the same in the adult as in the child because, like the child, the adult is always in the midst of an ongoing dynamic process, continually influenced by a constantly changing environment, body, and mind. Whereas child development focuses primarily

on the formation of psychic structure, adult development is concerned with the continuing evolution of existing psychic structure and with its use. Although the fundamental issues of childhood continue in altered form as central aspects of adult life, attempts to explain all adult behavior and pathology in terms of the experiences of childhood are considered reductionistic. The adult past must be taken into account in understanding adult behavior in the same way that the childhood past is considered. The aging body is understood to have a profound influence on psychological development in adulthood, as is the growing midlife recognition and acceptance of the finiteness of time and the inevitability of personal death.

Developing Midlife Friendships

Unlike friendships in latency and adolescence and, to some extent, in young adulthood, midlife friendships do not usually have a sense of urgency or the need for the frequent or nearly constant physical presence of the friend. Midlife individuals have neither the need to build a new psychic structure (as do latency-age children and adolescents) nor the pressing need to find new relationships (as do young adults). They may have many sources of gratification available through relationships with spouses, children, and colleagues.

As their firstborn sons progressed through high school, two women in their mid-40s became fast friends. In addition to raising money for the school activities in which their sons were involved, thus maintaining a close involvement with the boys, they spent many hours talking about the boys' activities, girlfriends, and college plans. Their husbands, who liked each other, became acquaintances, not friends. They directed their feelings about their sons into other relationships. After the boys left for college, the intensity of the friendship diminished, tending to peak again during vacation periods. (Courtesy of Calvin Colarusso, M.D.)

Because of their unique position in the life cycle, midlife adults are easily able to initiate and sustain friendships with individuals of different ages, as well as chronologic peers. In the face of a disrupted marriage or intimacy or

the pressure of other midlife developmental themes, friendships may quickly become vehicles for the direct expression of impulses.

Reappraising Relationships. Midlife is a time of serious reappraisal of marriage and committed relationships. In the process, individuals struggle with the question of whether to settle for what they have or to search for greater perfection with a new partner. For some, the conflict rages internally and is kept from others; others express it through actions that take the form of affairs, trial separations, and divorce.

Recent research on happy marriage indicates that these couples, despite internal and real conflict, have found or achieved a special *goodness-of-fit* between their individual needs, wishes, and expectations. In the eyes of these couples, marital success is based on the ongoing, successful engagement of several psychological tasks. Among the most important are providing a safe place for conflict and difference, holding a double vision of the other, and maintaining a satisfying sexual life.

The decision to leave a long-standing, committed relationship has great consequences, not only for the two individuals involved but also for their friends and loved ones. The effect on children, in particular, is especially profound, extending far beyond childhood. The impact on the abandoned spouse, parents, and close relatives may be nearly as severe.

Various forms of therapeutic intervention, such as marital counseling, individual psychotherapy, and psychoanalysis, can be extremely effective in helping uncertain individuals decide what to do or in helping those who leave deal with the consequences of their decision on the abandoned partner, children, and other loved ones. Problems relating to intimacy, love, and sex can occupy a prominent position in an outpatient practice.

The four case studies presented here by Calvin Colarusso, M.D., illustrate some of the issues described above.

A couple in their late 50s sought treatment to decide their marriage. Both had been unhappy for years and wanted to divorce, feeling that they had to act now while there was still time to begin new relationships that would fulfill them. Their concerns were for their children and grandchildren. How would they react? Would they respect their decision

to end a relationship of more than 30 years or attempt to stop the separation? As the work progressed, they decided that seeking happiness in the hopefully 20 or 30 years that they had left to live had to come ahead of the feelings of their loved ones. The fact that their decision was a mutual one facilitated their family's gradual acceptance of the divorce.

A 43-year-old patient, Mr. S, was continually preoccupied with his marriage during this 4-year psychoanalysis. Sexually inhibited during adolescence, he "married the only girl in the world who knew less about sex than I did." Both were virgins on their wedding night. As the marriage progressed, the couple gradually developed a "satisfactory" sex life, but the patient always wondered what he had missed. As his sexual inhibitions were explored, Mr. S's sense of having "missed out on a lot of opportunities" lead to visits to massage parlors and prostitutes. Eventually, such behavior ceased because of the recognition that his wife was a wonderful mother and loving wife and not the cause of the lack of sexual experience that he brought into the marriage. "I'll always feel that I missed out when I was young, but I've got so much going for me now, I'm not going to mess it up over something that I can't change."

A 38-year-old woman entered therapy after her husband discovered that she was having sexual relations with men in their early and middle 20s. She explained that she loved her husband, but he seemed to take her for granted. He no longer made her feel attractive and wanted. As the therapy progressed, it became clear that she felt that as long as she could attract younger men, she was still young and sexually desirable. Struggling with the early signs of physical aging, the realization that the young men were only using her to satisfy their own sexual needs was sobering and distressing. As she began to see that such behavior was self-destructive, she approached her husband about starting marital therapy.

Fifty-year-old Mrs. T left her "wonderful" husband because "I've missed

something. I just have to get out on my own." Married at 18 years of age, "after going from my parents' home to his home," she recognized that her rage at her husband for "not being all the other men I could have married, for closing off all the living I could have done" was irrational but uncontrollable. "I have to live on my own for a while to see if I can do it before it's too late." Fully intending to return to her husband, she continued exploring the infantile and adult issues that precipitated the separation, leaving the future of the marriage in doubt.

Sexuality

Whereas the young adult is preoccupied with developing the capacity for intimacy, the midlife individual is focused on maintaining intimacy in the face of deterring physical, psychological, and environmental pressures. In a long-standing relationship, these pressures include real and imaginary concerns about diminished sexual capability, emotional withdrawal because of preoccupation with developmental tasks, and the realistic pressures related to work and providing for dependent children and, sometimes, elderly parents as well. In relationships that begin in midlife, the maintenance of intimacy can be compromised by the absence of a common past, age and generational differences in interests and activities, and the difficulties involved in forming a stepfamily.

For sexual intimacy to continue, the participants must (1) accept the appearance of the partner's middle-aged body, (2) continue to find it sexually stimulating, and (3) accept the normative changes that occur in sexual functioning. For those who master these developmental issues, the partner's body remains sexually stimulating. Diminished sexual ability is compensated for by feelings of love and tenderness generated over the years by a satisfying relationship. Those who cannot accept the changes in the partner's body or their stop having sex, begin affairs or leave the relationship, usually in search of a younger partner.

Normative changes in midlife sexual functioning include diminished sexual drive and an increase in mechanical problems. Men have greater difficulty getting and sustaining erections and experience a longer refractory period after ejaculation. Because of diminished estrogen production, women experience a thinning of the vaginal mucosa, a decrease in secretions, and

fewer contractions at the time of orgasm. Women do not reach their sexual prime until their mid-30s; consequently, they have a greater capacity for orgasm in middle adulthood than in young adulthood. Women, however, are more vulnerable than men to narcissistic blows to their self-esteem as they lose their youthful appearance, which is overvalued in today's society. During middle adulthood, they may feel less sexually desirable than in early adulthood and, thus, feel less entitled to adequate sex life. An inability to deal with changes in body image prompts many women and men to undergo cosmetic surgery to maintain their youthful appearance.

The demands of raising children interfere with the privacy and emotional equilibrium required for intimacy, as do the pressures and responsibilities of work. Fatigue and diminished interest are common denominators in these circumstances. Patients with deeply rooted problems with sexuality or relationships may use aging, work, and relationships with children or elderly parents as a means of rationalizing their conflicts and refusing to analyze them.

Climacterium

Middle adulthood is the time of the male and female climacterium, the period in a life characterized by decreased biologic and physiologic functioning. For women, the menopausal period is considered the climacterium, and it may start anywhere from the 40s to the early 50s. Bernice Neugarten studied this period and found that more than 50 percent of women described menopause as an unpleasant experience. Still, a significant portion believed that their lives had not changed in any meaningful way, and many women experienced no adverse effects. Because they no longer had to worry about becoming pregnant, some women report feeling sexually freer after menopause than before its onset. Generally, the female climacterium has been stereotyped as a sudden or radical psychophysiological experience. Still, it is more often a gradual experience as estrogen secretion decreases with changes in the flow, timing, and eventual cessation of the menses. Vasomotor instability (hot flashes) can occur, and menopause can extend over several years. Some women experience anxiety and depression, but women who have a history of poor adaptation to stress are more predisposed to the menopausal syndrome.

For men, the climacterium has no clear demarcation; male hormones stay

reasonably constant through the 40s and 50s and then begin to decline. Nevertheless, men must adapt to a decline in biologic functioning and overall physical vigor. About age 50, a slight decrease in healthy sperm and seminal fluid occurs, not sufficient, however, to preclude insemination. Coincident with a decreased testosterone level may be fewer and less firm erections and decreased sexual activity generally. Some men experience a so-called midlife crisis during this period. The crisis can be mild or severe, characterized by a sudden drastic change in work or marital relationships, severe depression, increased use of alcohol or drugs, or a shift to an alternate lifestyle.

Midlife Transition and Crisis

The *midlife transition* has been defined as an intensive reappraisal of all aspects of life precipitated by the growing recognition that life is finite and approaching an end. It is characterized by mental turmoil, not action. For most people, the reappraisal results in decisions to keep most life structures, such as marriages and careers, which have been painstakingly built over time. When significant changes are made, they are thoughtful and considered, even when they include major shifts, such as divorce or a job change. The developmentally aware clinician recognizes that every patient in this age group is engaged in a midlife transition (whether the patient is talking about it or not) and facilitates the process by making it conscious and verbal.

A true *midlife crisis* is a major, revolutionary turning point in life, involving changes in commitments to career or spouse, or both, and accompanied by significant, ongoing emotional turmoil for the individual and others. It is an upheaval of substantial proportions. A flurry of impulsive actions follows a period of internal agitation, for example, leaving spouse and children, becoming involved with a new sexual partner, and quitting a job, all within days or weeks of each other. Although unrecognized warning signs may have existed, those who are left behind are often shocked by the suddenness and abruptness of the change.

Efforts by family members or therapists to get the individual to stop and to reconsider usually fall on deaf ears. The overwhelming need is to avoid anyone who counsels restraint and to ignore therapists who recommend examining motivations and feelings before making such major decisions. Usually, during the crisis, the therapist is left with the painful job of helping

those who have been left to deal with their shock and grief.

Empty-Nest Syndrome. Another phenomenon described in middle adulthood has been called the *empty-nest syndrome,* a depression that occurs in some men and women when their youngest child is about to leave home. Most parents, however, perceive the departure of the youngest child as a relief rather than stress. If no compensating activities have been developed, particularly by the mother, some parents become depressed. This is especially true of women whose predominant role in life has been mothering or of couples who decided to stay in an otherwise unhappy marriage "for the sake of the children."

Other Tasks of Middle Adulthood

As persons approach the age of 50, they clearly define what they want from work, family, and leisure. Men who have reached their highest level of advancement in work may experience disillusionment or frustration when they realize they can no longer anticipate new work challenges. For women who have invested themselves entirely in mothering, this period leaves them with no suitable identity after the children leave home. Sometimes, social rules become rigidly established; lack of freedom in lifestyle and a sense of entrapment can lead to depression and a loss of confidence. Also, unique financial burdens can occur in middle age, produced by pressures to care for aged parents at one end of the spectrum and children at the other end.

Daniel Levinson described a transitional period between the ages of 50 and 55, during which a developmental crisis may occur when persons feel incapable of changing an intolerable life structure. Although no single event characterizes the transition, the physiologic changes that begin to appear may have a dramatic effect on a person's sense of self. For example, a person may experience a decrease in cardiovascular efficiency that accompanies aging. Chronologic age and physical infirmity are not linear; however, those who exercise regularly, who do not smoke, and who eat and drink in moderation can maintain their physical health and emotional well-being.

Middle adulthood is when persons frequently feel overwhelmed by too many obligations and duties, but it is also a time of great satisfaction for most persons. They have developed a wide array of acquaintances, friendships, and

relationships, and the satisfaction they express about their network of friends predicts positive mental health. Some social ties, however, may be a source of stress when demands either cannot be met or assault a person's self-esteem. Middle-aged persons most generally possess power, leadership, wisdom, and understanding, and if their health and vitality remain intact, it is indeed the prime of life.

DIVORCE

Divorce is a significant crisis in life. Spouses often grow, develop, and change at different rates; one spouse may discover that the other is not the same as when they first married. In truth, both partners have changed and evolved, not necessarily in complementary directions. Frequently, one spouse blames a third person for alienation of affections and refuses to examine his or her role in the marital problems. Certain aspects of marital deterioration and divorce seem to be related to specific qualities of middle life—the need for change, weariness with acting responsibly, fear of facing up to oneself.

Types of Separation

Paul Bohannan, an anthropologist with expertise in marriage and divorce, described the types of separations that take place at the time of divorce.

Psychic Divorce. In psychic divorce, the love object is given up, and a grief reaction about the death of the relationship occurs. Sometimes a period of anticipatory mourning sets in before the divorce. Separating from a spouse forces a person to become autonomous, to change from a position of dependence. The separation may be difficult to achieve, mainly if both are used to being dependent on each other (as happens typically in marriage) or if one was so dependent as to be afraid or incapable of becoming independent. Most persons report such feelings as depression, ambivalence, and mood swings at the time of divorce. Studies indicate that recovery from divorce takes about 2 years; by then, the ex-spouse may be viewed neutrally, and each spouse accepts his or her new identity as a single person.

Legal Divorce. Legal divorce involves going through the courts so that each of the parties is remarriageable. Of divorced women and divorced men,

75 percent and 80 percent, respectively, remarry within 3 years of divorce. No-fault divorce, in which neither person is judged to be the guilty party, has become the most widely used legal mechanism for divorce.

Economic Divorce. Economic divorce involves significant concerns about the division of the couple's property between them and economic support for the wife. Many men who are ordered by the courts to pay alimony or child support flout the law and create a major social problem.

Community Divorce. The social network of the divorced couple changes markedly. A few relatives and friends are retained from the community, and new ones are added. The task of meeting new friends is often tricky for divorced persons, who may realize how dependent they were on their spouses for social exchanges.

Coparental Divorce. Coparental divorce is the separation of a parent from the child's other parent. Being a single parent differs from being a married parent.

Custody

The parental right doctrine is a legal concept that awards custody to the more fit natural parent and attempts to ensure that the best interests of the child are served. In the past, mothers were almost always awarded custody, but custody is now given to fathers in about 15 percent of cases. Custodial fathers are likely to be white, married, older, and better educated than custodial mothers. Women who are granted custody have a better chance of being awarded child support and of actually receiving payment than do men who are given custody. Nevertheless, women who accept payments still have lower incomes than men who receive compensation.

The types of custody include *joint custody,* in which a child spends equal time with each parent, an increasingly common practice; *split custody,* in which siblings are separated and each parent has custody of one or more of the children; and *single custody,* in which the children live solely with one parent and the other parent has rights of visitation that may be limited in some way by the court. Child support payments are more likely to be made when parents have joint custody or when the noncustodial parent is given

visitation rights.

Problems can surface in the parent–child relationship with the custodial or the noncustodial parent. The absence of the noncustodial parent in the home represents the reality of the divorce, and the custodial parent may become the target of the child's anger about the divorce. The parent under such stress may not be able to deal with the child's increased needs and emotional demands.

The noncustodial parent must cope with limits placed on time spent with the child. This parent loses the day-to-day gratification and the responsibilities involved with parenting. Emotional distress is common in parent and child. Joint custody offers a solution with some advantages, but it requires substantial maturity on the part of the parents and can present some problems. Parents must separate their child-rearing practices from their postdivorce resentments, and they must develop a spirit of cooperation about rearing the child. They must also be able to tolerate frequent communication with the ex-spouse.

Reasons for Divorce

Divorce tends to run in families, and rates are highest in couples who marry as teenagers or come from different socioeconomic backgrounds. Every marriage is psychologically unique, and so is each divorce. If a person's parents were divorced, he or she might choose to resolve a marital problem in the same way, through a divorce. Expectations of the spouse may be unrealistic: One partner may expect the other to act as an all-giving mother or a magically protective father. The parenting experience places the most significant strain on a marriage. In surveys of couples with and without children, those without children reported getting more pleasure from their spouse than those with children. Illness in the child creates the greatest strain of all and more than 50 percent of marriages in which a child has died through illness or accident end in divorce.

Other causes of marital distress are problems with sex and money. Both areas may be used as a means of control, and withholding sex or money is a means of expressing aggression. Also, less social pressure to remain married currently exists. As discussed above, the easing of divorce laws and the declining influence of religion and the extended family make divorce an

acceptable course of action today.

Intercourse Outside of Marriage. Adultery is defined as voluntary sexual intercourse between a married person and someone other than his or her spouse. For men, the first extramarital affair is often associated with the wife's pregnancy, when coitus may be interdicted. Most of these incidents are kept secret from the spouse and, if known, rarely account for divorce. Nevertheless, the infidelity can serve as the catalyst for basic dissatisfactions in the marriage to the surface, and these problems may then lead to its dissolution. Adultery may decline, as potentially fatal STDs such as acquired immune deficiency syndrome (AIDS) serve as sobering deterrents.

ADULT MATURITY

Success and happiness in adulthood are made possible by achieving a modicum of maturity—a mental state, not an age. The capacity for maturity, however, is a direct outgrowth of the engagement and mastery of the developmental tasks of young and middle adulthood. From a developmental perspective, maturity can be defined as a mental state found in healthy adults that is characterized by detailed knowledge of the parameters of human existence, a sophisticated level of self-awareness based on an honest appraisal of one's own experience within those basic parameters, and the ability to use this intellectual and emotional knowledge and insight caringly concerning one's self and others.

The achievement of maturity in midlife leads to the emergence of the capacity for wisdom. Those who possess wisdom have learned from the past and are fully engaged in life in the present. Just as important, they anticipate the future and make the necessary decisions to enhance prospects for health and happiness. In other words, a philosophy of life has been developed that includes understanding and acceptance of the person's place in the order of human existence. Unfortunately, the joys of midlife do not last forever. Old age lies ahead. Although the hope and statistical expectation is for many years of mental competence and independence, physical and mental decline, increased dependence, and, eventually, death must be anticipated. Late adulthood has its great pleasure, when there is a focus on continued mental and physical activity, a dominant preoccupation with the present and the

future, and involvement with and facilitation of the young. Then, death can be met with feelings of satisfaction and acceptance, the natural endpoint of human existence that follows a life lived and well loved.

32.3 Old Age

When we progress from youth to old age, the focus may change from pursuing wealth to maintaining health. In late adulthood, the aging body increasingly becomes a central concern, replacing the midlife preoccupations with career and relationships. This change is so because of diminution in function, altered physical appearance, and the increased incidence of physical illness. Despite these occurrences, the body in late adulthood can still be a source of considerable pleasure and can convey a sense of competence, particularly when giving attention to regular exercise, a healthy diet, adequate rest, and preventive maintenance medical care. The normal state in the aged is physical and mental health, not illness and debilitation. The developmental tasks of late adulthood that lead to mental health are listed in Table 32-18.

Table 32-18
Developmental Tasks of Late Adulthood

To maintain the body image and physical integrity
To conduct the life review
To maintain sexual interests and activities
To deal with the death of significant loved ones
To accept the implications of retirement
To accept the genetically programmed failure of organ systems
To divest oneself of the attachment to possessions
To accept changes in the relationship with grandchildren

Old age, or late adulthood, usually refers to the stage of the life cycle that begins at age 65. Gerontologists—those who study the aging process—divide older adults into two groups: young-old, ages 65 to 74, and old-old, ages 75 and beyond. Some use the term oldest-old to refer to those over 85. Older

adults can also be described as well-old (healthy persons) and sick-old (persons who have an infirmity that interferes with functioning and requires medical or psychiatric attention). The health needs of older adults have grown enormously as the population ages, and geriatric physicians and psychiatrists play significant roles in treating this population.

DEMOGRAPHICS

The number of individuals over age 65 is rapidly expanding. In 1900, for example, 4 percent of the US population was older than 65 years. By 2012 it was 13.7 percent, and by 2050, it is projected to be about 20 percent. That increase far exceeds the general population growth—tenfold compared with just over threefold between 1900 and 2000—and is projected to continue (e.g., 2.5 times vs. just over 1.5 times between 1990 and 2050) (Table 32-19).

Table 32-19
Aging Population of the United States: 1900–2050

Year	Median Age	Mean Age	Population, in Millions and as a Percentage of Total Population				
			All Ages	65 and Over		85 and Over	
			(N)	(N)	(%)	(N)	(%)
1900			76.0	3.1	4.1	0.1	0.1
1950			150.1	12.3	8.2	0.6	0.4
1990			248.7	31.1	12.5	3.0	1.2
2000	35.7	36.5	276.2	35.3	12.8	4.3	1.6
2010	37.2	37.8	300.4	40.1	13.3	6.0	2.0
2030	38.5	39.9	350.0	70.2	20.1	8.8	2.5
2050	38.1	40.3	392.0	80.1	20.4	18.9	4.8

Population: U.S. Bureau of the Census. Current Population Reports, Special Studies, P23-190, 65+ in the United States. Washington, DC: U.S. Government Printing Office; 1996.

Mean/Median Age, 2000–2050: Day JC. Population projections of the United States by age, sex, race, and Hispanic origin: 1995 to 2050. In: U.S. Bureau of the Census, Current Population Reports, P25–1130. Washington, DC: U.S. Government Printing Office; 1996.

The life expectancy for women at birth is projected to continue to exceed that for men by 7 years until 2050. By 2050, the composition of the US population by age and sex is estimated to differ markedly from that today. Such changes are bound to influence income and marital statistics, the percentage of elderly persons living alone or in long-term care facilities, and other aspects of the social network. A summary of demographic highlights of the aged is given in Table 32-20.

The accuracy of these projections, however, depends on the accuracy of other predications such as birth rates, immigration, and emigration—all of which are more difficult to gauge for the future than the remaining variables, death rates, or life expectancies. Projections concerning life expectancy, for example, can change substantially within a single decade.

BIOLOGY OF AGING

The aging process, or senescence (from the Latin *senescere*, "to grow old"), is characterized by a gradual decline in the functioning of all of the body's systems—cardiovascular, respiratory, genitourinary, endocrine, and immune, among others. However, the belief that old age is invariably associated with profound intellectual and physical infirmity is a myth. Many older persons retain their cognitive abilities and physical capacities to a remarkable degree.

An overview of the biologic changes that accompany old age is given in Table 32-21. The various decrements listed do not occur linearly in all systems. Not all organ systems deteriorate at the same rate, nor do they follow a similar pattern of decline for all persons. Each person is genetically endowed with one or more vulnerable systems, or a system may become vulnerable because of environmental stressors or intentional misuse, such as excessive ultraviolet exposure, smoking, or alcohol use. Moreover, not all organ systems deteriorate at the same time. Any one of several organ systems begins to deteriorate, and this deterioration then leads to illness or death.

Aging generally means the aging of cells. In the most commonly held theory, each cell has a genetically determined life span, during which it can replicate itself a limited number of times before it dies. Structural changes occur in cells with age. In the central nervous system, for example, age-related cell changes occur in neurons, which show signs of degeneration. In senility (characterized by severe memory loss and a loss of intellectual functioning), signs of degeneration are much more severe. An example is the neurofibrillary degeneration seen most commonly in dementia of the Alzheimer's type.

Structural changes and mutations in deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) are also found in aging cells; these have been attributed to genotypic programming, x-rays, chemicals, and food products, among others. Probably no single cause of aging exists, and all areas of the body are affected to some degree. Genetic factors have been implicated in disorders that commonly occur in older persons, such as hypertension, coronary artery disease, arteriosclerosis, and neoplastic disease. Family studies indicate inheritance factors for breast and stomach cancer, colon polyps, and certain mental disorders of old age. Huntington disease shows an autosomal dominant mode of inheritance with complete penetrance. The

average age of onset is between 35 and 40 years, but cases have occurred as late as 70 years.

Longevity

Longevity has been studied since the beginning of recorded history and has always been a topic of great interest. The research about longevity reveals that a family history of longevity is the best indicator of a long life; of persons who live past 80, half of their fathers also lived past 80. Nevertheless, many conditions leading to a shortened life can be prevented, ameliorated, or delayed with effective intervention. Heredity is but one factor—one beyond a person's control. Predictors of longevity that are within a person's control include regular medical checkups, minimal or no caffeine or alcohol consumption, work gratification, and a perceived sense of the self as being socially useful in an altruistic role, such as a spouse, teacher, mentor, parent, or grandparent. Healthy eating and adequate exercise are also associated with health and longevity.

Table 32-20
Demographic Highlights of the Aged

- The older population (65+) numbered 4.04 million in 2010, an increase of 5.4 million for 15.3 since 2000.
- The number of Americans aged 45–64—who will reach 65 over the next two decades—increased by 31% during this decade.
- Over one in every eight, or 13.1%, of the population is an older American.
- Persons reaching age 65 have an average life expectancy of an additional 18.8 yr (20 yr for females and 17.3 for males).
- Older women outnumber older men at 23 million older women to 17.5 million older men.
- In 2010, 20% of persons 65+ were minorities—8.4% were African American.[a] Persons of Hispanic origin (who may be of any race) represented 6.9% of the older population. About 3.5% were Asian or Pacific Islanders,[a] and less than 1% were American Indian or Native Alaskan.[a]

- In addition, 0.8% of persons 65+ identified themselves as being of two or more races.
- Older men were much more likely to be married than older women —72% of men vs. 42% of women. In 2010, 40% older women were widows.
- About 29% (11.3 million) of noninstitutionalized older persons live alone (8.1 million women, 3.2 million men).
- Almost half of older women (47%) age 75+ live alone.
- About 485,000 grandparents aged 65 or more had the primary responsibility for their grandchildren who lived with them.
- The population 65 and over has increased from 35 million in 2000 to 40 million in 2010 (a 15% increase) and is projected to increase up to 55 million in 2020 (a 36% increase for that decade).
- The 85+ population is projected to increase from 5.5 million in 2010 and then 6.6 million in 2020 (19%) for that decade.
- Minority populations have increased from 5.7 million in 2000 (16.3% of the elderly population) to 8.1 million in 2010 (20% of the elderly) and are projected to increase to 13.1 million in 2020 (24% of the elderly).
- The median income of older persons in 2010 was $25,704 for males and $15,072 for females. Median money income (after adjusting for inflation) of all households headed by older people fell 1.5% (not statistically significant) from 2009 to 2010. Households containing families headed by person 65+ reported a median income in 2010 of $45,763.
- The major sources of income as reported by older persons in 2009 were Social Security (reported by 87% of older persons), income from assets (reported by 53%), private pensions (reported by 28%), government employee pensions (reported by 14%), and earnings (reported by 26%).
- Social Security constituted 90% or more of the income received by 35% of beneficiaries in 2009 (22% married couples and 43% of nonmarried beneficiaries).
- Almost 3.5 million elderly persons (9.0%) were below the poverty level in 2010. This poverty rate is not statistically different from the

poverty rate in 2009 (8.9%). During 2011, the U.S. Census Bureau also released a new Supplemental Poverty Measure (SPM) that takes into account regional variations in the living costs, noncash benefits received, and nondiscretionary expenditures but does not replace the official poverty measure. The SPM shows a poverty level for older persons of 15.9%, an increase of over 75% over the official rate of 9% mainly due to medical out-of-pocket expenses.

- About 11% (3.7 million) of older Medicare enrollees received personal care from a paid or unpaid source in 1999.

[a]Principle source data for the profile are from the U.S. Census Bureau, the National Center for Health Statistics, and the Bureau of Labor Statistics. The profile incorporates the latest data (2010) available but not all items are updated on an annual basis.

Table 32-21
Biologic Changes Associated with Aging

Cellular Level

Change in cellular DNA (deoxyribonucleic acid) and RNA (ribonucleic acid) structures: intracellular organelle degeneration

Neuronal degeneration in central nervous system, primarily in superior temporal precentral and inferior temporal gyri; no loss in brainstem nuclei

Receptor sites and sensitivity altered

Decreased anabolism and catabolism of cellular transmitter substances

Intercellular collagen and elastin increase

Immune System

Impaired T-cell response to antigen

Increase in function of autoimmune bodies

Increased susceptibility to infection and neoplasia

Leukocytes unchanged, T lymphocytes reduced

Increased erythrocyte sedimentation (nonspecific)

Musculoskeletal

Decrease in height because of shortening of spinal column (2-in

- loss in both men and women from the second to the seventh decades)
- Reduction in lean muscle mass and muscle strength; deepening of thoracic cage
- Increase in body fat
- Elongation of nose and ears
- Loss of bone matrix, leading to osteoporosis
- Degeneration of joint surfaces may produce osteoarthritis
- Risk of hip fracture is 10–25% by age 90
- Continual closing of cranial sutures (parietomastoid suture does not attain complete closure until age 80)
- Men gain weight until about age 60, then lose; women gain weight until age 70, then lose

Integument

- Graying of hair results from decreased melanin production in hair follicles (by age 50, 50% of all persons male and female are at least 50% gray; pubic hair is last to turn gray)
- General wrinkling of skin
- Less active sweat glands
- Decrease in melanin
- Loss of subcutaneous fat
- Nail growth slowed

Genitourinary and Reproductive

- Decreased glomerular filtration rate and renal blood flow
- Decreased hardness of erection, diminished ejaculatory spurt
- Decreased vaginal lubrication
- Enlargement of prostate
- Incontinence

Special Senses

- Thickening of optic lens, reduced peripheral vision
- Inability to accommodate (presbyopia)
- High-frequency sound hearing loss (presbyacusis)—25% show loss by age 60, 65% by age 80

- Yellowing of optic lens
- Reduced acuity of taste, smell, and touch
- Decreased light-dark adaption

Neuropsychiatric

- Takes longer to learn new material, but complete learning still occurs
- Intelligence quotient (IQ) remains stable until age 80
- Verbal ability maintained with age
- Psychomotor speed declines

Memory

- Tasks requiring shifting attentions performed with difficulty
- Encoding ability diminishes (transfer of short- to long-term memory and vice versa)
- Recognition of right answer on multiple-choice tests remains intact
- Simple recall declines

Neurotransmitters

- Norepinephrine decreases in central nervous system
- Increased monoamine oxidase and serotonin in brain

Brain

- Decrease in gross brain weight, about 17% by age 80 in both sexes
- Widened sulci, smaller convolutions, gyral atrophy
- Ventricles enlarge
- Increased transport across blood–brain barrier
- Decreased cerebral blood flow and oxygenation

Cardiovascular

- Increase in size and weight of heart (contains lipofuscin pigment derived from lipids)
- Decreased elasticity of heart valves
- Increased collagen in blood vessels
- Increased susceptibility to arrhythmias
- Altered homeostasis of blood pressure

Cardiac output maintained in absence of coronary heart disease

Gastrointestinal (GI) System

At risk for atrophic gastritis, hiatal hernia, diverticulosis
Decreased blood flow to gut, liver
Diminished saliva flow
Altered absorption from GI tract (at risk for malabsorption syndrome and avitaminosis)
Constipation

Endocrine

Estrogen levels decrease in women
Adrenal androgen decreases
Testosterone production declines in men
Increase in follicle-stimulating hormone (FSH) and luteinizing hormone (LH) in postmenopausal women
Serum thyroxine (T_4) and thyroid-stimulating hormone (TSH) normal, triiodothyronine (T_3) reduced
Glucose tolerance test result decreases

Respiratory

Decreased vital capacity
Diminished cough reflex
Decreased bronchial epithelium ciliary action

Life Expectancy

In the United States, the average life expectancy has increased throughout the last century—from 48 years in 1900 to 77.4 years for men and 82.2 years for women in 2013. The projected life expectancy at birth, and age 65 is indicated in Table 32-22. Changes in morbidity and mortality have also occurred. Over the past 30 years, for example, a 60 percent decline has occurred in mortality from cerebrovascular disease and a 30 percent decline in mortality from coronary artery disease. In contrast, mortality from cancer, which rises steeply with age, has increased, especially cancer of the lung, colon, stomach, skin, and prostate.

The oldest-old, persons over 85 years of age, is the most rapidly growing

segment of the older population. Over the past 25 years, the population of all older persons increased by 100 percent, compared with 45 percent for the entire US population, but the increase for the 85 and older group exceeded 275 percent. It is expected that by 2050, the oldest-old will make up about 25 percent of the elderly population and 5 percent of the total population in the United States. Figure 32-7 gives projected percentages for the average annual growth rate of the elderly population to 2050.

Table 32-22
Projected Life Expectancy at Birth and Age 65, by Sex: 1990–2050 (in Years)

	At Birth			At Age 65		
Year	Men	Women	Difference	Men	Women	Difference
1990	72.1	79.0	6.9	15.0	19.4	4.4
2000	73.5	80.4	6.9	15.7	20.3	4.6
2010	74.4	81.3	6.9	16.2	21.0	4.8
2020	74.9	81.8	6.9	16.6	21.4	4.8
2030	75.4	82.3	6.9	17.0	21.8	4.8
2040	75.9	82.8	6.9	17.3	22.3	5.0
2050	76.4	83.3	6.9	17.7	22.7	5.0

Data from U.S. Bureau of the Census, Washington, DC.

The leading causes of death among older persons are heart disease, cancer, and stroke. Accidents are among the leading causes of death of persons over 65. Most fatal accidents are caused by falls, pedestrian incidents, and burns. Falls are most commonly the result of cardiac arrhythmias and hypotensive episodes.

Some gerontologists consider death in very old persons (over 85) to result from an aging syndrome characterized by diminished elastic-mechanical properties of the heart, arteries, lungs, and other organs. Death results from trivial tissue injuries that would not be fatal to a younger person; accordingly,

senescence is viewed as the cause of death.

Ethnicity and Race

The proportion of older persons in the black, Hispanic, and Asian populations is smaller than that in the white population, but it is increasing rapidly. By 2050, 20 percent of older persons will be nonwhite. The proportion of older persons who are Hispanic will increase from 4 percent to approximately 14 percent over the same period. According to the U.S. Census Bureau, Hispanic refers to persons "whose origins are Mexican, Puerto Rican, Cuban, Central or South American, and other Hispanic or Latino, regardless of race" (Fig. 32-8).

Sex Ratios

On average, women live longer than men and are more likely than men to live alone. The number of men per 100 women decreases sharply from ages 65 to 85 (Fig. 32-9).

Geographic Distribution

The most populous states have the largest number of older persons. California has the most (3.3 million), followed by New York, Pennsylvania, Texas, Michigan, Illinois, Florida, and Ohio, each with more than 1 million. States with high proportions of older persons include Pennsylvania, Florida, Nebraska, and North Dakota. Florida's high percentage of older adults related its popularity as a retirement locale. In other states, the reason is usually more young persons leaving.

Exercise, Diet, and Health

Diet and exercise play a role in preventing or ameliorating chronic diseases of older persons, such as arteriosclerosis and hypertension. Hyperlipidemia, which correlates with coronary artery disease, can be controlled by reducing body weight, decreasing the intake of saturated fat, and limiting the intake of cholesterol. Increasing the daily intake of dietary fiber can also help decrease serum lipoprotein levels. A daily intake of 1 oz (about 30 mL) of alcohol has been correlated with longevity and elevated high-density lipoproteins (HDLs). Studies have also clearly demonstrated that statin drugs that reduce

cholesterol have a dramatic effect on reducing cardiovascular disease in persons with diet-resistant or exercise-resistant hyperlipidemia.

Low salt intake (less than 3 g a day) is associated with a lowered risk of hypertension. Hypertensive geriatric patients can often correct their condition by moderate exercise and decreased salt intake without the addition of drugs.

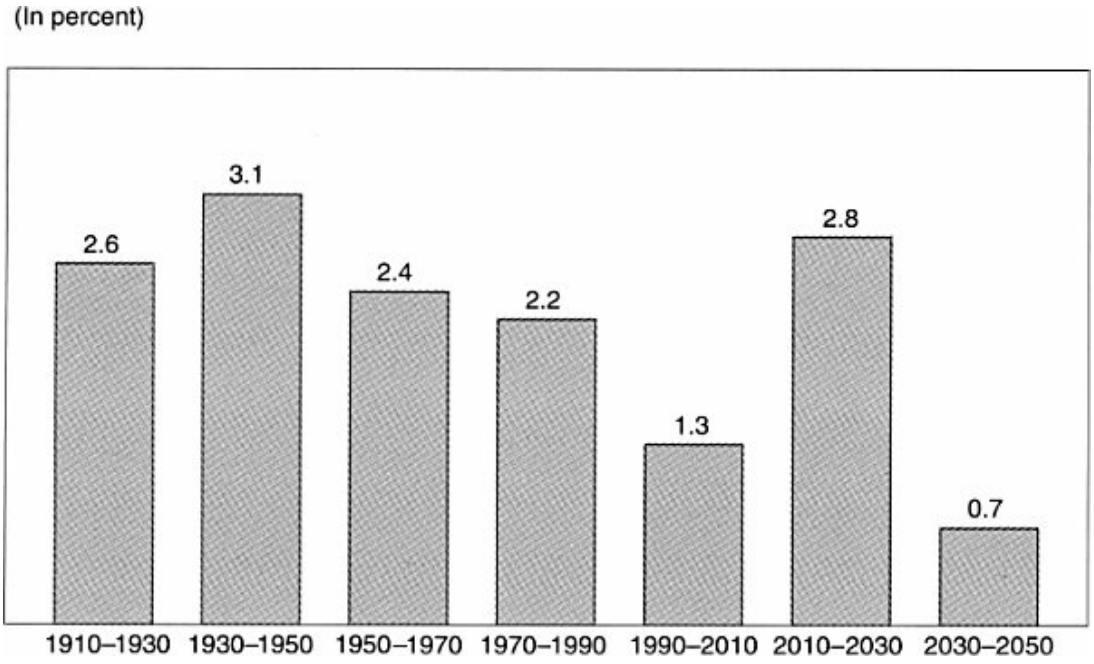

FIGURE 32-7
Average annual growth rate of the elderly population. (Data from U.S. Bureau of the Census.)

A regimen of moderate daily exercise (walking for 30 minutes a day) has been associated with a reduction in cardiovascular disease, decreased incidence of osteoporosis, improved respiratory function, the maintenance of ideal weight, and a general sense of well-being. Exercise has been shown to improve strength and function even among the very old. In many cases, a disease process has been reversed and even cured by diet and exercise, without additional medical or surgical intervention.

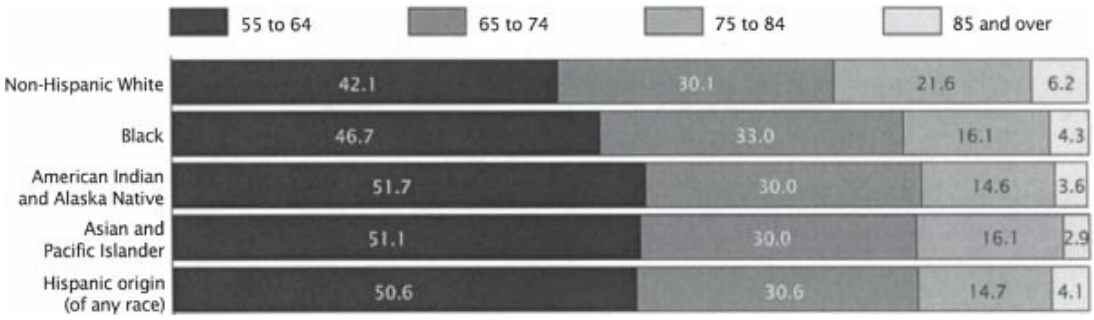

FIGURE 32-8
Percent distribution of people 55 years and over by race, Hispanic origin, and age: 2002. (Data from U.S. Bureau of the Census.)

Table 32-23 lists the biologic changes associated with diet and exercise. A comparison with Table 32-19 reveals that almost every biologic change associated with aging is positively affected by diet and exercise.

STAGE THEORIES OF PERSONALITY DEVELOPMENT

Early personality theorists proposed that development was completed by the end of childhood or adolescence. One of the first development theorists to propose that personality continues to develop and grow over the life span was Erik Erikson. Erikson believed that development proceeded through a series of psychosocial stages, each with its conflict that is resolved by the individual with greater or lesser success. Erikson termed the crisis of the last epoch of life integrity versus despair and believed that successful resolution of this crisis involved a process of life review and achieving a sense of peace and wisdom through coming to terms with how one's life was lived. For example, Erikson proposed that successful resolution of this crisis would be characterized by a sense of having lived one's life well, whereas a less successful resolution would be characterized by feeling that life was too short, that one did not choose wisely, and bitterness that one will not have a chance to live life over.

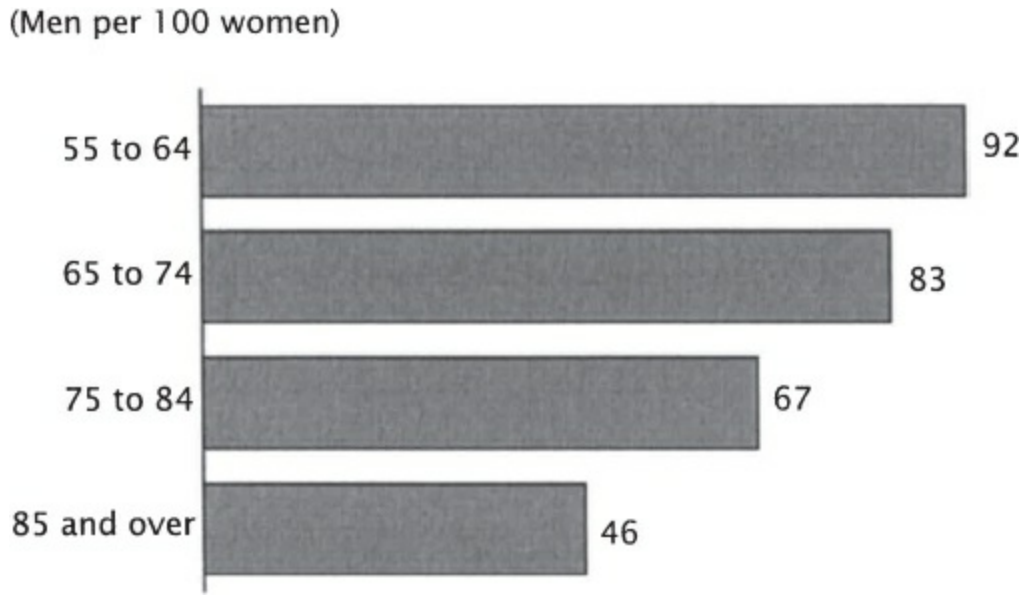

FIGURE 32-9
Sex ratio of people 55 years and over by age: 2002. (Data from U.S. Bureau of the Census.)

Table 32-23
Positive and Healthy Physiologic Effects of Exercise and Nutrition

Increases

- Strength of bones, ligaments, and muscles
- Muscle mass and body density
- Articular cartilage thickness
- Skeletal muscle ATP (adenosine triphosphatase), CRP (C-reactive protein), K^+ (potassium), and myoglobin
- Skeletal muscle oxidative enzyme content and mitochondria
- Skeletal muscle arterial collaterals and capillary density
- Heart volume and weight
- Blood volume and total circulating hemoglobin
- Cardiac stroke volume
- Myocardial contractility
- Maximal CO_2 (A-V)
- Maximal blood lactate concentration
- Maximal pulmonary ventilation

Maximal respiratory work
Maximal oxygen diffusing capacity
Maximal exercise capacity as measured by the maximal oxygen intake, exercise time, and distance
Serum high-density lipoprotein concentration
Anaerobic threshold
Plasma insulin concentration with submaximal exercise

Decreases

Heart rate at rest and during submaximal exercise
Blood lactate concentration during submaximal exercise
Pulmonary ventilation during submaximal work
Respiratory quotient during submaximal work
Serum triglyceride concentration
Body fatness
Serum low-density lipoprotein concentration
Systolic blood pressure
Core temperature threshold for initiation of sweating
Sweat sodium and chloride content
Plasma epinephrine and norepinephrine with submaximal exercise
Plasma glucagon and growth hormone concentrations with submaximal exercise
Relative hemoconcentration with submaximal exercise in the heat

Table 32-24
Old Age Developmental Theorists

Sigmund Freud	Increasing control of the ego and id with aging results in increased autonomy. Regression may permit primitive modes of functioning to reappear.
Erik Erikson	The central conflict in old age is between integrity, the sense of satisfaction people feel reflecting on a life lived productively, and despair, the sense that life

	has little purpose or meaning. Contentment in old age comes only with getting beyond narcissism and into intimacy and generativity.
Heinz Kohut	Old people must continually cope with narcissistic injury as they attempt to adapt to the biologic, psychological, and social losses associated with the aging process. The maintenance of self-esteem is a major task of old age.
Bernice Neugarten	The major conflict of old age relates to giving up the position of authority and evaluating achievements and former competence. It is a time of reconciliation with others and resolution of grief over the death of others and the approaching death of self.
Daniel Levinson	Ages 60–65 is a transition period (“the late adult transition”). People who are narcissistic and too heavily invested in body appearance are liable to become preoccupied with death. Creative mental activity is a normal and healthy substitute for reduced physical activity.

Several studies have attempted to validate aspects of Erikson’s theory. In one study, a sample of more than 400 men was studied prospectively, and the highest Eriksonian life stage each achieved was rated according to data gathered on the circumstances of his life. For example, if a man had achieved independence from his family of origin and was self-sufficient but was unable to develop an intimate relationship, the highest life stage achieved would be the identity stage, not the intimacy stage. This study found that Eriksonian stages are passed through in sequential order, although often not at the same age for every individual, and that the stages are surprisingly universal in populations that are ethnically and socioeconomically diverse.

A longitudinal study of approximately 500 subjects from two age cohorts found that the earlier age cohort scored significantly higher on integrity than the latter age cohort, and scores for both age cohorts on integrity had declined significantly by the final time of testing. These data suggest that the conflict

of integrity versus despair may have a more favorable outcome in earlier age cohorts than in later ones, raising the possibility that changing societal values have hurt the struggle for integrity. Another study found that wisdom, a construct related to integrity, bore a more substantial relation to life satisfaction in elderly adults than other variables, including finances, health, and living situation.

A survey of theories of development in old age is given in Table 32-24.

Personality Over the Life Span: Stability or Change?

Although Erikson and other stage theorists focused on unique developmental tasks and stages central to each phase of life, other theorists focused on defining core personality traits within the individual and determining their course over the life span. For example, do those who are gregarious or extroverted during early childhood and adolescence remain extroverted through midlife and old age? Several well-designed longitudinal studies that have followed individuals over periods ranging from 10 to 50 years have found strong evidence for stability in five essential personality traits: extroversion, neuroticism, agreeableness, openness to experience, and conscientiousness. Some studies found slight decreases in extroversion and slight increases in agreeableness as individuals move into the oldest-old category, which contrasts with early theories that proposed that personality rigidifies as individuals age.

Is the fact that personality appears to have considerable stability over time inconsistent with the basic tenets of stage theories? Perhaps not. It may be that although individuals are consistent over time in their basic personality structure, the themes and conflicts with which they struggle change considerably over the life span, from concerns about developing identity and a stable sense of self to finding a life partner, to issues related to life review, as hypothesized by the stage theories. Also, in developing theories about personality change, few studies have examined the impact of significant historical events on personality; thus, how these events may result in personality change have not been studied systematically.

PSYCHOSOCIAL ASPECTS OF AGING

Social Activity

Healthy older persons usually maintain a level of social activity that is only slightly changed from that of earlier years. For many, old age is a period of continued intellectual, emotional, and psychological growth. In some cases, however, physical illness or the death of friends and relatives may preclude continued social interaction. Moreover, as persons experience an increased sense of isolation, they may become vulnerable to depression. Growing evidence indicates that maintaining social activities is valuable for physical and emotional well-being. Contact with younger persons is also essential. Old persons can pass on cultural values and provide care services to the younger generation and thereby maintain a sense of usefulness that contributes to self-esteem.

Ageism

Ageism, a term coined by Robert Butler, refers to discrimination toward old persons and to the negative stereotypes about old age that are held by younger adults. Old persons may themselves resent and fear other old persons and discriminate against them. In Butler's scheme, persons often associate old age with loneliness, poor health, senility, and general weakness or infirmity. The experience of older persons, however, does not consistently support this attitude. For example, although 50 percent of young adults expect poor health to be a problem for those over 65 years old, 75 percent of persons 65 to 74 years of age describe their health as good. Two-thirds of persons 75 and older feel the same way. Health problems, when they do exist, more often involve chronic than acute conditions. More than four of five persons over the age of 65 have at least one chronic condition (Table 32-25).

Good health, however, is not the sole determinant of a good quality of life in old age. Surveys of old persons show that social contacts are at least as highly valued. The factors affecting good aging appear to be multidimensional. Aging "robustly" means considering aging in terms of productive involvement, affective status, functional status, and cognitive status. These four indicators are only minimally correlated. The most robustly aging individuals report more significant social contact, better health and vision, and fewer significant life events in the past 3 years than their less robustly aging counterparts. A linear, age-related decrease occurs in

robustness, but it can still be found among the oldest-old.

Table 32-25
Top Ten Chronic Conditions for People 65+, by Age and Race (Number Per 1,000 People)

	Age				Race (65+)		
Condition	65+	45–64	65–74	75+	White	Black	Black as of White
Arthritis	483.0	253.8	437.3	554.5	483.2	522.6	108
Hypertension	380.6	229.1	383.8	375.6	367.4	517.7	141
Hearing impairment	286.5	127.7	239.4	360.3	297.4	174.5	59
Heart disease	278.9	118.9	231.6	353.0	286.5	220.5	77
Cataracts	156.8	16.1	107.4	234.3	160.7	139.8	87
Deformity or orthopedic impairment	155.2	155.5	141.4	177.0	156.2	150.8	97
Chronic sinusitis	153.4	173.5	151.8	155.8	157.1	125.2	80
Diabetes	88.2	58.2	89.7	85.7	80.2	165.9	207
Visual impairment	81.9	45.1	69.3	101.7	81.1	77.0	95
Varicose veins	78.1	57.8	72.6	86.6	80.3	64.0	80

Data from National Center for Health Statistics, Washington, DC.

George Vaillant followed up a group of Harvard freshmen into old age and found the following about emotional health at age 65: Having been close to brothers and sisters during college correlated with emotional well-being; undergoing early traumatic life experiences, such as the death of a parent or parental divorce, did not correlate with poor adaptation in old age; being depressed at some point between ages 21 and 50 predicted emotional problems at age 65, and possessing the personality traits of pragmatism and dependability as a young adult was associated with a sense of well-being at age 65.

Transference

Several forms of transference, some of them unique to adulthood, are present in older adults. First is the well-recognized parental transference, in which the patient reacts to the therapist as a child to a parent. Peer or sibling transference, expressions of experiences from a variety of nonparental relationships, is also common. In this form of transference, the patient looks to the therapist to share experiences with siblings, spouses, friends, and associates. At first, therapists may be surprised by older patients' ability to ignore their age in creating such transferences.

In son or daughter transference, quite common in middle-aged individuals and the elderly, the therapist is cast in the role of the patient's child, grandchild, or son-in-law or daughter-in-law. The themes expressed in this form of transference are multiple and often center on defenses against dependency feelings, activity and dominance versus passivity and submission, and attempts to rework unsatisfying aspects of relationships with children before time runs out. Finally, sexual transferences in older individuals are frequent and intense, and the therapist needs to be able to accept them and manage his or her countertransference responses.

Countertransference

Older individuals are dealing with illness and signs of aging, the loss of spouses and friends, and the constant awareness of time limitation and the nearness of death. These are painful issues that are just beginning to come into focus for younger therapists who would prefer not to confront them with great intensity daily.

The second source of countertransference responses centers on the older patient's sexuality. The presence of a vivid fantasy life, masturbation, and intercourse is disconcerting in and of themselves if the therapist has not had much experience in working with individuals who are the same age as their parents and grandparents. Consider the experience presented in the case study of a 31-year-old female therapist who was treating a 62-year-old man.

> Early in the treatment process, Mr. E's sexual feelings emerged. His well-groomed appearance and adolescent-like nervousness caused the therapist discomfort. Her concern was how to engender respect and develop a therapeutic alliance with a patient who approached each session as a date, mainly because he was old enough to be her grandfather. At first shocked by his open expression of sexual interest in her, with the help of supervision and her therapy, she was able to recognize that she and the patient had similar conflicts to resolve, despite the 30-year age difference between them. She had hoped that Mr. E would be "all grown up," devoid of issues that she was grappling with also. She came to recognize that failure to help him understand the relation between his past and still vibrant sexuality would do the patient a great disservice. It would spring

from her a lack of understanding of late-life sexual development and her countertransference reaction to him based on her conflicted attitudes toward the sexuality of her parents and grandparents. (Courtesy of Calvin A. Colarusso, M.D.)

Socioeconomics

The economics of old age is of paramount importance to older persons themselves and society at large. The past 30 years have seen a dramatic decline in the proportion of the US elderly population who are poor, primarily as a result of the availability of Medicare, Social Security, and private pensions. In 1959, 35.2 percent of persons over 65 lived below the poverty line, but by 2012 this figure had declined to 9.1 percent. Persons over age 65 make up 12 percent of the population, but they include only 9 percent of those living at low socioeconomic levels. Women are more likely than men to be impoverished. Income sources vary for persons age 65 and older. Despite overall economic gains, many older persons are so preoccupied with money worries that their enjoyment of life is lessened. Obtaining proper medical care may be incredibly difficult when personal funds are not available or are insufficient.

Medicare (Title 18) provides both hospital and medical insurance for those over age 65. About 150 million medical bills are reimbursed under the Medicare program each year, but only about 40 percent of all medical expenses incurred by older persons are covered under Medicare. The rest is paid by private insurance, state insurance, or personal funds. Some services—such as outpatient psychiatric treatment, skilled nursing care, physical rehabilitation, and preventive physical examinations—are covered minimally or not at all.

In addition to Medicare, the Social Security program pays benefits to persons over age 65 (over age 67 in 2027) and pays benefits at reduced rates starting at age 62. To qualify for benefits, a person must have worked long enough to become insured: A worker must have worked for 10 years to be eligible for benefits. Benefits are also paid to widows, widowers, and dependent children if those receiving benefits or contributing to Social Security die (survivor benefits). Social Security is not a pension scheme but a pay-as-you-go income supplement to prevent mass destitution among older

persons. Benefits are paid by those currently working to those who are retired. Serious difficulties for Social Security are forecast for the next three decades when the number of baby boomers reaching old age will significantly exceed the number of younger workers paying into the plan.

Retirement

For many older persons, retirement is a time for the pursuit of leisure and freedom from the responsibility of previous working commitments. For others, it is a time of stress, mainly when retirement results in economic problems or a loss of self-esteem. Ideally, employment after age 65 should be a matter of choice. With the passage of the Age Discrimination in Employment Act of 1967 and its amendments, forced retirement at age 70 has been virtually eliminated in the private sector, and it is not legal in federal employment.

Most of those who retire voluntarily reenter the workforce within 2 years, for a variety of reasons, including adverse reactions to being retired, feelings of being unproductive, economic hardship, and loneliness. The amount of time spent in retirement has increased as the life span has nearly doubled since 1900. Currently, the number of years spent in retirement is almost equal to the number of years spent working.

People age 65 or older in need of long-term care: 1980–2040. (Reprinted from Manton B, Saldo J. *Dynamics of Health Changes in the Oldest Old: New Perspectives and Evidence*. Milbank Q; 1985;63:12, with permission.)

Sexual Activity

The frequency of orgasm, from coitus or masturbation, decreases with age in men and women. The most critical factors in determining the level of sexual activity with age are the health and survival of the spouse, one's health, and the level of past sexual activity. Although some degree of declining sexual interest and function is inevitable with age, social and cultural factors appear to be more responsible for the sexual changes observed than for the psychological changes of aging per se. Although satisfying sexual activity is possible for reasonably healthy elderly, many do not actualize this potential. The widely held notion that the elderly are essentially asexual is often a self-fulfilling prophecy.

Long-Term Care

Many older persons who are infirm require institutional care. Although only 5 percent are institutionalized in nursing homes at any one time, about 35 percent of older persons require care in a long-term facility at some time during their lives (Fig. 32-10). Older nursing home residents are mainly widowed women, and about 50 percent are over age 85.

Medicare does not cover nursing home care costs; they range from $20,000 to $1 million a year. About 20,000 long-term nursing care institutions are available in the United States. This number is not enough to meet the need. Those older persons who do not require skilled nursing care can be managed in other types of health-related facilities, such as centers they attend during the daytime hours, but the need for care far exceeds the availability of such centers.

Besides institutions, the older person's children tend to care for them. The most common caregivers are daughters and daughters-in-law, wives, and other women (Fig. 32-11). More than 50 percent of these women caregivers also work, and about 40 percent also care for their children. In general, women end up as caregivers more often than men because of cultural and societal expectations. According to the American Association of Retired Persons, daughters with jobs spend an average of 12 hours a week providing

care and currently spend about $150 a month for travel, telephone calls, special foods, and medication for older persons.

33 Contributions from the Neurosciences

The human brain is responsible for our cognitive processes, emotions, and behaviors—that is, everything we think, feel, and do. Although the early development and adult function of the brain are shaped by multiple factors (e.g., epigenetic, environmental, and psychosocial experiences), the brain is the final integrator of these influences. Despite the many advances in neural sciences, there has not been a genuine transformational advance in the treatment of mental disorders for more than half a century. The most apparent reason for the absence of more progress is the profound complexity of the human brain. A perhaps less apparent reason is the current practice of psychiatric diagnosis, which, for most clinicians, is based on syndrome-based classification systems.

The purpose of this chapter is to introduce the neural sciences sections, which describe the anatomy and function of the human brain, and then to discuss how an evolution of thinking toward a brain-based or biologically based diagnostic system for mental illness might facilitate our efforts to advance brain research, to develop better treatments, and to improve patient care.

In other fields of medicine, diagnosis is based on physical signs and symptoms, a medical history, and results of laboratory and radiologic tests. In psychiatry, a diagnosis is based primarily on the clinician's impression of the patient's interpretation of his or her thoughts and feelings. The patient's symptoms are then cross-referenced to a diagnostic or classification manual (e.g., *Diagnostic and Statistical Manual of Mental Disorders* [DSM-5], *International Statistical Classification of Diseases and Related Health Problems* [ICD]) containing hundreds of potential syndromes, and one or more diagnoses are applied to the particular patient. These standard

classification systems represent significant improvements in reliability over previous diagnostic systems, but there is little reason to believe that these diagnostic categories are valid, in the sense that they represent discrete, biologically distinct entities. Although a patient with no symptoms or complaints can be diagnosed as having diabetes, cancer, or hypertension based on blood tests, x-rays, or vital signs, a patient with no symptoms cannot be diagnosed with schizophrenia, for example, because there are no currently recognized objective, independent assessments.

The goals of clinicians and researchers are to reduce human suffering by increasing our understanding of diseases, developing new treatments to prevent or cure diseases, and caring for patients optimally. If the brain is the organ of focus for mental illnesses, then it may be time to be more ambitious in building the classification of patients with mental illnesses directly from our understanding of biology, rather than only from the assessment of a patient's symptoms.

THE HUMAN BRAIN

The following neural sciences sections each address a field of brain biology. Each of these fields could be relevant to the pathophysiology and treatment of mental illnesses. Although the complexity of the human brain is daunting compared with other organs of the body, progress can only be made if one approaches this complexity consistently, methodically, and bravely.

The neuronal and glial cells of the human brain are organized in a characteristic manner, which has been increasingly clarified through modern neuroanatomical techniques. Also, our knowledge of normal human brain development has become more robust in the last decade. The human brain evolved from the brains of lower animal species, allowing inferences to be made about the human brain from animal studies. Neurons communicate with one another through chemical and electrical neurotransmission. The major neurotransmitters are the monoamines, amino acids, and neuropeptides. Other chemical messengers include neurotrophic factors and an array of other molecules, such as nitric oxide. Electrical neurotransmission occurs through a wide range of ion channels. Chemical and electrical signals received by a neuron subsequently initiate various molecular pathways within other neurons that regulate the biology and function of individual neurons,

including the expression of individual genes and the production of proteins.

Also, to the central nervous system (CNS), the human body contains two other systems that have complex internal communicative networks: the endocrine system and the immune system. The recognition that these three systems communicate with each other has given birth to the fields of psychoneuroendocrinology and psychoneuroimmunology. Another property shared by the CNS, the endocrine system, and the immune system is the regular changes they undergo with time (e.g., daily, monthly), which is the basis of the field of chronobiology.

Psychiatry and the Human Brain

In the first half of the 20th century, our emphasis on psychodynamic and social psychiatry divorced psychiatric research from the study of the human brain. Since the 1950s, the appreciation of the effectiveness of medications in treating mental disorders and the mental effects of illicit drugs have reestablished a biologic view of mental illness, which had already been seeded by the introduction of electroconvulsive therapy (ECT) and James Papez's description of the limbic circuit in the 1930s. This biologic view has been reinforced further by the development of brain imaging techniques that have helped reveal how the brain performs in normal and abnormal conditions. During this period, countless discoveries have been made in basic neural science research using experimental techniques to assess the development, structure, biology, and function of the CNS of humans and animals.

Psychopharmacology. The effectiveness of drugs in the treatment of mental illness has been a significant feature of the last half-century of psychiatric practice. The first five editions of this textbook divided psychopharmacological treatment into four chapters on antipsychotic, antidepressant, antianxiety, and mood-stabilizing drugs. The prior division of psychiatric drugs into four classes is less valid now than it was in the past for the following reasons: (1) Many drugs of one class are used to treat disorders previously assigned to another class; (2) drugs from all four categories are used to treat disorders not previously treatable by drugs (e.g., eating disorders, panic disorders, and impulse control disorders); and (3) drugs such

as clonidine, propranolol, and verapamil can effectively treat a variety of psychiatric disorders and do not fit easily into the other categories of psychiatric drugs.

The primary motivation for this change was that the variety and application of the drug treatments no longer fit a division of disorders into psychosis, depression, anxiety, and mania. In other words, the clinical applications of biologically based treatments did not neatly align with our syndrome-based diagnostic system. An implication of this observation could be that drug response might be a better indicator of underlying biologic brain dysfunction than any particular group of symptoms. For example, although the DSM-5 distinguishes major depressive disorder from generalized anxiety disorder, most clinicians are aware that these are often overlapping symptoms and conditions in clinical practice. Moreover, the same drugs are used to treat both conditions.

The animal models that are used to identify new drug treatments may also have affected our ability to advance research and treatment. Many major classes of psychiatric drugs were discovered serendipitously. Specifically, the drugs were developed originally for nonpsychiatric indications, but observant clinicians and researchers noted that psychiatric symptoms improved in some patients, which led to a focused study of these drugs in psychiatric patients. The availability of these effective drugs, including monoaminergic antidepressants and antipsychotics, led to the development of animal models that could detect the effects of these drugs (e.g., tricyclic antidepressants [TCAs] increase the time mice spend trying to find a submerged platform in a “forced swim” test). These animal models were then used to screen new compounds in an attempt to identify drugs that were active in the same animal models. The potential risk of this overall strategy is that these animal models are merely a method for detecting a particular molecular mechanism of action (e.g., increasing serotonin concentrations), rather than a model for a true behavioral analog of human mental illness (e.g., behavioral despair in a depressed patient).

Endophenotypes. A possible diagnosis-related parallel to how this textbook separated the four classes of psychotropic drugs into approximately 30 different categories is the topic of *endophenotypes* in psychiatric patients. An endophenotype is an internal phenotype, which is a set of objective

characteristics of an individual that are not visible to the unaided eye. Because there are so many steps and variables that separate a particular set of genes from the final functioning of a whole human brain, it may be more tractable to consider intermediate assessments such as endophenotypes. This hypothesis is based on the assumption that the number of genes that are involved in an endophenotype might be fewer than the number of genes involved in causing what we would conceptualize as a disease. For psychiatry, an endophenotype is based on neuropsychological, cognitive, neurophysiologic, neuroanatomical, biochemical, and brain imaging data. Such an endophenotype, for example, might include specific cognitive impairments as just one of its objectively measured features. This endophenotype would not be limited to patients with a diagnosis of schizophrenia because it might also be found in some patients with depression or bipolar disorder.

The potential role of an endophenotype can be further clarified by stating what it is not. An endophenotype is not a symptom, and it is not a diagnostic marker. A classification based on the presence or absence of one or more endophenotypes would be based on objective biologic and neuropsychological measures with specific relationships to genes and brain function. A classification based on endophenotypes might also be a productive approach toward the development of more relevant animal models of mental illnesses, and thus the development of novel treatments.

Psychiatry and the Human Genome

Perhaps 70 to 80 percent of the 25,000 human genes are expressed in the brain, and because most genes code for more than one protein, there may be 100,000 different proteins in the brain. Perhaps 10,000 of these are known proteins with somewhat identified functions, and no more than 100 of these are the targets for existing psychotherapeutic drugs.

The study of families with the use of population genetic methods over the last 50 years has consistently supported a genetic, heritable component to mental disorders. More recent techniques in molecular biology have revealed that specific chromosomal regions and genes are associated with particular diagnoses. A potentially compelling application of these techniques has been to study transgenic models of behavior in animals. These transgenic models

can help us understand the effects of individual genes as well as discover completely novel molecular targets for drug development.

It may be a natural response to resist “simple” genetic explanations for human features. Nonetheless, research on humans generally has found that approximately 40 to 70 percent of aspects of cognition, temperament, and personality are attributable to genetic factors. Because these are the very domains that are affected in mentally ill patients, it would not be surprising to discover a similar level of genetic influence on mental illness, mostly if we were able to assess this impact at a more discrete level, such as with endophenotypes.

Individual Genes and Mental Disorders. Several types of data and observations suggest that any single gene is likely to have only a modest effect on the development of a mental disorder and that when a mental disorder is present in an individual, it represents the effects of multiple genes, speculatively on the order of five to ten genes. This hypothesis is also supported by our failure to find single genes with significant effects on mental illnesses. Some researchers, however, still consider it a possibility that genes with significant effects will be identified.

“Nature” and “Nurture” within the CNS. In 1977, George Engel, at the University of Rochester, published a paper that articulated the biopsychosocial model of disease, which stressed an integrated approach to human behavior and disease. The biologic system refers to the anatomical, structural, and molecular substrates of disease; the psychological system refers to the effects of psychodynamic factors; and the social system examines cultural, environmental, and familial influences. Engel postulated that each system affects and is affected by the others.

The observation that a significant percentage of identical twins are discordant for schizophrenia is one example of the type of data that supports the understanding that there are many significant interactions between the genome and the environment (i.e., the biologic basis of the biopsychosocial concept). Studies in animals have also demonstrated that many factors—including activity, stress, drug exposure, and environmental toxins—can regulate the expression of genes and the development and functioning of the brain.

Mental Disorders Reflect Abnormalities in Neuroanatomical Circuits and Synaptic Regulation. Although genes lead to the production of proteins, the actual functioning of the brain needs to be understood at the level of regulation of complex pathways of neurotransmission and intraneuronal signaling, and networks of neurons within and between brain regions. In other words, the downstream effects of abnormal genes are modifications in discrete attributes such as axonal projections, synaptic integrity, and specific steps in intraneuronal molecular signaling.

Why Not a Genetic-Based Diagnostic System? Some researchers have proposed moving psychiatry toward a completely genetic-based diagnostic system. This proposal, however, seems premature based on the complexity of the genetic factors presumably involved in psychiatric disorders, the current absence of sufficient data to make these genetic connections, and the importance of epigenetic and environmental influences on the final behavioral outcomes resulting from an individual's genetic information.

Lessons from Neurology

Clinical and research neurologists seem to have been able to think more than psychiatrists about their diseases of interest and their causes, perhaps because the symptoms are generally nonbehavioral. Neurologists have biologically grounded differential diagnoses and treatment choices. This clarity of approach has helped lead to significant advances in neurology in the last two decades, for example, clarification of the amyloid precursor protein abnormalities in some patients with Alzheimer disease, the presence of trinucleotide repeat mutations in Huntington disease and spinocerebellar ataxia, and the appreciation of alpha-synucleinopathies, such as Parkinson disease and Lewy body dementia.

The continued separation of psychiatry from neurology is, in itself, a potential impediment to good patient care and research. Many neurologic disorders have psychiatric symptoms (e.g., depression in patients following a stroke or with multiple sclerosis or Parkinson disease), and several of the most severe psychiatric disorders have been associated with neurologic

symptoms (e.g., movement disorders in schizophrenia). This overlap is not surprising given that the brain is the organ shared by psychiatric and neurologic diseases, and the division between these two disease areas is arbitrary. For example, patients with Huntington disease are at much greater risk for a wide range of psychiatric symptoms and syndromes, and thus many different DSM-5 diagnoses. Because we know that Huntington disease is an autosomal dominant genetic disorder, the observation that it can manifest with so many different DSM-5 diagnoses does not speak to a reliable biologic distinction among the existing DSM-5 categories.

Examples of Complex Human Behaviors

The goal to understand the human brain and its normal and abnormal functioning is genuinely one of the last frontiers for humans to explore. Trying to explain why a particular individual is the way he or she is, or what causes schizophrenia, for example, will remain too large a challenge for some decades. It is more approachable to consider more discrete aspects of human behavior.

It is not the role of textbooks to set policies or to write diagnostic manuals, but rather to share knowledge, generate ideas, and encourage innovation. The authors believe, however, that it is time to reap the insights of decades of neural science and clinical brain research and to build the classification of mental illnesses on fundamental principles of biology and medicine. Regardless of official diagnostic systems, however, clinicians and researchers should fully understand the biologic component of the biopsychosocial model, and not let research or patient care suffer because of a diagnostic system that is not founded on biologic principles.

FUNCTIONAL NEUROANATOMY

The sensory, behavioral, affective, and cognitive phenomena and attributes experienced by humans are mediated through the brain. It is the organ that perceives and affects the environment and integrates past and present. The brain is the organ of the mind that enables persons to sense, do, feel, and think.

Sensory systems create an internal representation of the external world by processing external stimuli into neuronal impulses. A separate map is formed

for each sensory modality. *Motor systems* enable persons to manipulate their environment and to influence the behavior of others through communication. In the brain, sensory input, representing the external world, is integrated with internal drivers, memories, and emotional stimuli in *association units,* which in turn drive the actions of motor units. Although psychiatry is concerned primarily with the brain's association function, an appreciation of information processing of the sensory and motor systems is essential for sorting logical thought from the distortions introduced by psychopathology.

Brain Organization

The human brain contains approximately 86 billion *neurons* (nerve cells) and approximately 85 billion *glial cells.* Neurons most classically consist of a *soma,* or cell body, which contains the nucleus; usually multiple *dendrites,* which are processes that extend from the cell body and receive signals from other neurons; and a single *axon,* which extends from the cell body and transmits signals to other neurons. Connections between neurons are made at *axon terminals;* there, the axons of one neuron generally contact the dendrite or cell body of another neuron. Neurotransmitter release occurs within axon terminals and is one of the central mechanisms for intraneuronal communications, and also for the effects of psychotropic drugs.

There are three types of glial cells, and although they have often been thought of as having only a supportive role for neuronal functioning, glia has been increasingly appreciated as potentially involved in brain functions that may contribute more directly to both normal and disease mental conditions. The most common type of glial cells are *astrocytes,* which have several functions, including the nutrition of neurons, deactivation of some neurotransmitters, and integration with the blood–brain barrier (BBB). The *oligodendrocytes* in the CNS and the *Schwann cells* in the peripheral nervous system wrap their processes around neuronal axons, resulting in *myelin sheaths* that facilitate the conduction of electrical signals. The third type of glial cells, the *microglia,* which are derived from macrophages, are involved in removing cellular debris following neuronal death.

The neurons and glial cells are arranged in regionally distinct patterns within the brain. Neurons and their processes form groupings in many different ways, and these patterns of organization, or architecture, can be

evaluated by several approaches. The pattern of distribution of nerve cell bodies, called *cytoarchitecture*, is revealed by aniline dyes called Nissl stains that stain ribonucleotides in the nuclei and the cytoplasm of neuronal cell bodies. The Nissl stains show the relative size and packing density of the neurons and, consequently, reveal the organization of the neurons into the different layers of the cerebral cortex.

Sensory Systems

The external world offers an infinite amount of potentially relevant information. In this overwhelming volume of sensory information in the environment, the sensory systems must both detect and discriminate stimuli; they winnow relevant information from the mass of confounding input by applying filtration at all levels. Sensory systems first transform external stimuli into neural impulses and then filter out irrelevant information to create an internal image of the environment, which serves as a basis for reasoned thought. Feature extraction is the quintessential role of sensory systems, which achieve this goal with their hierarchical organizations, first by transforming physical stimuli into neural activity in the primary sense organs and then by refining and narrowing the neural activity in a series of higher cortical processing areas. This neural processing eliminates irrelevant data from higher representations and reinforces crucial features. At the highest levels of sensory processing, neural images are transmitted to the association areas to be acted on in the light of emotions, memories, and drives.

Somatosensory System. The *somatosensory system,* an intricate array of parallel point-to-point connections from the body surface to the brain, was the first sensory system to be understood in anatomical detail. The six somatosensory modalities are light touch, pressure, pain, temperature, vibration, and proprioception (position sense). The organization of nerve bundles and synaptic connections in the somatosensory system encodes spatial relationships at all levels so that the organization is strictly *somatotopic* (Fig. 33-1).

Within a given patch of skin, various receptor nerve terminals act in concert to mediate distinct modalities. The mechanical properties of the skin’s mechanoreceptors and thermoreceptors generate neural impulses in

response to dynamic variations in the environment while they suppress static input. Nerve endings are either fast or slow responders; their depth in the skin also determines their sensitivity to sharp or blunt stimuli. Thus the representation of the external world is significantly refined at the level of the primary sensory organs.

The receptor organs generate coded neural impulses that travel proximally along the sensory nerve axons to the spinal cord. These far-flung routes are susceptible to varying systemic medical conditions and pressure palsies. Pain, tingling, and numbness are the typical presenting symptoms of peripheral neuropathies.

All somatosensory fibers project to and synapse in the thalamus. The thalamic neurons preserve the somatotopic representation by projecting fibers to the somatosensory cortex, located immediately posterior to the Sylvian fissure in the parietal lobe. Despite the considerable overlap, several bands of cortex roughly parallel to the Sylvian fissure are segregated by a somatosensory modality. Within each band is the sensory “homunculus,” the culmination of the careful somatotopic segregation of the sensory fibers at the lower levels. The clinical syndrome of *tactile agnosia* (*astereognosis*) is defined by the inability to recognize objects based on touch, although the primary somatosensory modalities—light touch, pressure, pain, temperature, vibration, and proprioception—are intact. This syndrome, localized at the border of the somatosensory and association areas in the posterior parietal lobe, appears to represent an isolated failure of only the highest order of feature extraction, with preservation of the more basic levels of the somatosensory pathway.

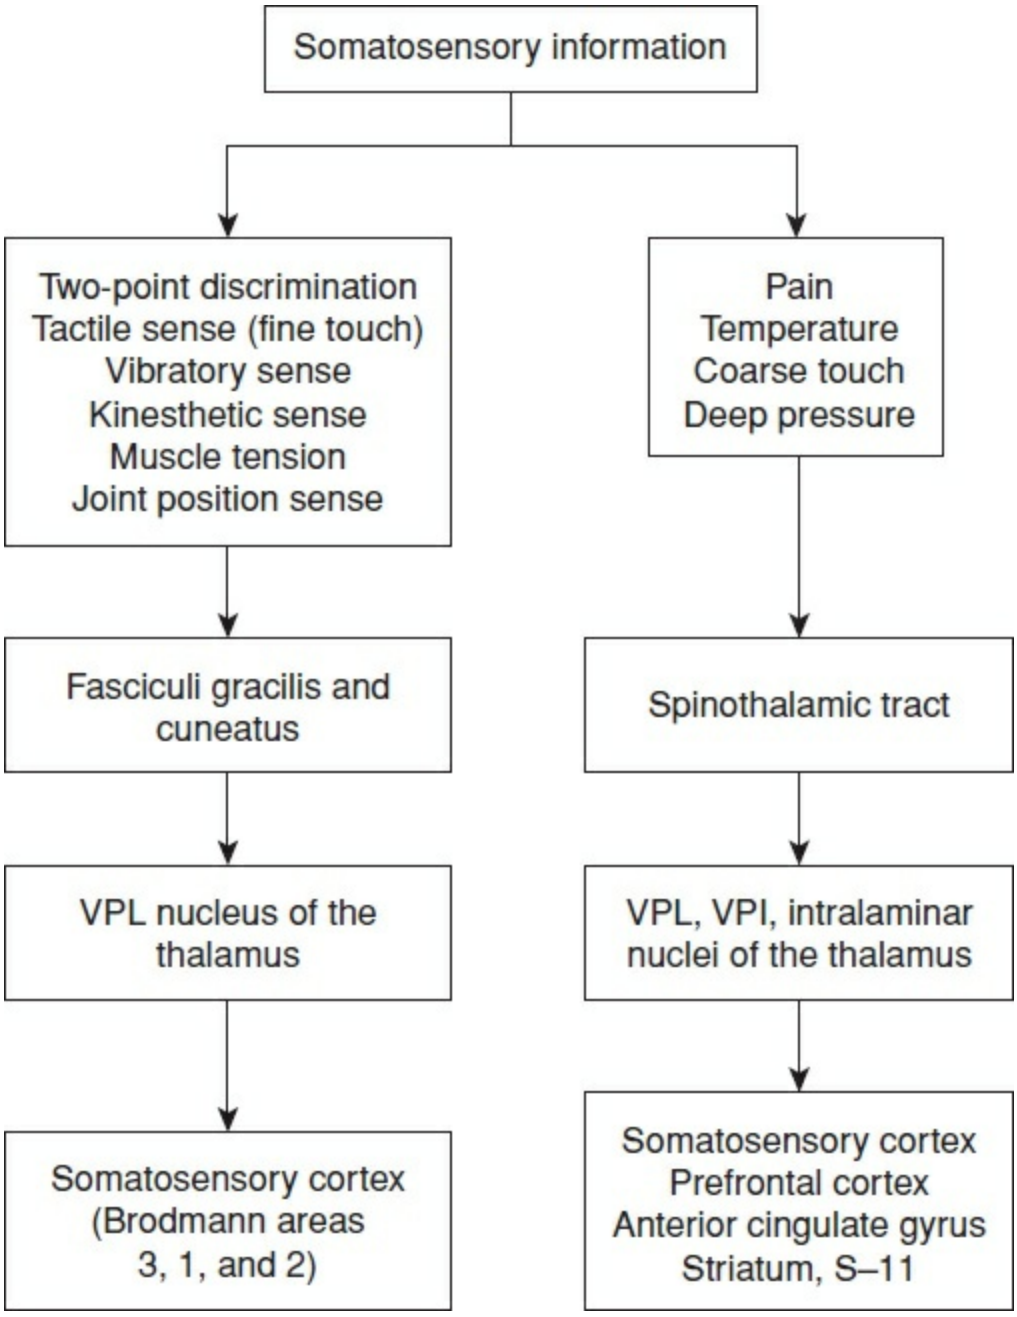

FIGURE 33-1
Pathway of somatosensory information processing. (Adapted from Patestas MA, Gartner LP. *A Textbook of Neuroanatomy*. Malden, MA: Blackwell; 2006:149.)

Reciprocal connections are a critical anatomical feature of crucial importance to conscious perception—as many fibers project down from the cortex to the thalamus as project up from the thalamus to the cortex. These reciprocal fibers play a critical role in filtering sensory input. In normal states, they facilitate the sharpening of internal representations, but in

pathologic states, they can generate false signals or inappropriately suppress sensation. Such cortical interference with sensory perception is thought to underlie many psychosomatic syndromes, such as the hemisensory loss that characterizes conversion disorder.

The prenatal development of the strict point-to-point pattern that characterizes the somatosensory system remains an area of active study. Patterns of sensory innervation result from a combination of axonal guidance by particular molecular cues and pruning of exuberant synaptogenesis based on an organism's experience. Leading hypotheses weigh contributions from a genetically determined molecular map—in which the arrangement of fiber projections is organized by fixed and diffusible chemical cues—against contributions from the modeling and remodeling of projections based on coordinated neural activity. Thumbnail calculations suggest that the 30,000 to 40,000 genes in human deoxyribonucleic acid (DNA) are far too few to completely encode the position of all the trillions of synapses in the brain. Genetically determined positional cues probably steer growing fibers toward the general target, and activity-dependent mechanisms fine-tune the pattern of projections. Recent data suggest that well-established adult thalamocortical sensory projections can be gradually remodeled as a result of a reorientation of coordinated sensory input or in response to the loss of part of the somatosensory cortex, for instance, in stroke.

DEVELOPMENT OF THE SOMATOSENSORY SYSTEM. A strict somatotopic representation exists at each level of the somatosensory system. During development, neurons extend axons to connect to distant brain regions; after arriving at the destination, a set of axons must therefore sort itself to preserve the somatotopic organization. A classic experimental paradigm for this developmental process is the representation of a mouse's whiskers in the somatosensory cortex. The murine somatosensory cortex contains a barrel field of cortical columns, each of which corresponds to one whisker. When mice are inbred to produce fewer whiskers, fewer somatosensory cortex barrels appear. Each barrel is expanded in area, and the entire barrel field covers the same area of the somatosensory cortex as it does in normal animals. This experiment demonstrates that specific higher cortical structures can form in response to peripheral input and that different input complexities determine different patterns of synaptic connectivity. Although the

mechanisms by which peripheral input molds cortical architecture are mostly unknown, animal model paradigms are beginning to yield clues. For example, in a mutant mouse that lacks monoamine oxidase A and, thus, has exceptionally high cortical levels of serotonin, barrels fail to form in the somatosensory cortex. This result indirectly implicates serotonin in the mechanism of barrel field development.

In adults, the classic mapping studies of Wilder Penfield suggested the existence of a homunculus, an immutable cortical representation of the body surface. More recent experimental evidence from primate studies and stroke patients, however, has promoted a more plastic conception than that of Penfield. Minor variations exist in the cortical pattern of ordinary individuals, yet dramatic shifts in the map can occur in response to the loss of cortex from stroke or injury. When a stroke ablates a significant fraction of the somatosensory homunculus, the homuncular representation begins to contract and shift proportionately to fill the remaining intact cortex.

Moreover, the cortical map can be rearranged solely in response to a change in the pattern of tactile stimulation of the fingers. The somatotopic representation of the proximal and distal segments of each finger typically forms a contiguous map, presumably because both segments contact surfaces simultaneously. However, under experimental conditions in which the distal segments of all fingers are simultaneously stimulated while contact of the distal and proximal parts of each finger is separated, the cortical map gradually shifts 90 degrees to reflect the new sensory experience. In the revised map, the cortical representation of the proximal segment of each finger is no longer contiguous with that of the distal segment.

These data support the notion that the internal representation of the external world, although static in gross structure, can be continuously modified at the level of synaptic connectivity to reflect relevant sensory experiences. The cortical representation also tends to shift to fit entirely into the available amount of cortex.

These results also support the notion that cortical representations of sensory input, or memories, may be holographic rather than spatially fixed: The pattern of activity, rather than the physical structure, may encode information. In sensory systems, this plasticity of cortical representation allows recovery from brain lesions; the phenomenon may also underlie learning.

Visual System. Visual images are transduced into neural activity within the retina and are processed through a series of brain cells, which respond to increasingly complex features, from the eye to the higher visual cortex. The neurobiologic basis of feature extraction is best understood in the finest detail in the visual system. Beginning with classic work in the 1960s, research in the visual pathway has produced two main paradigms for all sensory systems. The first paradigm, mentioned earlier for the somatosensory system, evaluates the contributions of genetics and experience—or nature and nurture—in the formation of the final synaptic arrangement. Transplantation experiments, resulting in an accurate point-to-point pattern of connectivity, even when the eye was surgically inverted, have suggested an innate, genetically determined mechanism of synaptic pattern formation. The crucial role of early visual experience in establishing the adult pattern of visual connections, on the other hand, crystallized the hypothesis of the activity-dependent formation of synaptic connectivity. The final adult pattern is the result of both factors.

The second central paradigm, most revealed in the visual system, is that of highly specialized brain cells that respond exclusively to particular stimuli. Recent work, for example, has identified cells in the inferior temporal cortex that respond only to faces viewed at a specific angle. An individual's response to a particular face requires the activity of large neural networks and may not be limited to a single neuron. Nevertheless, the cellular localization of specific feature extraction is of critical importance in defining the boundary between sensory and association systems, but only in the visual system has this significant question been posed experimentally.

In the primary visual cortex, columns of cells respond specifically to lines of a specific orientation. The cells of the primary visual cortex project to the secondary visual cortex. There the cells respond specifically to particular movements of lines and angles. In turn, these cells project to two association areas, where additional features are extracted and conscious awareness of images forms.

The inferior temporal lobe detects the shape, form, and color of the object—the *what* questions; the posterior parietal lobe tracks the location, motion, and distance—the *where* questions. The posterior parietal lobe contains distinct sets of neurons that signal the intention either to look into a specific

part of visual space or to reach for a particular object. In the inferior temporal cortices (ITCs), adjacent cortical columns respond to complex forms. Responses to facial features tend to occur in the left ITC, and responses to complex shapes tend to occur in the right ITC. The brain devotes specific cells to the recognition of facial expressions and the aspect and position of faces of others for the individual.

The crucial connections between the feature-specific cells and the association areas involved in memory and conscious thought remain to be delineated. Much elucidation of feature recognition is based on invasive animal studies. In humans, the clinical syndrome of *prosopagnosia* describes the inability to recognize faces in the presence of preserved recognition of other environmental objects. Based on the pathologic and radiologic examination of individual patients, prosopagnosia is thought to result from the disconnection of the left ITC from the visual association area in the left parietal lobe. Such lesional studies are useful in identifying necessary components of a mental pathway, but they may be inadequate to define the entire pathway. One noninvasive technique that is still being perfected and is beginning to reveal the full anatomical relation of the human visual system to conscious thought and memory is functional neuroimaging.

As is valid for language, there appears to be a hemispheric asymmetry for individual components of visuospatial orientation. Although both hemispheres cooperate in perceiving and drawing complex images, the right hemisphere, especially the parietal lobe, contributes the overall contour, perspective, and right-left orientation, and the left hemisphere adds internal detail, embellishment, and complexity. The brain can be fooled in optical illusions.

Neurologic conditions such as strokes and other focal lesions have permitted the definition of several disorders of visual perception. *Apperceptive visual agnosia* is the inability to identify and draw items using visual cues, with preservation of other sensory modalities. It represents a failure of transmission of information from the higher visual sensory pathway to the association areas and is caused by bilateral lesions in the visual association areas. *Associative visual agnosia* is the inability to name or use objects despite the ability to draw them. It is caused by bilateral medial occipitotemporal lesions and can occur along with other visual impairments. Color perception may be ablated in lesions of the dominant occipital lobe that

include the splenium of the corpus callosum. *Color agnosia* is the inability to recognize a color despite being able to match it. *Color anomia* is the inability to name a color despite being able to point to it. *Central achromatopsia* is a complete inability to perceive color.

Anton syndrome is a failure to acknowledge blindness, possibly owing to the interruption of fibers involved in self-assessment. It is seen with bilateral occipital lobe lesions. The most common causes are hypoxic injury, stroke, metabolic encephalopathy, migraine, herniation resulting from mass lesions, trauma, and leukodystrophy. *Balint syndrome* consists of a triad of optic ataxia (the inability to direct optically guided movements), *oculomotor apraxia* (inability to direct gaze rapidly), and *simultanagnosia* (inability to integrate a visual scene to perceive it as a whole). Balint syndrome is seen in bilateral parietooccipital lesions. *Gerstmann syndrome* includes agraphia, calculation difficulties (acalculia), right-left disorientation, and finger agnosia. It has been attributed to lesions of the dominant parietal lobe.

DEVELOPMENT OF THE VISUAL SYSTEM. In humans, the initial projections from both eyes intermingle in the cortex. During the development of visual connections in the early postnatal period, there is a window of time during which binocular visual input is required for the development of ocular dominance columns in the primary visual cortex. Ocular dominance columns are stripes of cortex that receive input from only one eye, separated by stripes innervated only by fibers from the other eye. Occlusion of one eye during this critical period eliminates the persistence of its fibers in the cortex and allows the fibers of the active eye to innervate the entire visual cortex. In contrast, when normal binocular vision is allowed during the critical development window, the usual dominance columns form, occluding one eye after the completion of innervation of the cortex, produces no subsequent alteration of the ocular dominance columns. This paradigm crystallizes the importance of early childhood experience on the formation of adult brain circuitry.

Auditory System. Sounds are instantaneous, incremental changes in ambient air pressure. The pressure changes cause the ear’s tympanic membrane to vibrate; the vibration is then transmitted to the ossicles (malleus, incus, and stapes) and thereby to the endolymph or fluid of the cochlear spiral. Vibrations of the endolymph move cilia on hair cells, which

generate neural impulses. The hair cells respond to sounds of different frequencies in a tonotopic manner within the cochlea, like an extended, spiral piano keyboard. Neural impulses from the hair cells travel in a tonotopic arrangement to the brain in the fibers of the cochlear nerve. They enter the brainstem cochlear nuclei, are relayed through the lateral lemniscus to the inferior colliculi, and then to the medial geniculate nucleus (MGN) of the thalamus. MGN neurons project to the primary auditory cortex in the posterior temporal lobe. Dichotic listening tests, in which different stimuli are presented to each ear simultaneously, demonstrate that most of the input from one ear activates the contralateral auditory cortex and that the left hemisphere tends to be dominant for auditory processing.

Sonic features are extracted through a combination of mechanical and neural filters. The representation of sound is roughly tonotopic in the primary auditory cortex, whereas *lexical processing* (i.e., the extraction of vowels, consonants, and words from the auditory input) occurs in higher language association areas, especially in the left temporal lobe. The syndrome of *word deafness,* characterized by intact hearing for voices but an inability to recognize speech, may reflect damage to the left parietal cortex. This syndrome is thought to result from the disconnection of the auditory cortex from Wernicke area. A rare, complementary syndrome, *auditory sound agnosia*, is defined as the inability to recognize nonverbal sounds, such as a horn or a cat's meow, in the presence of intact hearing and speech recognition. Researchers consider this syndrome to be the right hemisphere correlate of pure word deafness.

DEVELOPMENT OF THE AUDITORY SYSTEM. Some children are unable to process auditory input and therefore have impaired speech and comprehension of spoken language. Studies on some of these children have determined that they can discriminate speech if the consonants and vowels—the phonemes—are slowed two- to fivefold by a computer. Based on this observation, a tutorial computer program was designed that initially asked questions in a slowed voice and, as subjects answered questions correctly, gradually increased the rate of phoneme presentation to approximate typical rates of speech. Subjects gained some ability to discriminate routine speech over 2 to 6 weeks and appeared to retain these skills after the tutoring period was completed. This finding probably has therapeutic applicability to 5 to 8

percent of children with speech delay, but ongoing studies may expand the eligible group of students. This finding, moreover, suggests that neuronal circuits required for auditory processing can be recruited and be made more efficient long after language is usually learned, provided that the circuits are allowed to finish their task correctly, even if this requires slowing the rate of input. Circuits thus functioning with high fidelity can then be trained to speed their processing.

A recent report has extended the age at which language acquisition may be acquired for the first time.

> A boy who had intractable epilepsy of one hemisphere was mute because the uncontrolled seizure activity precluded the development of organized language functions. At the age of 9 years, he had the abnormal hemisphere removed to cure epilepsy. Although up to that point in his life he had not spoken, he initiated an accelerated acquisition of language milestones beginning at that age and ultimately gained language abilities only a few years delayed relative to his chronologic age.

Researchers cannot place an absolute upper limit on the age at which language abilities can be learned, although acquisition at ages beyond the usual childhood period is usually incomplete. Anecdotal reports document the acquisition of reading skills after the age of 80 years.

Olfaction. Odorants, or volatile chemical cues, enter the nose, are solubilized in the nasal mucus, and bind to odorant receptors displayed on the surface of the sensory neurons of the olfactory epithelium. Each neuron in the epithelium displays a unique odorant receptor, and cells displaying a given receptor are arranged randomly within the olfactory epithelium. Humans possess several hundred distinct receptor molecules that bind the massive variety of environmental odorants; researchers estimate that humans can discriminate 10,000 different odors. Odorant binding generates neural impulses, which travel along the axons of the sensory nerves through the cribriform plate to the olfactory bulb. Within the bulb, all axons corresponding to a given receptor converge onto only 1 or 2 of 3,000 processing units called *glomeruli.* Because each odorant activates several

receptors that activate a characteristic pattern of glomeruli, the identity of external chemical molecules is represented internally by a spatial pattern of neural activity in the olfactory bulb.

Each glomerulus projects to a unique set of 20 to 50 separate columns in the olfactory cortex. In turn, each olfactory cortical column receives projections from a unique combination of glomeruli. The connectivity of the olfactory system is genetically determined. Because each odorant activates a unique set of several receptors and thus a unique set of olfactory bulb glomeruli, each olfactory cortical column is tuned to detect a different odorant of some evolutionary significance to the species. Unlike the signals of the somatosensory, visual, and auditory systems, olfactory signals do not pass through the thalamus but project directly to the frontal lobe and the limbic system, especially the pyriform cortex. The connections to the limbic system (amygdala, hippocampus, and pyriform cortex) are significant. Olfactory cues stimulate strong emotional responses and can evoke powerful memories.

Olfaction, the most ancient sense in evolutionary terms, is tightly associated with sexual and reproductive responses. A related chemosensory structure, the vomeronasal organ, is thought to detect *pheromones*, chemical cues that trigger unconscious, stereotyped responses. In some animals, ablation of the vomeronasal organ in early life may prevent the onset of puberty. Recent studies have suggested that humans also respond to pheromones in a manner that varies according to the menstrual cycle. The structures of higher olfactory processing in phylogenetically more primitive animals have evolved in humans into the limbic system, the center of the emotional brain, and the gate through which experience is admitted into memory according to emotional significance. The elusive basic animal drives with which clinical psychiatry constantly grapples may, therefore, originate from the ancient centers of higher olfactory processing.

DEVELOPMENT OF THE OLFACTORY SYSTEM. During normal development, axons from the nasal olfactory epithelium project to the olfactory bulb and segregate into about 3,000 equivalent glomeruli. If an animal is exposed to a single dominant scent in the early postnatal period, then one glomerulus expands massively within the bulb at the expense of the surrounding glomeruli. Thus, as discussed earlier concerning the barrel fields of the

somatosensory cortex, the size of brain structures may reflect the environmental input.

Taste. Soluble chemical cues in the mouth bind to receptors in the tongue and stimulate the gustatory nerves, which project to the nucleus solitarius in the brainstem. The sense of taste is believed to discriminate only in broad classes of stimuli: sweet, sour, bitter, salty and umami. Each modality is mediated through a unique set of cellular receptors and channels, of which several may be expressed in each taste neuron. The detection and the discrimination of foods, for example, involve a combination of the senses of taste, olfaction, touch, vision, and hearing. Taste fibers activate the medial temporal lobe, but the higher cortical localization of taste is only poorly understood.

Autonomic Sensory System. The autonomic nervous system (ANS) monitors the essential functions necessary for life. The activity of visceral organs, blood pressure, cardiac output, blood glucose levels, and body temperature are all transmitted to the brain by autonomic fibers. Most autonomic sensory information remains unconscious; if such information rises to conscious levels, it is only as a vague sensation, in contrast to the capacity of the primary senses to transmit sensations rapidly and precisely.

Alteration of Conscious Sensory Perception through Hypnosis. *Hypnosis* is a state of heightened suggestibility attainable by a certain proportion of the population. Under a state of hypnosis, gross distortions of perception in any sensory modality and changes in the ANS can be achieved instantaneously. The anatomy of the sensory system does not change, yet the same specific stimuli may be perceived with opposed emotional value before and after induction of the hypnotic state. For example, under hypnosis, a person may savor an onion as if it were a luscious chocolate truffle, only to reject the onion as abhorrently pungent seconds later when the hypnotic suggestion is reversed. The localization of the hypnotic switch has not been determined, but it presumably involves both sensory and association areas of the brain. Experiments tracing neural pathways in human volunteers via functional neuroimaging have demonstrated that shifts in attention in an environmental setting determine changes in the regions of the brain that are

activated on an instantaneous time scale. Thus the organizing centers of the brain may route conscious and unconscious thoughts through different sequences of neural processing centers, depending on a person's ultimate goals and emotional state. These attention-mediated variations in synaptic utilization can occur instantaneously, much like the alteration in the routing of associational processing that may occur in hypnotic states.

Motor Systems

Body muscle movements are controlled by the lower motor neurons, which extend axons—some as long as 1 m—to the muscle fibers. Lower motor neuron firing is regulated by the summation of upper motor neuron activity. In the brainstem, primitive systems produce gross coordinated movements of the entire body. Activation of the rubrospinal tract stimulates flexion of all limbs, whereas activation of the vestibulospinal tract causes all limbs to extend. Newborn infants, for example, have all limbs tightly flexed, presumably through the dominance of the rubrospinal system. The movements of an anencephalic infant, who completely lacks a cerebral cortex, may be indistinguishable from the movements of an average newborn. In the first few months of life, the flexor spasticity is gradually mitigated by the opposite actions of the vestibulospinal fibers, and more limb mobility occurs.

At the top of the motor hierarchy is the corticospinal tract, which controls fine movements and which eventually dominates the brainstem system during the first years of life. The upper motor neurons of the corticospinal tract reside in the posterior frontal lobe, in a section of the cortex known as the *motor strip*. Planned movements are conceived in the association areas of the brain, and in consultation with the basal ganglia and cerebellum, the motor cortex directs their smooth execution. The importance of the corticospinal system becomes immediately evident in strokes, in which spasticity returns as the cortical influence is ablated, and the actions of the brainstem motor systems are released from cortical modulation.

Basal Ganglia. The *basal ganglia*, a subcortical group of gray matter nuclei, appear to mediate postural tone. The four functionally distinct ganglia are the striatum, the pallidum, the substantia nigra, and the subthalamic

nucleus. Collectively known as the corpus striatum, the caudate and putamen harbor components of both motor and association systems. The caudate nucleus plays a vital role in the modulation of motor acts. Anatomical and functional neuroimaging studies have correlated decreased activation of the caudate with obsessive-compulsive behavior. When functioning correctly, the caudate nucleus acts as a gatekeeper to allow the motor system to perform only those acts that are goal-directed. When it fails to perform its gatekeeper function, extraneous acts are performed, as in obsessive-compulsive disorder (OCD) or the tic disorders, such as Tourette disorder. Overactivity of the striatum owing to lack of dopaminergic inhibition (e.g., in parkinsonian conditions) results in *bradykinesia,* an inability to initiate movements. The caudate, in particular, shrinks dramatically in Huntington disease. This disorder is characterized by rigidity, on which is gradually superimposed choreiform, or "dancing," movements. Psychosis may be a prominent feature of Huntington disease, and suicide is not uncommon. The caudate is also thought to influence associative or cognitive processes.

The globus pallidus contains two parts linked in series. In a cross-section of the brain, the internal and external parts of the globus pallidus are nested within the concavity of the putamen. The globus pallidus receives input from the corpus striatum and projects fibers to the thalamus. This structure may be severely damaged in Wilson disease and in carbon monoxide poisoning, which are characterized by dystonic posturing and flapping movements of the arms and legs.

The substantia nigra is named the black substance because the presence of melanin pigment causes it to appear black to the naked eye. It has two parts, one of which is functionally equivalent to the globus pallidus interna. The other part degenerates in Parkinson disease. Parkinsonism is characterized by rigidity and tremor and is associated with depression in more than 30 percent of cases.

Finally, lesions in the subthalamic nucleus yield ballistic movements, sudden limb jerks of such velocity that they are compared to projectile movement.

Together, the nuclei of the basal ganglia appear capable of initiating and maintaining the full range of useful movements. Investigators have speculated that the nuclei serve to configure the activity of the overlying motor cortex to fit the purpose of the association areas. Also, they appear to

integrate proprioceptive feedback to maintain an intended movement.

Cerebellum. The cerebellum consists of a simple six-cell pattern of circuitry that is replicated roughly 10 million times. Simultaneous recordings of the cerebral cortex and the cerebellum have shown that the cerebellum is activated several milliseconds before a planned movement. Moreover, the ablation of the cerebellum renders intentional movements coarse and tremulous. These data suggest that the cerebellum carefully modulates the tone of agonistic and antagonistic muscles by predicting the relative contraction needed for smooth motion. This prepared motor plan is used to ensure that precisely the right amount of flexor and extensor stimuli is sent to the muscles. Recent functional imaging data have shown that the cerebellum is active, even during the mere imagination of motor acts when no movements ultimately result from its calculations. The cerebellum harbors two, and possibly more, distinct "homunculi" or cortical representations of the body plan.

Motor Cortex. Penfield's groundbreaking work defined a motor homunculus in the precentral gyrus, Brodmann area 4 (Fig. 33-2), where a somatotopic map of the motor neurons is found. Individual cells within the motor strip cause contraction of single muscles. The brain region immediately anterior to the motor strip is called the *supplementary motor area*, Brodmann area 6. This region contains cells that, when individually stimulated, can trigger more complex movements by influencing a firing sequence of motor strip cells. Recent studies have demonstrated a broad representation of motor movements in the brain.

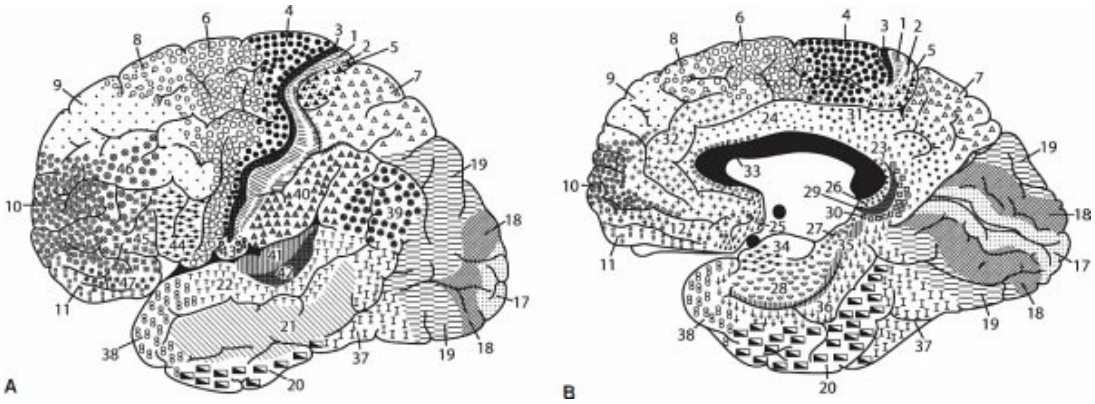

FIGURE 33-2

Drawing of the lateral view (**A**) and medial view (**B**) of the cytoarchitectonic subdivisions of the human brain as determined by Brodmann. (From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2009.)

The skillful use of the hands is called *praxis,* and deficits in skilled movements are termed *apraxias.* The three levels of apraxia are limb-kinetic, ideomotor, and ideational. *Limb-kinetic apraxia* is the inability to use the contralateral hand in the presence of preserved strength; it results from isolated lesions in the supplementary motor area, which contains neurons that stimulate functional sequences of neurons in the motor strip.

Ideomotor apraxia is the inability to perform an isolated motor act on command, despite preserved comprehension, strength, and spontaneous performance of the same act. Ideomotor apraxia simultaneously affects both limbs and involves functions so specialized that they are localized to only one hemisphere. Conditions in two separate areas can produce this apraxia. Disconnection of the language comprehension area, Wernicke area, from the motor regions causes an inability to follow spoken commands, and lesions to the left premotor area may impair the actual motor program as the higher-order motor neurons generate it. This program is transmitted across the corpus callosum to the right premotor area, which directs the movements of the left hand. A lesion in this callosal projection can also cause isolated ideomotor apraxia in the left hand. This syndrome implies the representation of specific motor acts within discrete sections of the left premotor cortex. Thus just as some cells respond selectively to specific environmental features in the higher sensory cortices, some cells in the premotor cortex direct specific complex motor tasks.

Ideational apraxia occurs when the individual components of a sequence of skilled acts can be performed in isolation, but the entire series cannot be organized and executed as a whole. For example, the sequence of opening an envelope, removing the letter, unfolding it, and placing it on the table cannot be performed in order, even though the individual acts can be performed in isolation. The representation of the concept of a motor sequence may involve several areas, specifically the left parietal cortex, but it likely also relies on the sequencing and executive functions of the prefrontal cortex. This apraxia is a typical finding of diffuse cortical degeneration, such as Alzheimer disease.

Autonomic Motor System. The *autonomic system* is divided into a sensory component (described earlier) and a motor component. The *autonomic motor system* is divided into two branches: the sympathetic and the parasympathetic. As a rule, organs are innervated by both types of fibers, which often serve antagonistic roles. The *parasympathetic system* slows the heart rate and begins the process of digestion. In contrast, the *sympathetic system* mediates the fight or flight response, with increased heart rate, shunting of blood away from the viscera, and increased respiration. The sympathetic system is highly activated by sympathomimetic drugs, such as amphetamine and cocaine, and may also be activated by withdrawal from sedating drugs such as alcohol, benzodiazepines, and opioids. Investigators who have found an increased risk of heart attacks in persons with high levels of hostility have suggested that chronic activation of the sympathetic fight or flight response, with the elevated secretion of adrenaline, may underlie this association.

The brain center that drives the autonomic motor system is the *hypothalamus*, which houses a set of paired nuclei that appear to control appetite, rage, temperature, blood pressure, perspiration, and sexual drive. For example, lesions to the ventromedial nucleus, the satiety center, produce a voracious appetite and rage. In contrast, lesions to the upper region of the lateral nucleus, the hunger center, produce a profound loss of appetite. Numerous research groups are making intense efforts to define the biochemical regulation of appetite and obesity and frequently target the role of the hypothalamus.

In the regulation of sexual attraction, the role of the hypothalamus has also become an area of active research. In the 1990s, three groups independently reported neuroanatomical differences between some of the hypothalamic nuclei of straight and gay men. Researchers interpreted this finding to suggest that human sexual orientation has a neuroanatomical basis, and this result has stimulated several follow-up studies of the biologic basis of sexual orientation. At present, however, these controversial findings are not accepted without question (including by some of the original authors), and no clear consensus has emerged about whether the structure of the hypothalamus consistently correlates with sexual orientation. In animal studies, early nurturing and sexual experiences consistently alter the size of specific hypothalamic nuclei.

Primitive Reflex Circuit. Sensory pathways function as extractors of specific features from the overwhelming multitude of environmental stimuli, whereas motor pathways carry out the wishes of the organism. These pathways may be linked directly, for example, in the spinal cord, where a primitive reflex arc may mediate the brisk withdrawal of a limb from a painful stimulus, without immediate conscious awareness. In this loop, the peripheral stimulus activates the sensory nerve, the sensory neuron synapses on and directly activates the motor neuron, and the motor neuron drives the muscle to contract. This response is strictly local and all-or-none. Such primitive reflex arcs, however, rarely generate an organism's behaviors. In most behaviors, sensory systems project to association areas, where sensory information is interpreted in terms of internally determined memories, motivations, and drives. The exhibited behavior results from a plan of action determined by the associated components and carried out by the motor systems.

Localization of Brain Functions. Many theorists have subdivided the brain into functional systems. Brodmann defined 47 areas based on cytoarchitectonic distinctions, a cataloging that has been remarkably durable as the functional anatomy of the brain has been elucidated. Various distinct functions, based on data from lesion studies and functional neuroimaging, have been assigned to nearly all Brodmann areas. At the other extreme, individual experts have distinguished only three processing blocks: The brainstem and the thalamic reticular activating system provide arousal and set up attention; the posterior cortex integrates perceptions and generates language; and, at the highest level, the frontal cortex generates programs and executes plans like an orchestra conductor.

Hemispheric lateralization of function is a crucial feature of higher cortical processing. The primary sensory cortices for touch, vision, hearing, smell, and taste are represented bilaterally, and the first level of abstraction for these modalities is also usually represented bilaterally. The highest levels of feature extraction, however, are generally unified in one brain hemisphere only. For example, recognition of familiar and unfamiliar faces seems localized to the left inferior temporal cortex, and cortical processing of olfaction occurs in the right frontal lobe.

Hypotheses about the flow of thought in the brain are based on few experimental data, although this scarcity of findings has not impeded numerous theoreticians from speculating about functional neuroanatomy. Several roles have been tentatively assigned to specific lobes of the brain, based on the functional deficits resulting from the localized injury. These data indicate that some areas of the cortex may be necessary for a specific function, but they do not define the complete set of structures that suffices for a complicated task. Anecdotal evidence from surface electrocorticography for the study of epilepsy, for example, suggests that a right parietal seizure impulse may shoot immediately to the left frontal lobe and then to the right temporal lobe before spreading locally to the remainder of the parietal lobe. This evidence illustrates the limitations of naively assigning a mental function to a single brain region. Functional neuroimaging studies frequently reveal the simultaneous activation of disparate brain regions during the performance of even a simple cognitive task. Nevertheless, particularly in the processing of vision and language, fairly well-defined lobar syndromes have been confirmed.

Language. The clearest known example of hemispheric lateralization is the localization of language functions to the left hemisphere. Starting with the work of Pierre Broca and Karl Wernicke in the 19th century, researchers have drawn a detailed map of language comprehension and expression.

At least eight types of aphasias in which one or more components of the language pathway are inured have been defined. *Prosody,* the emotional and affective components of language, or "body language," appears to be localized in a mirror set of brain units in the right hemisphere.

Because of the significant role of verbal and written language in human communication, the neuroanatomical basis of language is the most wholly understood association function. Language disorders, also called *aphasias,* are readily diagnosed in routine conversation, whereas perceptual disorders may escape notice, except during detailed neuropsychological testing, although these disorders may be caused by injury of an equal volume of the cortex. Among the earliest models of cortical localization of function were Broca's 1865 description of a loss of fluent speech caused by a lesion in the left inferior frontal lobe and Wernicke's 1874 localization of language comprehension to the left superior temporal lobe. Subsequent analyses of

patients rendered aphasic by strokes, trauma, or tumors have led to the definition of the entire language association pathway from sensory input through the motor output.

Language most demonstrates hemispheric localization of function. In most persons, the hemisphere dominant for language also directs the dominant hand. Ninety percent of the population is right-handed, and 99 percent of right-handers have left hemispheric dominance for language. Of the 10 percent who are left-handers, 67 percent also have left-hemispheric language dominance; the other 33 percent have either mixed or right-hemispheric language dominance. This innate tendency to lateralization of language in the left hemisphere is positively associated with an asymmetry of the planum temporale, a triangular cortical patch on the superior surface of the temporal lobe that appears to harbor Wernicke area. Patients with mixed hemispheric dominance for language lack the expected asymmetry of the planum temporale. That asymmetry has been observed in prenatal brains suggests a genetic determinant. Indeed, the absence of asymmetry runs in families, although both genetic and intrauterine influences probably contribute to the final pattern.

Language comprehension is processed at three levels. First, in *phonologic processing,* individual sounds, such as vowels or consonants, are recognized in the inferior gyrus of the frontal lobes. Phonologic processing improves if lip reading is allowed, if speech is slowed, or if contextual clues are provided. Second, *lexical processing* matches the phonologic input with recognized words or sounds in the individual’s memory. Lexical processing determines whether a sound is a word. Recent evidence has localized lexical processing to the left temporal lobe, where the representations of lexical data are organized according to the semantic category. Third, *semantic processing* connects the words to their meaning. Persons with an isolated defect in semantic processing may retain the ability to repeat words in the absence of an ability to understand or spontaneously generate speech. Semantic processing activates the middle and superior gyri of the left temporal lobe, whereas the representation of the conceptual content of words is widely distributed in the cortex. Language production proceeds in the opposite direction, from the cortical semantic representations through the left temporal lexical nodes to either the oromotor phonologic processing area (for speech) or the graphomotor system (for writing). Each of these areas can be

independently or simultaneously damaged by stroke, trauma, infection, or tumor, resulting in a specific type of aphasia.

The garbled word salad or illogic utterances of an aphasic patient leave little uncertainty about the diagnosis of left-sided cortical injury, but the right hemisphere contributes a somewhat more subtle, but equally important, affective quality to language. For example, the phrase “I feel good” may be spoken with an infinite variety of shadings, each of which is understood differently. The perception of prosody and the appreciation of the associated gestures, or “body language,” appear to require an intact right hemisphere. Behavioral neurologists have mapped an entire pathway for prosody association in the right hemisphere that mirrors the language pathway of the left hemisphere. Patients with right hemisphere lesions, who have impaired comprehension or expression of prosody, may find it difficult to function in society despite their intact language skills.

Developmental dyslexia is defined as an unexpected difficulty with learning in the context of adequate intelligence, motivation, and education. Whereas speech consists of the logical combination of 44 basic phonemes of sounds, reading requires a broader set of brain functions and, thus, is more susceptible to disruption. The awareness of specific phonemes develops at about the ages of 4 to 6 years. It appears to be a prerequisite to the acquisition of reading skills. The inability to recognize distinct phonemes is the best predictor of a reading disability. Functional neuroimaging studies have localized the identification of letters to the occipital lobe adjacent to the primary visual cortex. Phonologic processing occurs in the inferior frontal lobe, and semantic processing requires the superior and middle gyri of the left temporal lobe. A recent finding of uncertain significance is that phonologic processing in men activates only the left inferior frontal gyrus, whereas phonologic processing in women activates the inferior frontal gyrus bilaterally. Careful analysis of an individual’s particular reading deficits can guide remedial tutoring efforts that can focus on weaknesses and thus attempt to bring the reading skills up to the general level of intelligence and verbal skills.

In children, developmental nonverbal learning disorder is postulated to result from right hemisphere dysfunction. A nonverbal learning disorder is characterized by poor fine-motor control in the left hand, deficits in the visuoperceptual organization, problems with mathematics, and incomplete or

disturbed socialization.

Patients with nonfluent aphasia, who cannot complete a simple sentence, may be able to sing an entire song, apparently because many aspects of music production are localized to the right hemisphere. Music is represented predominantly in the right hemisphere, but the full complexity of musical ability seems to involve both hemispheres. Trained musicians appear to transfer many musical skills from the right hemisphere to the left as they gain proficiency in musical analysis and performance.

Arousal and Attention. Arousal, or the establishment and maintenance of an awake state, appears to require at least three brain regions. Within the brainstem, the ascending reticular activating system (ARAS), a diffuse set of neurons, appears to set the level of consciousness. The ARAS projects to the intralaminar nuclei of the thalamus, and these nuclei, in turn, project widely throughout the cortex. Electrophysiologic studies show that both the thalamus and the cortex fire rhythmical bursts of neuronal activity at rates of 20 to 40 cycles per second. During sleep, these bursts are not synchronized. During wakefulness, the ARAS stimulates the thalamic intralaminar nuclei, which in turn coordinate the oscillations of different cortical regions. The greater the synchronization, the higher the level of wakefulness. The absence of arousal produces stupor and coma. In general, small discrete lesions of the ARAS can produce a stuporous state, whereas, at the hemispheric level, large bilateral lesions are required to cause the same depression in alertness. One particularly unfortunate but instructive condition involving extensive, permanent, bilateral cortical dysfunction is the persistent vegetative state. Sleep–wake cycles may be preserved, and the eyes may appear to gaze, but the external world does not register, and no evidence of conscious thought exists. This condition represents the expression of the isolated actions of the ARAS and the thalamus.

The maintenance of attention appears to require an intact right frontal lobe. For example, a widely used test of persistence requires scanning and identifying only the letter A from a long list of random letters. Healthy persons can usually maintain the performance of such a task for several minutes, but in patients with right frontal lobe dysfunction, this capacity is severely curtailed. Lesions of similar size in other regions of the cortex usually do not affect persistence tasks. In contrast, the more generally

adaptive skill of maintaining a coherent line of thought is diffusely distributed throughout the cortex. Many medical conditions can affect this skill and may produce acute confusion or delirium.

One widely diagnosed disorder of attention is attention-deficit/hyperactivity disorder (ADHD). No pathologic findings have been consistently associated with this disorder. Functional neuroimaging studies, however, have variously documented either frontal lobe or right hemisphere hypometabolism in patients with ADHD, compared with normal controls. These findings strengthen the notion that the frontal lobes—especially the right frontal lobe—are essential to the maintenance of attention.

Memory. The clinical assessment of memory should test three periods, which have distinct anatomical correlates. *Immediate memory* functions over seconds; *recent memory* applies on a scale of minutes to days, and *remote memory* encompasses months to years. Immediate memory is implicit in the concept of attention and the ability to follow a train of thought. This ability has been divided into phonologic and visuospatial components, and functional imaging has localized them to the left and right hemispheres, respectively. A related concept, incorporating immediate and recent memory, is *working memory,* which is the ability to store information for several seconds, whereas other, related cognitive operations take place on this information. Recent studies have shown that single neurons in the dorsolateral prefrontal cortex not only record features necessary for working memory but also record the certainty with which the information is known and the degree of expectation assigned to the permanence of a particular environmental feature. Some neurons fire rapidly for an item that is eagerly awaited but may cease firing if hopes are dashed unexpectedly. The encoding of the emotional value of an item contained in the working memory may be of great usefulness in determining goal-directed behavior. Some researchers localize working memory predominantly to the left frontal cortex. Clinically, however, bilateral prefrontal cortex lesions are required for severe impairment of working memory. Other types of memory have been described: episodic, semantic, and procedural.

Three brain structures are critical to the formation of memories: the medial temporal lobe, specific diencephalic nuclei, and the basal forebrain. The *medial temporal lobe* houses the *hippocampus,* an elongated, highly

repetitive network. The *amygdala* is adjacent to the anterior end of the hippocampus. The amygdala has been suggested to rate the emotional importance of experience and to activate the level of hippocampal activity accordingly. Thus an emotionally intense experience is indelibly etched in memory, but neutral stimuli are quickly disregarded.

Animal studies have defined a hippocampal place code, a pattern of cellular activation in the hippocampus that corresponds to the animal's location in space. When the animal is introduced to a novel environment, the hippocampus is broadly activated. As the animal explores and roams, the firing of certain hippocampal regions begins to correspond to specific locations in the environment. In about 1 hour, a highly detailed internal representation of the external space (a "cognitive map") appears in the form of specific firing patterns of the hippocampal cells. These patterns of neuronal firing may bear little spatial resemblance to the environment they represent; instead, they may seem randomly arranged in the hippocampus. If the animal is manually placed in a particular part of a familiar space, only the corresponding hippocampal regions show intense neural activity. When recording continues into sleep periods, firing sequences of hippocampal cells outlining a coherent path of navigation through the environment are registered, even though the animal is motionless. If the animal is removed from the environment for several days and then returned, the previously registered hippocampal place code is immediately reactivated. A series of animal experiments have dissociated the formation of the hippocampal place code from either visual, auditory, or olfactory cues, although each of these modalities may contribute to place code generation. Other factors may include internal calculations of distances based on counting footsteps or other proprioceptive information. Data from targeted genetic mutations in mice have implicated both the *N*-methyl-D-aspartate (NMDA) glutamate receptors and the calcium-calmodulin kinase II (CaMKII) in the proper formation of hippocampal place fields. These data suggest that the hippocampus is a significant site for the formation and storage of immediate and recent memories. Although no data yet support the notion, it is conceivable that the hippocampal cognitive map is inappropriately reactivated during a *déjà vu* experience.

The most famous human subject in the study of memory is H. M., a man with intractable epilepsy, who had both his hippocampi and amygdalae surgically removed to alleviate his condition. The epilepsy was controlled, but he was left with a complete inability to form and recall memories of facts. H. M.’s learning and memory skills were relatively preserved, which led to the suggestion that declarative or factual memory may be separate within the brain from procedural or skill-related memory. A complementary deficit in procedural memory with preservation of declarative memory may be seen in persons with Parkinson disease, in whom dopaminergic neurons of the nigrostriatal tract degenerate. Because this deficit in procedural memory can be ameliorated with treatment with levodopa, which is thought to potentiate dopaminergic neurotransmission in the nigrostriatal pathway, a role has been postulated for dopamine in procedural memory. Additional case reports have further implicated the amygdala and the afferent and efferent fiber tracts of the hippocampus as essential to the formation of memories. Also, lesional studies have suggested mild lateralization of hippocampal function in which the left hippocampus is more efficient at forming verbal memories, and the right hippocampus tends to form nonverbal memories. After unilateral lesions in humans, however, the remaining hippocampus may compensate to a large extent. Medical causes of amnesia include alcoholism, seizures, migraine, drugs, vitamin deficiencies, trauma, strokes, tumors, infections, and degenerative diseases.

The motor system within the cortex receives directives from the association areas. The performance of a novel act requires constant feedback from the sensory and association areas for completion, and functional neuroimaging studies have demonstrated widespread activation of the cortex during unskilled acts. Memorized motor acts initially require activation of the medial temporal lobe. With practice, however, the performance of ever-larger segments of an act necessary to achieve a goal become encoded within discrete areas of the premotor and parietal cortices, particularly the left parietal cortex, with the result that a much more limited activation of the

cortex is seen during highly skilled acts, and the medial temporal lobe is bypassed. This process is called the *corticalization of motor commands.* In lay terms, the process suggests a neuroanatomical basis for the adage "practice makes perfect."

Within the diencephalon, the dorsal medial nucleus of the thalamus and the mammillary bodies appear necessary for memory formation. These two structures are damaged in thiamine deficiency states usually seen in chronic alcoholics, and their inactivation is associated with Korsakoff syndrome. This syndrome is characterized by severe inability to form new memories and a variable inability to recall remote memories.

Alzheimer disease is the most common clinical memory disorder. Alzheimer disease is characterized pathologically by the degeneration of neurons and their replacement by senile plaques and neurofibrillary tangles. Clinicopathologic studies have suggested that cognitive decline is best correlated with the loss of synapses. Initially, the parietal and temporal lobes are affected, with relative sparing of the frontal lobes. This pattern of degeneration correlates with the early loss of memory, which is mostly a temporal lobe function. Also, syntactical language comprehension and visuospatial organization, functions that rely heavily on the parietal lobe, are impaired early in the course of Alzheimer disease.

In contrast, personality changes, which reflect frontal lobe function, are relatively late consequences of Alzheimer disease. A rarer, complementary cortical degeneration syndrome, Pick disease, first affects the frontal lobes while sparing the temporal and parietal lobes. In Pick disease, disinhibition and impaired language expression, which are signs of frontal dysfunction, appear early, with relatively preserved language comprehension and memory.

Memory loss can also result from disorders of the subcortical gray matter structures, specifically the basal ganglia and the brainstem nuclei, from the disease of the white matter, or from disorders that affect both gray and white matter.

Emotion. Individual emotional experiences occupy the attention of all mental health professionals. Emotion derives from basic drives, such as feeding, sex, reproduction, pleasure, pain, fear, and aggression, which all animals share. The neuroanatomical basis for these drives appears to be centered in the limbic system. Distinctly human emotions, such as affection,

pride, guilt, pity, envy, and resentment, are primarily learned and most likely are represented in the cortex. The regulation of drives appears to require an intact frontal cortex. The complex interplay of the emotions, however, is far beyond the understanding of functional neuroanatomists. Where, for example, are the representations of the id, the ego, and the superego? Through what pathway are ethical and moral judgments shepherded? What processes allow beauty to be in the eye of the beholder? These philosophical questions represent a real frontier of human discovery.

Several studies have suggested that within the cortex exists a hemispheric dichotomy of emotional representation. The left hemisphere houses the analytical mind but may have a limited emotional repertoire. For example, lesions to the right hemisphere, which cause profound functional deficits, may be noted with indifference by the intact left hemisphere. The denial of illness and of the inability to move the left hand in cases of right hemisphere injury is called *anosognosia.* In contrast, left hemisphere lesions, which cause profound aphasia, can trigger a catastrophic depression, as the intact right hemisphere struggles with the realization of the loss. The right hemisphere also appears dominant for affect, socialization, and body image.

Damage to the left hemisphere produces intellectual disorder and loss of the narrative aspect of dreams. Damage to the right hemisphere produces affective disorders, loss of the visual aspects of dreams, and a failure to respond to humor, shadings of metaphor, and connotations. In dichotic vision experiments, two scenes of varied emotional content were displayed simultaneously to each half of the visual field and were perceived separately by each hemisphere. A more intense emotional response attended the scenes displayed to the left visual field that was processed by the right hemisphere. Moreover, hemisensory changes representing conversion disorders have been repeatedly noted to involve the left half of the body more often than the right, an observation that suggests an origin in the right hemisphere.

Within the hemispheres, the temporal and frontal lobes play a prominent role in emotion. The temporal lobe exhibits a high frequency of epileptic foci, and temporal lobe epilepsy (TLE) presents an exciting model for the role of the temporal lobe in behavior. In studies of epilepsy, abnormal brain activation is analyzed, rather than the deficits in activity analyzed in classic lesional studies. TLE is of particular interest in psychiatry because patients with temporal lobe seizures often manifest bizarre behavior without the

classic grand mal shaking movements caused by seizures in the motor cortex. A proposed TLE personality is characterized by hyposexuality, emotional intensity, and a perseverative approach to interactions termed *viscosity.* Patients with left TLE may generate references to personal destiny and philosophical themes and display a humorless approach to life. In contrast, patients with right TLE may display excessive emotionality, ranging from elation to sadness. Although patients with TLE may display excessive aggression between seizures, the seizure itself may evoke fear.

The inverse of a TLE personality appears in persons with bilateral injury to the temporal lobes after head trauma, cardiac arrest, herpes simplex encephalitis, or Pick disease. This lesion resembles the one described in the Klüver–Bucy syndrome, an experimental model of temporal lobe ablation in monkeys. Behavior in this syndrome is characterized by hypersexuality, placidity, a tendency to explore the environment with the mouth, inability to recognize the emotional significance of visual stimuli, and continually shifting attention, called *hypermetamorphosis.* In contrast to the aggression-fear spectrum sometimes seen in patients with TLE, complete experimental ablation of the temporal lobes appears to produce a uniform, bland reaction to the environment, possibly because of an inability to access memories.

The prefrontal cortices influence mood in a complementary way. Whereas activation of the left prefrontal cortex appears to lift the mood, activation of the right prefrontal cortex causes depression. A lesion to the left prefrontal area, at either the cortical or the subcortical level, abolishes the typical mood-elevating influences and produces depression and uncontrollable crying. In contrast, a comparable lesion to the right prefrontal area may produce laughter, euphoria, and *witzelsucht,* a tendency to joke and make puns. Effects opposite to those caused by lesions appear during seizures, in which occurs abnormal, excessive activation of either prefrontal cortex. A seizure focus within the left prefrontal cortex can cause gelastic seizures, for example, in which the ictal event is laughter. Functional neuroimaging has documented left prefrontal hypoperfusion during depressive states, which normalized after the depression was treated successfully.

Limbic System Function. James Papez delineated the limbic system in 1937. The Papez circuit consists of the hippocampus, the fornix, the mammillary bodies, the anterior nucleus of the thalamus, and the cingulate

gyrus (Fig. 33-3). The boundaries of the limbic system were subsequently expanded to include the amygdala, septum, basal forebrain, nucleus accumbens, and orbitofrontal cortex.

Although this schema creates an anatomical loop for emotional processing, the specific contributions of the individual components other than the hippocampus or even whether a given train of neural impulses travels along the entire pathway is unknown.

The amygdala appears to be a critically important gate through which internal and external stimuli are integrated. Information from the primary senses is interwoven with internal drives, such as hunger and thirst, to assign emotional significance to sensory experiences. The amygdala may mediate learned fear responses, such as anxiety and panic, and may direct the expression of certain emotions by producing a particular affect. Neuroanatomical data suggest that the amygdala exerts a more powerful influence on the cortex, to stimulate or suppress cortical activity than the cortex exerts on the amygdala. Pathways from the sensory thalamic relay stations separately send sensory data to the amygdala and the cortex, but the subsequent effect of the amygdala on the cortex is the more potent of the two reciprocal connections.

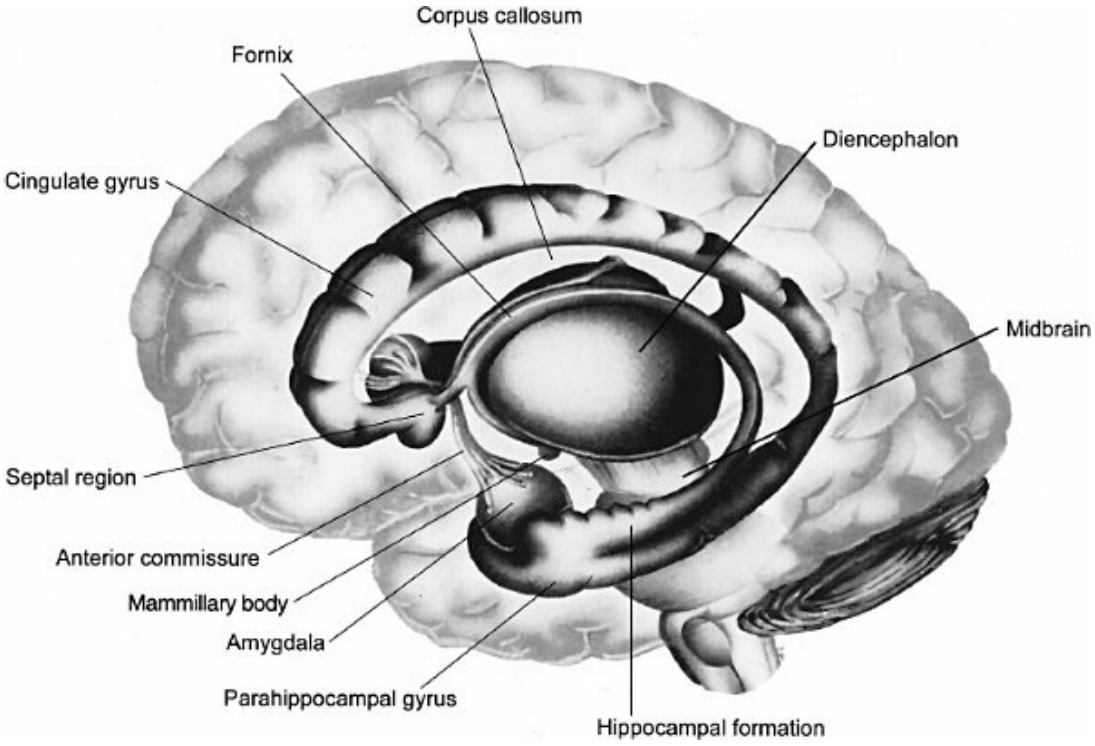

FIGURE 33-3
Schematic drawing of the major anatomic structures of the limbic system. The cingulate and parahippocampal gyri form the "limbic lobe," a rim of tissue located along the junction of the diencephalon and the cerebral hemispheres. (Adapted from Hendelman WJ. *Student's Atlas of Neuroanatomy*. Philadelphia, PA: WB Saunders; 1994:179.)

In contrast, damage to the amygdala has been reported to ablate the ability to distinguish fear and anger in other persons' voices and facial expressions. Persons with such injuries may have a preserved ability to recognize happiness, sadness, or disgust. The limbic system appears to house the emotional association areas, which direct the hypothalamus to express the motor and endocrine components of the emotional state.

Fear and Aggression. The electrical stimulation of animals throughout the subcortical area involving the limbic system produces rage reactions (e.g., growling, spitting, and arching of the back). Whether the animal flees or attacks depends on the intensity of the stimulation.

Limbic System and Schizophrenia. The limbic system has been particularly implicated in neuropathologic studies of schizophrenia. Eugen Bleuler's well-known four A's of schizophrenia—affect, associations, ambivalence, and autism—refer to brain functions served in part by limbic structures. Several clinicopathologic studies have found a reduction in the brain weight of the gray matter but not of the white matter in persons with schizophrenia. In pathologic as well as in magnetic resonance imaging (MRI) reports, persons with schizophrenia may have reduced the volume of the hippocampus, amygdala, and parahippocampal gyrus. Schizophrenia may be a late sequela of a temporal epileptic focus, with some studies reporting an association in 7 percent of patients with TLE.

Functional neuroimaging studies have demonstrated decreased activation of the frontal lobes in many patients with schizophrenia, particularly during tasks requiring willed action. A reciprocal increase in activation of the temporal lobe can occur during willed actions, such as finger movements or speaking, in persons with schizophrenia. Neuropathologic studies have shown a decreased density of neuropil, the intertwined axons, and dendrites of the neurons in the frontal lobes of these patients. During development, the density of neuropil is highest around age 1 year and then is reduced

somewhat through synaptic pruning; the density plateaus throughout childhood and is further reduced to adult levels in adolescence. One hypothesis of the appearance of schizophrenia in the late teenage years is that excessive adolescent synaptic pruning occurs and results in too little frontolimbic activity. Some experts have suggested that hypometabolism and paucity of interneuronal connections in the prefrontal cortex may reflect inefficiencies in working memory, which permits the disjointed discourse and loosening of associations that characterize schizophrenia. At present, the molecular basis for the regulation of the density of synapses within the neuropil is unknown. Other lines of investigation aimed at understanding the biologic basis of schizophrenia have documented inefficiencies in the formation of cortical synaptic connections in the middle of the second trimester of gestation, which may result from a viral infection or malnutrition. Neurodevelopmental surveys administered during childhood found an increased incidence of subtle neurologic abnormalities before the appearance of the thought disorder in persons who subsequently exhibited signs of schizophrenia.

In one intriguing study, positron emission tomography (PET) scanning was used to identify the brain regions that are activated when a person hears spoken language. A consistent set of cortical and subcortical structures demonstrated increased metabolism when speech was processed. The researchers then studied a group of patients with schizophrenia who were experiencing active auditory hallucinations. They found that the same brain areas that were activated when actual sounds were playing were activated while the patients were hallucinating. This included the primary auditory cortex. At the same time, decreased activation was seen of areas thought to monitor speech, including the left middle temporal gyrus and the supplementary motor area. This study raises the questions of what brain structure is activating the hallucinations, and by what mechanism do neuroleptic drugs suppress the hallucinations. Functional imaging has much to tell about the neuroanatomical basis of schizophrenia.

Frontal Lobe Function. The *frontal lobes,* the region that determines how the brain acts on its knowledge, constitute a category unto themselves. In comparative neuroanatomical studies, the massive size of the frontal lobes is the main feature that distinguishes the human brain from that of other

primates, and that lends it uniquely human qualities. There are four subdivisions of the frontal lobes. The first three—the motor strip, the supplemental motor area, and Broca area—are mentioned in the preceding discussion of the motor system and language. The fourth, most anterior, division is the prefrontal cortex. The prefrontal cortex contains three regions in which lesions produce distinct syndromes: the *orbitofrontal,* the *dorsolateral,* and the *medial.* Dye-tracing studies have defined dense reciprocal connections between the prefrontal cortex and all other brain regions. Therefore, to the extent that anatomy can predict function, the prefrontal cortex is ideally connected to allow sequential use of the entire palette of brain functions in executing the goal-directed activity. Indeed, frontal lobe injury usually impairs the executive functions: motivation, attention, and sequencing of actions.

Bilateral lesions of the frontal lobes are characterized by changes in personality—how persons interact with the world. The *frontal lobe syndrome,* which is most commonly produced by trauma, infarcts, tumors, lobotomy, multiple sclerosis, or Pick disease, consists of slow thinking, poor judgment, decreased curiosity, social withdrawal, and irritability. Patients typically display apathetic indifference to experience that can explode into impulsive disinhibition. Unilateral frontal lobe lesions may be mostly unnoticed because the intact lobe can compensate with high efficiency.

Frontal lobe dysfunction may be challenging to detect using highly structured, formal neuropsychological tests. Intelligence, as reflected in the intelligence quotient (IQ), may be average, and functional neuroimaging studies have shown that the IQ seems to require mostly parietal lobe activation. For example, during the administration of the Wechsler Adult Intelligence Scale-Revised (WAIS-R), the highest levels of increased metabolic activity during verbal tasks occurred in the left parietal lobe, whereas the highest levels of increased metabolic activity during performance skills occurred in the right parietal lobe. In contrast, frontal lobe pathology may become apparent only under unstructured, stressful, real-life situations.

A famous case illustrating the result of frontal lobe damage involves Phineas Gage, a 25-year-old railroad worker. While he was working with explosives, an accident drove an iron rod through Gage’s head. He

survived, but both frontal lobes were severely damaged. After the accident, his behavior changed dramatically. The case was written up by J. M. Harlow, M.D., in 1868, as follows: [George] is fitful, irreverent, indulging at times in the grossest profanity (which was not previously his custom), manifesting but little deference for his fellows, impatient of restraint or advice when it conflicts with his desires … His mind was radically changed, so decidedly that his friends and acquaintances said he was “no longer Gage” (see Fig. 33-4).

In one study of right-handed males, lesions of the right prefrontal cortex eliminated the tendency to use internal, associative memory cues and led to an extreme tendency to interpret the task at hand in terms of its immediate context. In contrast, right-handed males who had lesions of the left prefrontal cortex produced no context-dependent interpretations and interpreted the tasks entirely in terms of their internal drives. A mirror image of the functional lateralization appeared in left-handed subjects. This test thus revealed the most precise known association of higher cortical functional lateralization with the subjects’ dominant hand. Future experiments in this vein will attempt to reproduce these findings with functional neuroimaging. If corroborated, these studies suggest a remarkable complexity of functional localization within the prefrontal cortex and may also have implications for the understanding of psychiatric diseases in which prefrontal pathology has been postulated, such as schizophrenia and mood disorders.

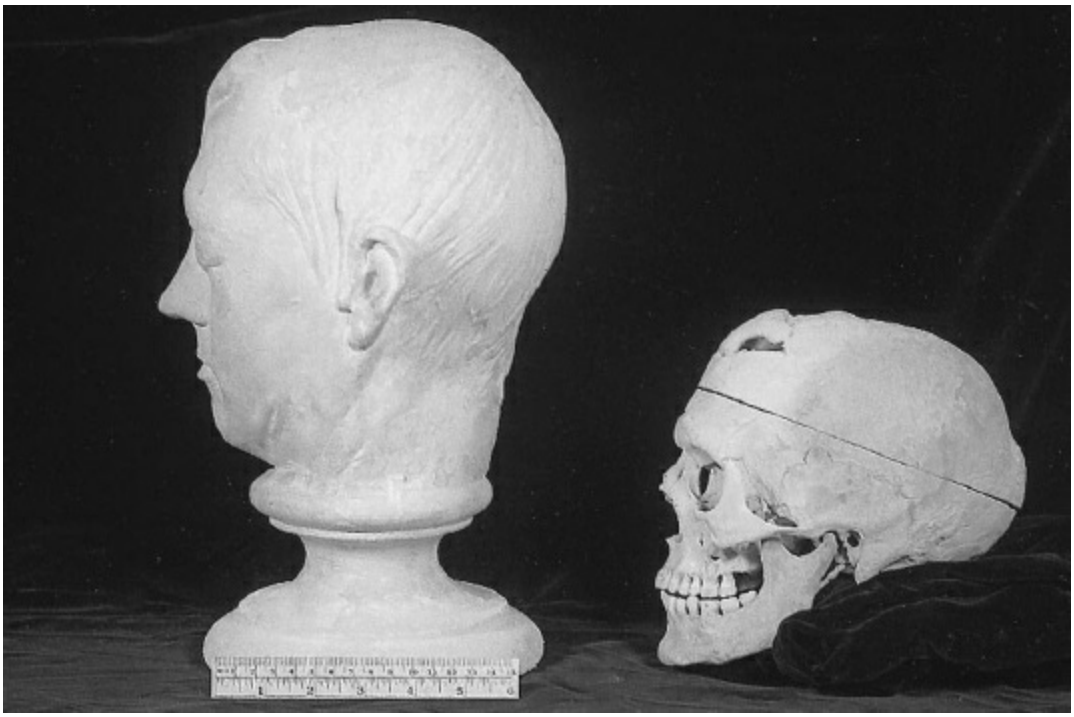

FIGURE 33-4
The life mask and skull of Phineas Gage. Note damage to the frontal region. “A famous case illustrating the result of frontal lobe damage involves Phineas Gage, a 25-year-old railroad worker. While he was working with explosives, an accident drove an iron rod through Gage’s head. He survived, but both frontal lobes were severely damaged. After the accident, his behavior changed dramatically. The case was written up by J.M. Harlow, M.D., in 1868, as follows: [Gage] is fitful, irreverent, indulging at times in the grossest profanity (which was not previously his custom), manifesting but little deference for his fellows, impatient of restraint or advice when it conflicts his desires…His mind was radically changed, so decidedly that his friends and acquaintances said he was ‘no longer Gage’.” (Courtesy of Anthony A. Walsh, Ph.D.)

The massive innervation of the frontal lobes by dopamine-containing nerve fibers is of interest because of the action of antipsychotic medications. At the clinical level, antipsychotic medications may help to organize the rambling associations of a patient with schizophrenia. At the neurochemical level, most typical antipsychotic medications block the actions of dopamine at the D_2 receptors. The frontal lobes, therefore, may be a significant therapeutic site of action for antipsychotic medications.

Development

The nervous system is divided into central and peripheral nervous systems (CNS and PNS). The CNS consists of the brain and spinal cord; the PNS

refers to all the sensory, motor, and autonomic fibers and ganglia outside the CNS. During development, both divisions arise from the neural tube. The neural tube forms through the folding of the neural plate, a specialization of the ectoderm (the outermost of the three embryonic layers). During embryonic development, the neural tube itself becomes the CNS; the ectoderm immediately superficial to the neural tube becomes the neural crest, which gives rise to the PNS. The formation of these structures requires chemical communication between the neighboring tissues in the form of cell surface molecules and diffusible chemical signals.

In many cases, an earlier-formed structure, such as the notochord, is said to *induce* the surrounding ectoderm to form a later structure, in this case, the neural plate. The identification of the chemical mediators of tissue induction is an active area of research. Investigators have begun to examine whether failures of the interactions of these mediators and their receptors could underlie errors in brain development that cause psychopathology.

Neuronal Migration and Connections. The life cycle of a neuron consists of a cell birth, migration to the adult position, extension of an axon, elaboration of dendrites, synaptogenesis, and, finally, the onset of chemical neurotransmission. Individual neurons are born in proliferative zones, generally located along the inner surface of the neural tube. At the peak of neuronal proliferation in the middle of the second trimester, 250,000 neurons are born each minute. Postmitotic neurons migrate outward to their adult locations in the cortex, guided by radially oriented astrocytic glial fibers. Glia-guided neuronal migration in the cerebral cortex occupies much of the first 6 months of gestation. For some neurons in the prefrontal cortex, migration occurs over a distance 5,000 times the diameter of the neuronal cell body. Neuronal migration requires a complex set of cell-cell interactions and is susceptible to errors in which neurons fail to reach the cortex and instead reside in ectopic positions. A group of such incorrectly placed neurons is called a *heterotopia.* Neuronal heterotopias have been shown to cause epilepsy and are positively associated with mental retardation. In a neuropathologic study of the planum temporale of four consecutive patients with dyslexia, heterotopias were a common finding. Recently, heterotopic neurons within the frontal lobe have been postulated to play a causal role in some cases of schizophrenia.

Many neurons lay down an axon as they migrate, whereas others do not initiate axon outgrowth until they have reached their cortical targets. Thalamic axons that project to the cortex initially synapse on a transient layer of neurons called the *subplate neurons.* In normal development, the axons subsequently detach from the subplate neurons and proceed superficially to synapse on the actual cortical cells. The subplate neurons then degenerate. Some brains from persons with schizophrenia reveal an abnormal persistence of subplate neurons, suggesting a failure to complete axonal pathfinding in the brains of these persons. This finding does not correlate with the presence of schizophrenia in every case, however. A characteristic branched dendritic tree elaborates once the neuron has completed migration. Synaptogenesis occurs at a furious rate from the second trimester through the first 10 years or so of life. The peak of synaptogenesis occurs within the first 2 postnatal years when as many as 30 million synapses form each second. Ensheathment of axons by myelin begins prenatally; it is mostly complete in early childhood but does not reach its full extent until late in the third decade of life. Myelination of the brain is also sequential.

Neuroscientists are tremendously interested in the effect of experience on the formation of brain circuitry in the first years of life. As noted earlier, many examples are seen of the impact of early sensory experience on the wiring of cortical sensory processing areas. Similarly, early movement patterns are known to reinforce neural connections in the supplemental motor area that drive specific motor acts. Neurons rapidly form a fivefold excess of synaptic connections; then, through a Darwinian process of elimination, only those synapses that serve a relevant function persist. This synaptic pruning appears to preserve input in which the presynaptic cell fires in synchrony with the postsynaptic cell, a process that reinforces repeatedly activated neural circuits. One molecular component that is thought to mediate synaptic reinforcement is the postsynaptic NMDA glutamate receptor. This receptor allows the influx of calcium ions only when activated by glutamate at the same time as the membrane in which it sits is depolarized. Thus, glutamate binding without membrane depolarization or membrane depolarization without glutamate binding fails to trigger calcium influx. NMDA receptors open in dendrites that are exposed to repeated activation, and their activation stimulates the stabilization of the synapse. Calcium is a crucial intracellular messenger that initiates a cascade of events, including gene regulation and the

release of trophic factors that strengthen particular synaptic connections. Although less experimental evidence exists for the role of experience in modulating synaptic connectivity of association areas than has been demonstrated in sensory and motor areas, neuroscientists assume that similar activity-dependent mechanisms may apply in all areas of the brain.

Adult Neurogenesis. A remarkable recent discovery has been that new neurons can be generated in specific brain regions (notably the dentate gyrus of the hippocampus) in adult animals, including humans. This discovery is in marked contrast to the previous belief that no neurons were produced after birth in most species. This discovery has a potentially profound impact on our understanding of normal development, incorporation of experiences, as well as the ability of the brain to repair itself after various types of injuries.

Neurologic Basis of Development Theories. In the realm of emotion, early childhood experiences have been suspected to be at the root of psychopathology since the earliest theories of Sigmund Freud. Freud's psychoanalytic method aimed at tracing the threads of a patient's earliest childhood memories. Franz Alexander added the goal of allowing the patient to relive these memories in a less pathologic environment, a process known as a *corrective emotional experience.* Although neuroscientists have no data demonstrating that this method operates at the level of neurons and circuits, emerging results reveal a profound effect of early caregivers on an adult individual's emotional repertoire. For example, the concept of attunement is defined as the process by which caregivers "playback a child's inner feelings." If a baby's emotional expressions are reciprocated consistently and sensitively, specific emotional circuits are reinforced. These circuits likely include the limbic system, in particular, the amygdala, which serves as a gate to the hippocampal memory circuits for emotional stimuli. In one anecdote, for example, a baby whose mother repeatedly failed to mirror her level of excitement emerged from childhood a too passive girl, who was unable to experience a thrill or a feeling of joy.

The relative contributions of nature and nurture are perhaps nowhere more indistinct than in the maturation of emotional responses, partly because the localization of emotion within the adult brain is only poorly understood. It is reasonable to assume, however, that the reactions of caregivers during a

child's first 2 years of life are eventually internalized as distinct neural circuits, which may be only incompletely subject to modification through subsequent experience. For example, axonal connections between the prefrontal cortex and the limbic system, which probably play a role in modulating basic drives, are established between the ages of 10 and 18 months. Recent work suggests that a pattern of terrifying experiences in infancy may flood the amygdala and drive memory circuits to be specifically alert to threatening stimuli, at the expense of circuits for language and other academic skills. Thus infants raised in a chaotic and frightening home may be neurologically disadvantaged for the acquisition of complex cognitive skills in school.

An adult correlate to this cascade of detrimental overactivity of the fear response is found in posttraumatic stress disorder (PTSD), in which persons exposed to an intense trauma involving death or injury may have feelings of fear and helplessness for years after the event. A PET scanning study of patients with PTSD revealed abnormally high activity in the right amygdala while the patients were reliving their traumatic memories. The researchers hypothesized that the stressful hormonal milieu present during the registration of the memories might have served to burn the memories into the brain and to prevent their erasure by the usual memory modulation circuits. As a result, the traumatic memories exerted a pervasive influence and led to a state of constant vigilance, even in safe, familiar settings.

Workers in the related realms of mathematics have produced results documenting the organizing effects of early experiences on internal representations of the external world. Since the time of Pythagoras, music has been considered a branch of mathematics. A series of studies have shown that groups of children who were given 8 months of intensive classical music lessons during preschool years later had significantly better spatial and mathematical reasoning in school than a control group. Nonmusical tasks, such as navigating mazes, drawing geometric figures, and copying patterns of two-color blocks, were performed significantly more skillfully by the musical children. Early exposure to music, thus, may be ideal preparation for later acquisition of complex mathematical and engineering skills.

These tantalizing observations suggest a neurologic basis for the developmental theories of Jean Piaget, Erik Erikson, Margaret Mahler, John Bowlby, Sigmund Freud, and others. Erikson's epigenetic theory states that

normal adult behavior results from the successful, sequential completion of each of several infantile and childhood stages. According to the epigenetic model, failure to complete an early stage is reflected in subsequent physical, cognitive, social, or emotional maladjustment. By analogy, the experimental data just discussed suggest that early experience, particularly during the critical window of opportunity for establishing neural connections, primes the necessary circuitry for language, emotions, and other advanced behaviors. Miswiring of an infant's brain may lead to severe handicaps later when the person attempts to relate to the world as an adult. These findings support the vital need for adequate public financing of Early Intervention and Head Start programs, programs that may be the most cost-effective means of improving persons' mental health.

NEURAL DEVELOPMENT AND NEUROGENESIS

The human brain is a structurally and functionally complex system that exhibits ongoing modification in response to both experience and disease. The anatomical and neurochemical systems that underlie the cognitive, social, emotional and sensorimotor functions of the mature nervous system emerge from neuronal and glial cell populations that arise during the earliest periods of development.

An understanding of molecular and cellular mechanisms mediating nervous system development is critical in psychiatry because abnormalities of developmental processes contribute to many brain disorders. Although a developmental basis may not be surprising in early childhood disorders, such as autism, fragile X mental retardation, and Rett syndrome, even mature diseases, including schizophrenia and depression, reflect ontogenetic factors. For example, evidence from brain pathology and neuroimaging indicates that there are reductions in forebrain region volumes, neuron and glial cell numbers, and some classes of interneurons in schizophrenia that are apparent at the time of diagnosis. Similarly, in autism, early brain growth is abnormally increased, and abnormalities of the cellular organization are observed that reflect disturbances in the fundamental processes of cell proliferation and migration. When there is abnormal regulation of early brain development, a foundation of altered neuron populations that may differ in cell types, numbers, and positions is laid down. They may also develop

abnormal connections, which also have consequences for interacting glial populations. With progressive postnatal development, the maturing brain systems call upon component neurons to achieve increasing levels of complex information processing, which may be deficient should initial conditions be disturbed. New neural properties emerge during maturation as neuron populations elaborate additional functional networks based on and modified by ongoing experience. Given the brain's dynamic character, we may expect that developmental abnormalities in neural populations and systems, caused by genetic as well as environmental factors, will manifest at diverse times in a person's life.

Overview of Nervous System Morphologic Development

In considering brain development, several overarching principles need to be considered. First, different brain regions and neuron populations are generated at distinct times of development and exhibit specific temporal schedules. This pattern has implications for the consequences of specific developmental insults, such as the production of autism following fetal exposure to the drug thalidomide only during days 20 to 24 of gestation. Second, the sequence of cellular processes comprising ontogeny predicts that abnormalities in early events necessarily lead to differences in subsequent stages, although not all abnormalities may be accessible to our clinical tools. For example, a deficit in the number of neurons will likely lead to reductions in axonal processes and ensheathing white matter in the mature brain. However, at the clinical level, since glial cells outnumber neurons 8 to 1, the glial cell population, the oligodendrocytes, and their myelin appear as an altered white matter on neuroimaging with little evidence of a neuronal disturbance. Third, it is clear that specific molecular signals, such as extracellular growth factors and cognate receptors or transcription factors, play roles at multiple developmental stages of the cell. For example, both insulin-like growth factor I (IGF-I) and brain-derived neurotrophic factor (BDNF) regulate multiple cellular processes during the developmental generation and mature function of neurons, including cell proliferation, survival promotion, neuron migration, process outgrowth, and the momentary synaptic modifications (plasticity) underlying learning and memory. Thus changes in expression or regulation of a ligand or its receptor, by experience,

environmental insults, or genetic mechanisms, will have effects on multiple developmental and mature processes.

The Neural Plate and Neurulation. The nervous system of the human embryo first appears between 2½ and 4 weeks of gestation. During development, the emergence of new cell types, including neurons, results from interactions between neighboring layers of cells. On gestational day 13, the embryo consists of a sheet of cells. Following gastrulation (days 14 to 15), which forms a two-cell–layered embryo consisting of ectoderm and endoderm, the neural plate region of the ectoderm is delineated by the underlying mesoderm, which appears on day 16. The mesoderm forms by cells entering a midline cleft in the ectoderm called the primitive streak. After migration, the mesodermal layer lies between the ectoderm and endoderm and induces the overlying ectoderm to become a neural plate. Induction usually involves the release of soluble growth factors from one group of cells, which in turn bind receptors on neighboring cells, eliciting changes in nuclear transcription factors that control downstream gene expression. In some cases, cell–cell contact-mediated mechanisms are involved. In the gene-patterning section below, the critical roles of soluble growth factors and transcription factor expression are described.

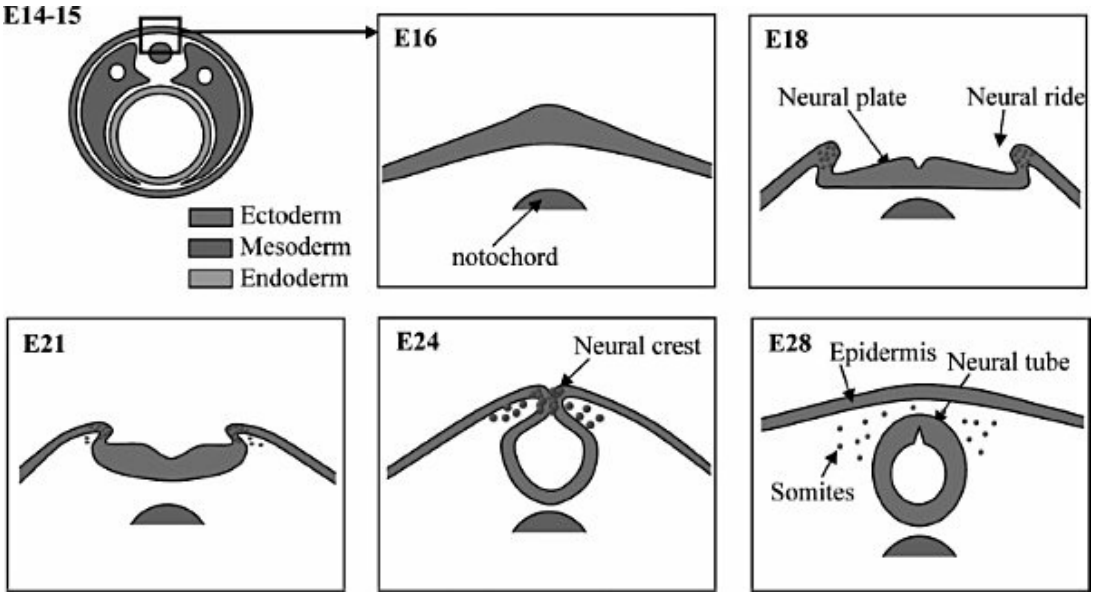

FIGURE 33-5
Mechanisms of neurulation. Neurulation begins with the formation of a neural plate in response to soluble growth factors released by the underlying notochord. The neural plate originates as a thickening of the ectoderm that results from

cuboidal epithelial cells becoming columnar in shape. With further changes in cell shape and adhesion, the edges of the plate fold and rise, meeting in the midline to form a tube. Cells at the tips of the neural folds come to lie between the neural tube and overlying epidermis, forming the neural crest that gives rise to the peripheral nervous system and other structures. (From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2009:44.)

The neural plate, the induction of which is complete by 18 days, is a sheet of columnar epithelium and is surrounded by ectodermal epithelium. After formation, the edges of the neural plate elevate, forming the neural ridges. Subsequently, changes in intracellular cytoskeleton and cell-extracellular matrix attachment cause the ridges to merge in the midline and fuse, a process termed neurulation, forming the neural tube, with a central cavity presaging the ventricular system (Fig. 33-5). Fusion begins in the cervical region at the hindbrain level (medulla and pons) and continues rostrally and caudally. Neurulation occurs at 3 to 4 weeks of gestation in humans, and its failure results in anencephaly rostrally and spina bifida caudally. Neurulation defects are well known following exposure to retinoic acid in dermatologic preparations and anticonvulsants, especially valproic acid, as well as diets deficient in folic acid.

Another product of neurulation is the neural crest, the cells of which derive from the edges of the neural plate and dorsal neural tube. From this position, neural crest cells migrate dorsolaterally under the skin to form melanocytes and ventromedially to form dorsal root sensory ganglia and sympathetic chains of the peripheral nervous system and ganglia of the enteric nervous system. However, neural crest gives rise to diverse tissues, including cells of neuroendocrine, cardiac, mesenchymal, and skeletal systems, forming the basis of many congenital syndromes involving the brain and other organs. The neural crest origin at the border of neural and epidermal ectoderm and its generation of melanocytes forms the basis of the neurocutaneous disorders, including tuberous sclerosis and neurofibromatosis. Finally, another nonneuronal structure of mesodermal origin formed during neurulation is the notochord found on the ventral side of the neural tube. As we will describe later in this chapter, the notochord plays a critical role during neural tube differentiation, since it is a signaling source of soluble growth factors, such as sonic hedgehog (Shh), which affect gene patterning and cell determination.

Regional Differentiation of the Embryonic Nervous System. After closure, the neural tube expands differentially to form major morphologic subdivisions that precede the major functional divisions of the brain. These subdivisions are important developmentally because different regions are generated according to specific schedules of proliferation and subsequent migration and differentiation. The neural tube can be described in three dimensions, including longitudinal, circumferential, and radial. The longitudinal dimension reflects the rostrocaudal (anterior–posterior) organization, which mostly consists of the brain and spinal cord. Organization in the circumferential dimension, tangential to the surface, represents two significant axes: In the dorsoventral axis, cell groups are uniquely positioned from top to bottom.

On the other hand, in the medial to the lateral axis, there is mirror-image symmetry, consistent with the right-left symmetry of the body. Finally, the radial dimension represents the organization from the innermost cell layer adjacent to the ventricles to the outermost surface and exhibits region-specific cell layering. At 4 weeks, the human brain is divided longitudinally into the prosencephalon (forebrain), mesencephalon (midbrain), and rhombencephalon (hindbrain). These three subdivisions or “vesicles” divide further into five divisions by 5 weeks, consisting of the prosencephalon, which forms the telencephalon (including cortex, hippocampus, and basal ganglia) and diencephalon (thalamus and hypothalamus), the mesencephalon, (midbrain), and the rhombencephalon, yielding metencephalon (pons and cerebellum) and myelencephalon (medulla). Morphologic transformation into five vesicles depends on the region-specific proliferation of precursor cells adjacent to the ventricles, the so-called ventricular zones (VZs). As discussed later, proliferation intimately depends on soluble growth factors made by proliferating cells themselves or released from regional signaling centers. In turn, growth factor production and cognate receptor expression also depend on region-specific patterning genes. We now know that VZ precursors, which appear morphologically homogeneous, express a checkerboard array of molecular genetic determinants that control the generation of specific types of neurons in each domain (Fig. 33-6).

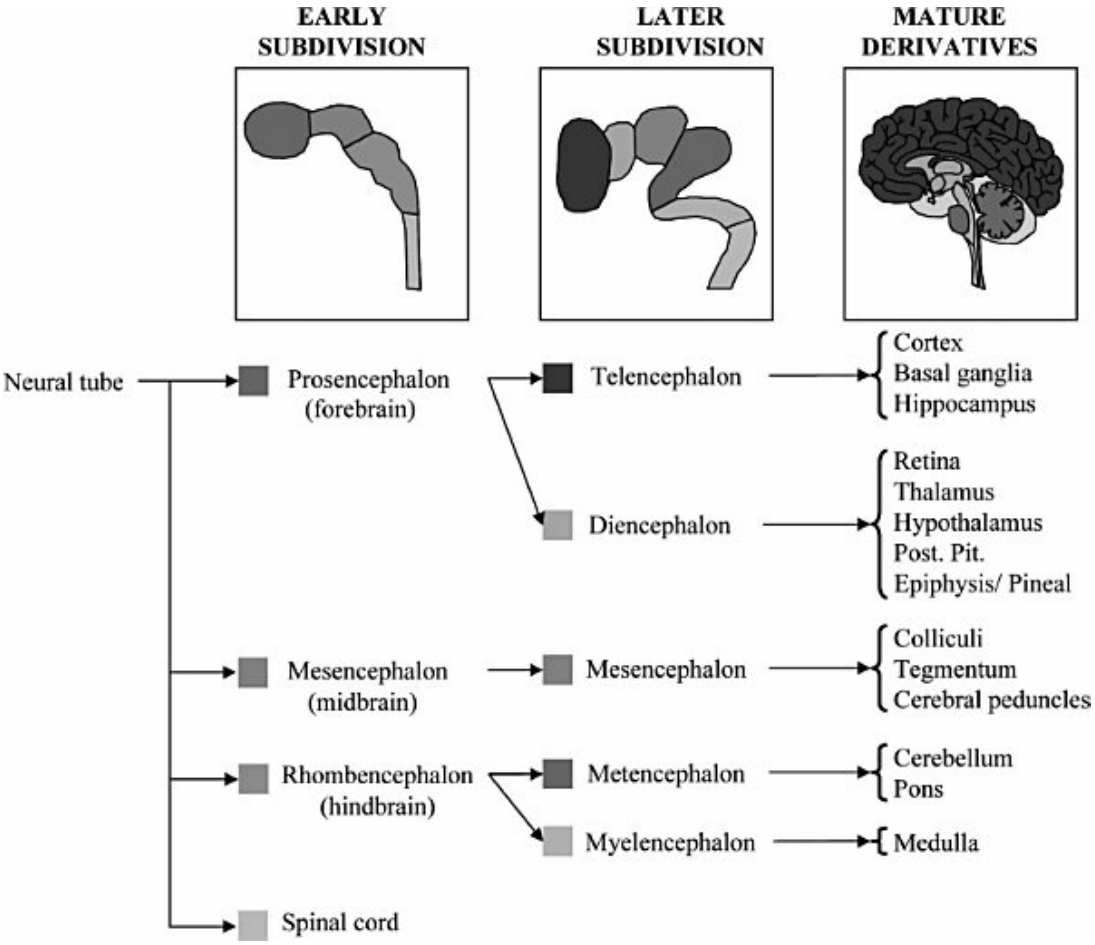

FIGURE 33-6
Progression of brain regional differentiation. Early after neurulation, the neural tube differentiates into four regions (forebrain, midbrain, hindbrain, and spinal cord) that give rise following later divisions and maturation to the different brain structures. (From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2009:45.)

In the circumferential dimension, the organization begins very early and extends over many rostrocaudal subdivisions. In the spinal cord, the majority of tissue comprises the lateral plates, which later divide into dorsal or alar plates, composed of sensory interneurons, and motor or basal plates, consisting of ventral motor neurons. Two other diminutive plates, termed the roof plate and floor plate, are virtually absent in maturity; however, they play critical regulatory roles as growth factor signaling centers in the embryo. Indeed, the floor plate, in response to Shh from the ventrally located notochord, produces its own Shh, which in turn induces neighboring cells in the ventral spinal cord and brainstem to express region-specific transcription

factors that specify cell phenotype and function. For example, in combination with other factors, floor plate Shh induces midbrain precursors to differentiate into dopamine-secreting neurons of the substantia nigra.

Similarly, the roof plate secretes growth factors, such as bone morphogenetic proteins (BMPs), which induce dorsal neuron cell fate in the spinal cord. In the absence of a roof plate, dorsal structures fail to form, such as the cerebellum, and midline hippocampal structures are missing. Finally, in the radial dimension, the organization of layers is subdivision specific, produced by differential proliferation of VZ precursors and cell migration, as described later.

The Ventricular and Subventricular Proliferative Zones. The distinct patterns of precursor proliferation and migration in different regions generate the radial organization of the nervous system. In each longitudinal subdivision, the final population size of a brain region depends on the interplay of regulated neurogenesis with programmed cell death. Traditional concepts had suggested that there was excess cell production everywhere and that final cell number regulation was achieved primarily after neurogenesis through selective cell death mediated by target-derived survival (trophic) factors. We now know that the patterning genes discussed later play significant roles in directing regional precursor proliferation that is coordinated with final structural requirements, and that programmed cell death occurs at multiple stages. Consequently, in diseases characterized by brain regions smaller than usual, such as schizophrenia, there may be a failure to generate neurons initially, as opposed to normal generation with subsequent cell loss.

Radial and Tangential Patterns of Neurogenesis and Migration. Of interest to psychiatry, the cerebral cortex is the paradigmatic model of inside-to-outside neurogenesis. A large number of studies now relate specific genetic mutations to distinct cortical malformations that alter neurogenesis, migration, and cellular organization, thereby increasing our knowledge of both normal and pathophysiologic cortical development. The characteristic six-cell layers represent a common cytoarchitectural and physiologic basis for the neocortical function and are derived from the embryonic forebrain telencephalic vesicles. Within each layer, neurons exhibit related axodendritic

morphologies, use common neurotransmitters, and establish similar afferent and efferent connections. In general, pyramidal neurons in layer 3 establish synapses within and between cortical hemispheres, whereas deeper layer 5/6 neurons project primarily to subcortical nuclei, including the thalamus, brainstem, and spinal cord. The majority of cortical neurons originate from the forebrain VZ. At the earliest stages, the first postmitotic cells migrate outward from the VZ to establish a superficial layer termed the preplate. Two consequential cell types comprise the preplate—Cajal–Retzius cells, which form outermost layer one or marginal zone, and subplate neurons, which lay beneath future layer 6. These distinct regions form when later-born cortical plate neurons migrate within and divide the preplate in two (Fig. 33-7).

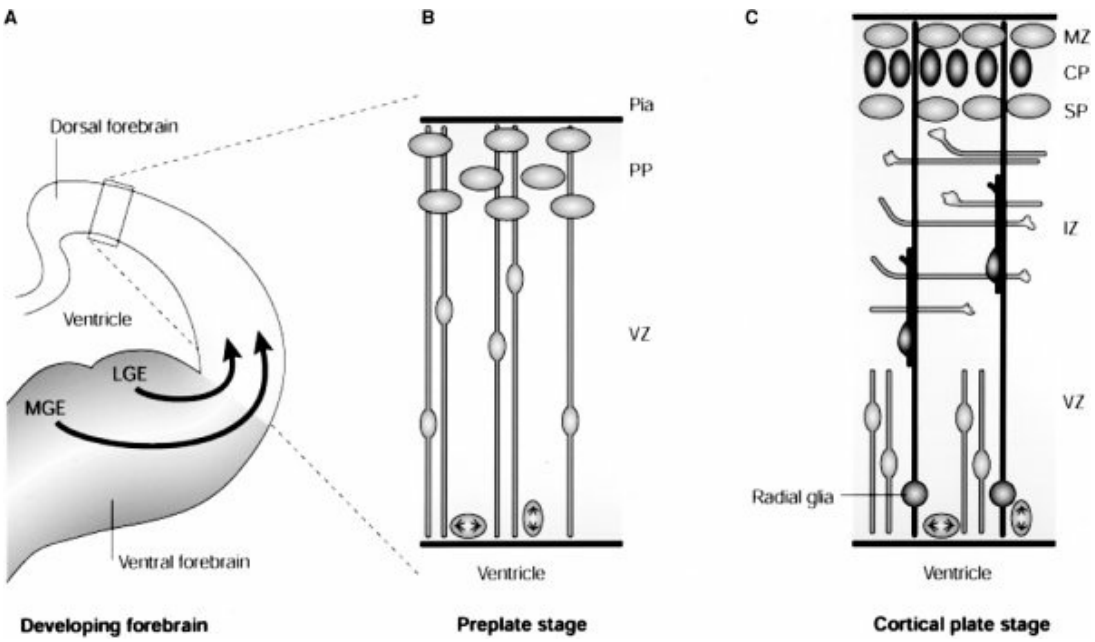

FIGURE 33-7

Schematic drawing of radial and tangential migration during cerebral cortex development. **A:** A coronal section of one-half of the developing rat forebrain. The dorsal forebrain gives rise to the cerebral cortex. Medial ganglionic eminences (MGEs) and lateral ganglionic eminences (LGEs) of the ventral forebrain generate neurons of the basal ganglia and the cortical interneurons. The *arrows* indicate the tangential migration route for γ-aminobutyric acid (GABA) interneurons to the cortex. The boxed area (enlarged in **B** and **C**) shows the developing cortex at early and late stages. **B:** In the dorsal forebrain, the first cohort of postmitotic neurons migrate out from the ventricular zone (VZ) and create a preplate (PP) below the pial surface. **C:** Subsequent postmitotic neurons will migrate along radial glia through the intermediate zone (IZ) and take position in the middle of the preplate, creating a cortical plate (CP) between the outer marginal zone (MZ) and inner subplate (SP). Ultimately, the CP will be composed of six layers that are born sequentially, migrating in an inside-to-outside pattern. Horizontal processes

in the IZ represent axon terminals of thalamic afferents. (From Nadarajah B, Parnavelas JG. Modes of neuronal migration in the developing cerebral cortex. *Nat Neurosci*. 2002;3:423, with permission.)

A recent discovery, postulated for years, has changed the view of the origins of cortical neuron populations involved in human brain disease. Neuron tracing experiments in culture and in vivo demonstrate that the neocortex, a dorsal forebrain derivative, is also populated by neurons generated in the ventral forebrain (see Fig. 33-7). Molecular studies of patterning genes, especially *Dlx*, strongly support this model (see below). In contrast to excitatory pyramidal neurons, the overwhelming majority of inhibitory γ-aminobutyric acid (GABA)-secreting interneurons originate from mitotic precursors of the ganglionic eminences that generate the neurons of the basal ganglia. Subsets of interneurons also secrete neuropeptides, such as neuropeptide Y (NPY) and somatostatin, and express nitrous oxide (NOS)-generating enzyme. Not associated with cortical VZ radial glia, these GABA interneurons reach the cortical plate by migrating tangentially, in either the superficial marginal zone or a deep position above the VZ, the subplate region where thalamic afferents are also growing. Significantly, in brains from patients with schizophrenia, the prefrontal cortex exhibits a reduced density of interneurons in layer 2. Also, there is upregulation of $GABA_A$-receptor binding, a potential functional compensation, as well as a relative deficiency of NOS-expressing neurons. These observations have led to the hypothesis that schizophrenia is due to reduced GABAergic activity. The origin of GABA interneurons from the ganglionic eminences and their association with specific patterning genes raises new genetic models of disease causation and possible strategies for disease intervention. Thus, more broadly, normal cortical development depends on a balance of two principal patterns of neurogenesis and migration, consisting of radial migration of excitatory neurons from the dorsal forebrain VZ and tangential migration of inhibitory neurons from the ventral forebrain.

In contrast to inside-to-outside neurogenesis observed in the cortex, phylogenetically older regions, such as the hypothalamus, spinal cord, and hippocampal dentate gyrus, exhibit the reverse order of cell generation. First-formed postmitotic neurons lie superficially, and last-generated cells localize toward the center. Although this outside-to-inside pattern might reflect

passive cell displacement, radial glia, and specific migration signaling molecules are involved. Furthermore, cells do not always lie in direct extension from their locus of VZ generation. Instead, some groups of cells migrate to specific locations, as observed for neurons of the inferior olivary nuclei.

Of prime importance in psychiatry, the hippocampus demonstrates both radial and nonradial patterns of neurogenesis and migration. The pyramidal cell layer, Ammon's horn Cornu Ammonis (CA) 1 to 3 neurons, is generated in a typical outside-to-inside fashion in the dorsomedial forebrain for a discrete period, from 7 to 15 weeks of gestation, and exhibits intricate migration patterns. In contrast, the other significant population, dentate gyrus granule neurons, start appearing at 18 weeks and exhibits prolonged postnatal neurogenesis, originating from several migrating secondary proliferative zones. In rats, for instance, granule neurogenesis starts at embryonic day 16 (E16) with proliferation in the forebrain VZ. At E18, an aggregate of precursors migrates along a subpial route into the dentate gyrus. There, they generate granule neurons in situ. After birth, there is another migration, localizing proliferative precursors to the dentate hilus, which persists until 1 month of life. After that, granule precursors move to a layer just under the dentate gyrus, termed the subgranular zone (SGZ), which produces neurons throughout life in adult rats, primates, and humans. In rodents, SGZ precursors proliferate in response to cerebral ischemia, tissue injury, and seizures, as well as growth factors. Finally, the diminished hippocampal volume reported in schizophrenia raises the possibility that disordered neurogenesis plays a role in pathogenesis, as either a basis for dysfunction or a consequence of brain injuries, consistent with associations of gestational infections with disease manifestation.

Finally, a different combination of radial and nonradial migration is observed in the cerebellum, which is a brain region that plays an essential function in nonmotor tasks, with particular significance for autism spectrum disorders (ASDs). Except for granule cells, the other significant neurons, including Purkinje and deep nuclei, originate from the primary VZ of the fourth ventricle, coincident with other brainstem neurons. In rats, this occurs at E13 to E15, and in humans, at 5 to 7 weeks of gestation. The granule neurons, as well as the basket and stellate interneurons, originate in the secondary proliferative zone, the external germinal cell layer (EGL), which

covers the newborn cerebellum at birth. EGL precursors originate in the fourth ventricle VZ and migrate dorsally through the brainstem to reach this superficial position. The rat EGL proliferates for 3 weeks, generating more neurons than in any other structure, whereas, in humans, EGL precursors exist for at least 7 weeks and up to 2 years. When an EGL precursor stops proliferating, the cell body sinks below the surface and grows bilateral processes that extend transversely in the molecular layer, and then the soma migrates further down into the internal granule layer (IGL). Cells reach the IGL along specialized Bergmann glia, which serve guidance functions similar to those of the radial glia. However, in this case, cells originate from a secondary proliferative zone that generates neurons exclusively of the granule cell lineage, indicating a restricted neural fate. Clinically, this postnatal population in infants makes cerebellar granule neurogenesis vulnerable to infectious insults of early childhood and an undesirable target of several therapeutic drugs, such as steroids, well known to inhibit cell proliferation. Also, proliferative control of this stem cell population is lost in the common childhood brain tumor, medulloblastoma (see Fig. 33-8).

Developmental Cell Death. During nervous system development, cell elimination is required to coordinate the proportions of interacting neural cells. Developmental cell death is a reproducible, spatially, and temporally restricted death of cells that occurs during the organism's development. Three types of developmental cell death have been described: (1) phylogenetic cell death that removes structures in one species that served evolutionarily earlier ones, such as the tail or the vomeronasal nerves; (2) morphogenetic cell death, which sculpts the fingers from the embryonic paddle and is required to form the optic vesicles, as well as the caudal neural tube; and (3) histogenetic cell death, a widespread process that allows the removal of select cells during development of specific brain regions. Numerous studies have focused on histogenetic cell death, the impact of which varies among brain regions but can affect 20 to 80 percent of neurons in some populations. A significant role for developmental cell death was proposed in the 1980s based on the paradigm of nerve growth factor, suggesting that following neurogenesis, neurons compete for trophic factors. In this model, the survival of differentiating neurons depended absolutely on establishing axonal connections to the correct targets in order to obtain survival-promoting

(trophic) growth factors, such as the neurotrophins. Otherwise, they would be eliminated by programmed cell death. This competitive process was thought to ensure the proper matching of new neuronal populations with the size of its target field. Although such interactions are involved in controlling cell degeneration, this model is overly simplistic: Developmental cell death also occurs in neural precursors and immature neurons, before any synaptic contacts are established.

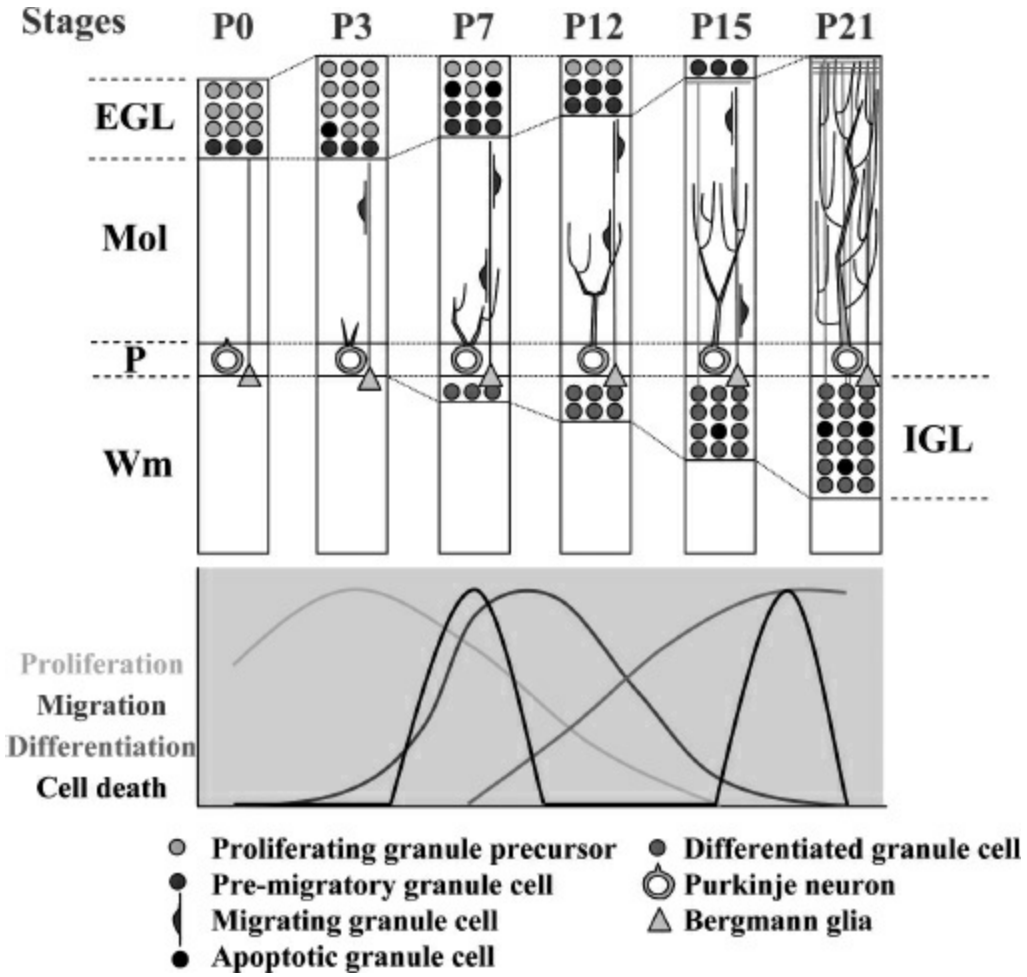

FIGURE 33-8
Neurogenesis, migration, and differentiation of granule cells during cerebellar development. Granule cell precursors proliferate in the external germinal layer. After exiting the cell cycle, they migrate through the molecular layer and past the Purkinje neurons to reach the internal granule layer where they differentiate and make synapses. Neurons that do not migrate properly or that do not establish proper synaptic connections undergo apoptosis. EGL, external germinal cell layer; Mol, molecular layer; P, Purkinje cell layer; IGL, internal granule cell layer; Wm, white matter. (From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2009:48.)

APOPTOSIS. Apoptotic cell death, or apoptosis, is the primary type of developmental cell degeneration. Apoptosis or "programmed cell death" involves specific molecules that possess enzymatic activities such as cysteine-containing aspartate-specific proteases, also called "caspases," which participate in complex intracellular mechanisms. A large number of signals (both proapoptotic and antiapoptotic) converge to regulate common signaling pathways. Of importance for psychiatry, both developmental as well as pathologic cell death, involves many of the same signaling cascades. A failure to inhibit apoptosis is involved in cancers and autoimmune diseases (multiple sclerosis), whereas excess stimulation of apoptosis is observed in neurodegenerative diseases during both development (Huntington disease, lysosomal diseases, and leukodystrophy) and aging (Alzheimer and Parkinson diseases). Massive apoptotic cell death is also observed during acquired developmental brain injuries such as hypoxia-ischemia, fetal alcohol syndrome, and exposure to ionizing radiations and neurotoxicants. Thus dysregulation of apoptotic cell death during development can lead to severe brain abnormalities, which may only manifest later as mature functional impairments.

Programmed cell death is a necessary process during neurodevelopment, as genetic deletion of caspases in embryonic mice produces enlarged and disorganized brains with marked regional specificity. Programmed cell death occurs at multiple stages of nervous system development, interacting with neurogenesis and differentiation with precise and complex mechanisms. As many neuropathologies also involve dysregulation of apoptosis, future studies hold promise for elucidation and treatment of neurologic diseases.

The Concept of Neural Patterning

Principles of Function. The morphologic conversion of the nervous system through the embryonic stages, from the neural plate through the neural tube to brain vesicles, is controlled by interactions between extracellular factors and intrinsic genetic programs. In many cases, extracellular signals are soluble growth factors secreted from regional signaling centers, such as the notochord, floor, or roof plates, or surrounding mesenchymal tissues. The precursor's ability to respond (competence)

depends on cognate receptor expression, which is determined by patterning genes whose proteins regulate gene transcription. The remarkable new observation is that the subdivisions of the embryonic telencephalon that were initially based on mature differences in morphology, connectivity, and neurochemical profiles are also distinguished embryonically by distinct patterns of gene expression. Classical models had suggested that the cerebral cortex was generated as a reasonably homogeneous structure, unlike most epithelia, with individual functional areas specified relatively late, after cortical layer formation, by the ingrowth of afferent axons from the thalamus. In marked contrast, recent studies indicate that proliferative VZ precursors themselves display regional molecular determinants, a “protomap,” which the postmitotic neurons carry with them as they migrate along radial glia to the cortical plate.

Consequently, innervating thalamic afferents may serve to modulate only intrinsic molecular determinants of the protomap. Indeed, in two different genetic mutants, *Gbx2* and *Mash1*, in which thalamocortical innervation is disrupted, expression of cortical patterning genes proceeds unaltered. On the other hand, thalamic afferent growth may be directed by patterning genes and subsequently play roles in modulating regional expression patterns. Thus experience-dependent processes may contribute less to cortical specialization than initially postulated.

The term patterning genes connotes families of proteins that serve primarily to control transcription of other genes, the products of which include other transcription factors or proteins involved in cellular processes, such as proliferation, migration, or differentiation. Characteristically, transcription factor proteins contain two principal domains, one that binds DNA promoter regions of genes and the other that interacts with other proteins, either transcription factors or components of intracellular second messengers. Notably, transcription factors form multimeric protein complexes to control gene activation. Therefore, a single transcription factor will play diverse roles in multiple cell types and processes, according to what other factors are present, the so-called cellular environment. The combinatorial nature of gene promoter regulation leads to a diversity of functional outcomes when a single patterning gene is altered.

Furthermore, because protein interactions depend on protein–protein affinities, there may be complex changes as a single factor’s expression level

is altered. This process may be a critical mechanism of human variation and disease susceptibility, since polymorphisms in gene promoters, known to be associated with human disease, can alter levels of gene protein products. A transcription factor may associate primarily with one partner at a low concentration but with another at a higher titer. The multimeric nature of regulatory complexes allows a single factor to stimulate one process while simultaneously inhibiting another. During development, a patterning gene may thus promote one event, say the generation of neurons, by stimulating one gene promoter, while simultaneously sequestering another factor from a different promoter whose activity is required for an alternative phenotype, such as glial cell fate. Finally, the factors frequently exhibit cross-regulatory functions, where one factor negatively regulates the expression of another. This activity leads to the establishment of tissue boundaries, allowing the formation of regional subdivisions, such as basal ganglia and cerebral cortex in the forebrain.

Also, to combinatorial interactions, patterning genes exhibit distinct temporal sequences of expression and function, acting hierarchically. Functional hierarchies were established experimentally by using genetic approaches, either deleting a gene (loss of function) or over-/ectopically expressing it (gain of function), and defining developmental consequences. At the most general level, genetic analyses indicate that regionally restricted patterning genes participate in specifying the identity, and therefore function, of cells in which they are expressed. Subdivisions of the brain and cerebral cortex specifically, are identified by regionalized gene expression in the proliferative VZ of the neural tube, leading to subsequent differentiation of distinct types of neurons in each mature (postmitotic) region. Thus the protomap of the embryonic VZ predicts the cortical regions it will generate and may instruct the hierarchical temporal sequence of patterning gene expression. It appears that the different genes underlie multiple stages of brain development, including the following: (1) determining that ectoderm will give rise to the nervous system (as opposed to the skin); (2) defining the dimensional character of a region, such as positional identity in dorsoventral or rostrocaudal axes; (3) specifying cell class, such as neuron or glia; (4) defining when proliferation ceases, and differentiation begins, (5) determining specific cell subtype, such as GABA interneuron, as well as projection pattern; and (6) defining laminar position in the region, such as

cerebral cortex. Although investigations are ongoing, studies indicate that these many steps depend on interactions of transcription factors from multiple families. Furthermore, a single transcription factor plays regulatory roles at multiple stages in the developmental life of a cell, yielding complex outcomes, for instance, in genetic loss of function studies and human disease.

Recent advances in molecular biology have led to the identification of another principle of nervous system organization, which, if sustained by further studies, may provide a molecular basis for brain system diseases, such as Parkinson disease and autism. Using molecular techniques to permanently identify cells that had expressed during the development of a specific gene, in this case, the soluble growth factor, Wnt3a, investigators were able to determine where cells originated embryonically and could trace their path of migration along the neuraxis during development. These genetic-fate mapping studies indicate that cells that expressed Wnt3a migrated widely from the dorsal midline into the dorsal regions of the brain and spinal cord, thereby contributing to diverse adult structures in the diencephalon, midbrain, and brainstem, and rostral spinal cord. Of interest, most of these structures were linked into a functional neural network, specifically the auditory system. The observation that a single functional system emerges from a specific group of fated cells would allow for restricted neurologic system–based disorders, such as deficits in dopamine or catecholamine neurons, or for the dysfunction of inter-related brain regions that subserve social cognition and interaction, a core symptom of the ASDs. Other adult system degenerations may also be considered. This new observation may change the way that we consider temporal changes in patterning gene expression of specific brain regions during development.

Finally, patterning gene expression in nervous system subdivisions is not insensitive to environmental factors. On the contrary, the expression is intimately regulated by growth factors released from regional signaling centers. Indeed, although a century of classical experimental embryology described the induction of new tissues between neighboring cell layers morphologically, we have only recently defined molecular identities of soluble protein morphogens and cell response genes underlying development. Signaling molecules from discrete centers establish tissue gradients that provide positional information (dorsal or ventral), impart cell specification, or control regional growth. Signals include the BMPs, the Wingless-Int proteins

(Wnts), Shh, fibroblast growth factors (FGFs), and epidermal growth factors (EGFs), to name a few. These signals set up developmental domains characterized by expression of specific transcription factors, which in turn control further regional gene transcription and developmental processes. The importance of these mechanisms for cerebral cortical development is only now emerging, altering our concepts of the roles of subsequent thalamic innervation and experience-dependent processes. In light of the temporal and combinatorial principles discussed earlier, brain development can be viewed as a complex and evolving interaction of extrinsic and intrinsic information.

Specific Inductive Signals and Patterning Genes in Development

Induction of the CNS begins at the neural plate stage when the notochord, underlying mesenchyme, and surrounding epidermal ectoderm produce signaling molecules that affect the identity of neighboring cells. Specifically, the ectoderm produces BMPs that prevent neural fate determination by promoting and maintaining epidermal differentiation. In other words, neural differentiation is a default state that manifests unless it is inhibited. In turn, neural induction proceeds when inhibitory proteins block BMP's epidermis-inducing activity, such as noggin, follistatin, and chordin, which are secreted by Hensen's node (homologous to the amphibian Spemann organizer), a signaling center at the rostral end of the primitive streak. Once the neural tube closes, the roof plate and floor plate become new signaling centers, organizing dorsal and ventral neural tube, respectively. The same ligand/receptor system is used sequentially for multiple functions during development. BMPs are a case in point since they prevent neural development at the neural plate stage, whereas after neurulation, the factors are produced by the dorsal neural tube itself to induce sensory neuron fates.

The Spinal Cord. The spinal cord is a prime example of the interaction of soluble signaling factors with intrinsic patterning gene expression and function. The synthesis, release, and diffusion of inductive signals from signaling sources produce concentration gradients that impose distinct neural fates in the spinal cord (Fig. 33-9). The notochord and floor plate secrete Shh, which induces motoneurons and interneurons ventrally, whereas the epidermal ectoderm and roof plate release several BMPs that impart neural

crest and sensory relay interneuron fates dorsally. Growth factor inductive signals act to initiate discrete regions of transcription factor gene expression. For instance, high concentrations of Shh induce winged-helix transcription factor *Hnf3β* gene in floor plate cells and *Nkx6.1* and *Nkx2.2* in the ventral neural tube, whereas the expression of more dorsal genes, *Pax6, Dbx1/2, Irx3,* and *Pax7,* is repressed. In response to Shh, ventral motoneurons express transcription factor gene *Isl1*, whose protein product is essential for neuron differentiation. Subsequently, ventral interneurons differentiate, expressing *En1* or *Lim1/2* independent of Shh signaling.

In contrast, the release of BMPs by dorsal cord and roof plate induces a distinct cascade of patterning genes to elicit sensory interneuron differentiation. In aggregate, the coordinated actions of Shh and BMPs induce the dorsoventral dimension of the spinal cord. Similarly, other inductive signals determine the rostrocaudal organization of the CNS, such as retinoic acid, an upstream regulator of *hox* patterning genes, anteriorly, and the FGFs posteriorly. The overlapping and unique expression of the many *hox* gene family members are essential for establishing the segmental pattern in the anterior–posterior axis of the hindbrain and spinal cord, now-classic models well described in previous reviews.

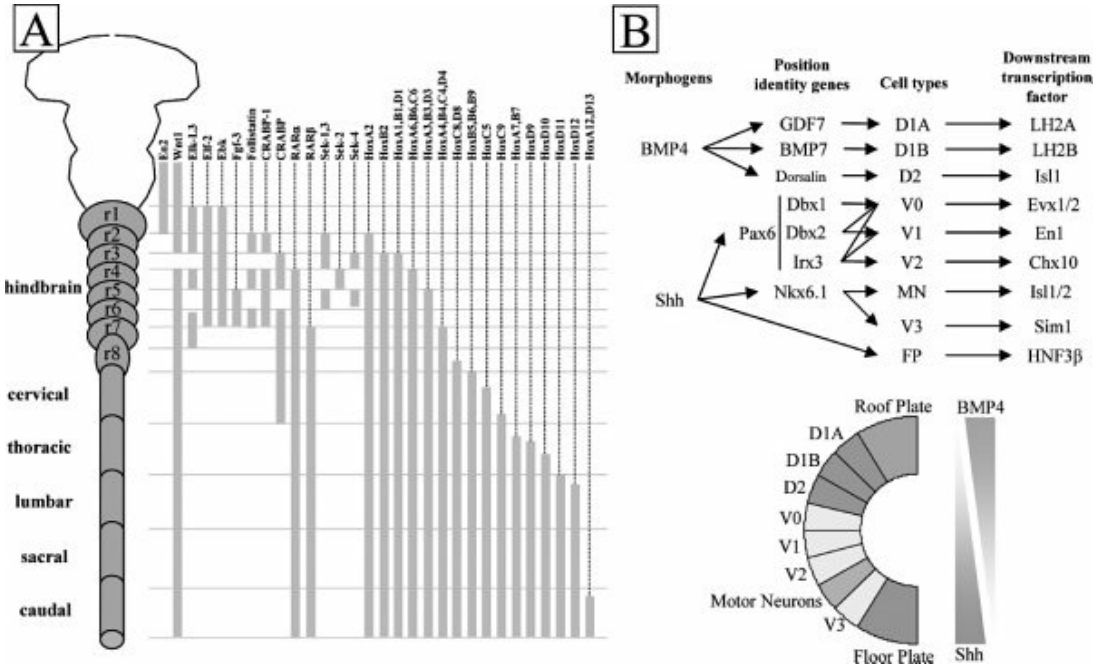

FIGURE 33-9

Patterning genes in the spinal cord. **A:** Diagram illustrating the localization of gene expression in the developing "trunk." Rhombomere boundaries are specified

by specific combinations of transcription factors. (Modified from Darnell, 2005.) **B:** Morphogen induction of spinal cord cell fate. Dorsoventral gradients of sonic hedgehog (Shh) and bone morphogenetic protein (BMP) induce expression of several position identity genes. Combinatorial effects of these factors establish progenitor domains and result in the expression of specific downstream molecular markers. D, dorsal neurons; V, ventral neurons. (From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2009:51.)

Recent advances in spinal cord transcription factor expression and function reinforce that these factors play roles at multiple developmental cell stages. This is likely due to their participation in diverse protein regulatory complexes: The transcription factors Pax6, Olig2, and Nkx2.2, which define the positional identity of multipotent progenitors early in development, also play crucial roles in controlling the timing of neurogenesis and gliogenesis in the developing ventral spinal cord.

The Cerebral Cortex. Recent evidence suggests that forebrain development also depends on inductive signals and patterning genes, as observed in more caudal neural structures. In the embryo, the dorsal forebrain structures include the hippocampus medially, the cerebral cortex dorsolaterally, and the entorhinal cortex ventrolaterally, whereas in the basal forebrain, the globus pallidus lies medially and the striatum laterally. Based on gene expression and morphologic criteria, it has been hypothesized that the forebrain is divided into a checkerboard-like grid pattern of domains generated by the intersection of longitudinal columns and transverse segments, perpendicular to the longitudinal axis. The columns and segments (prosomeres) exhibit restricted expression of patterning genes, allowing for unique combinations of factors within each embryonic subdivision. Many of these genes, including *Hnf3β, Emx2, Pax6,* and *Dlx2,* are first expressed even before neurulation in the neural plate. They are then maintained, providing the "protomap" determinants of the VZ described earlier. As in the spinal cord, initial forebrain gene expression is influenced by a similar array of signaling center soluble factors—Shh, BMP, and retinoic acid. As the telencephalic vesicles form, signaling centers localize to the edges of the cortex. In the dorsal midline, there is the anterior neural ridge, anterior cranial mesenchyme secreting FGF8, the roof plate, and, at the junction of the roof plate with the telencephalic vesicle, the cortical hem (Fig. 33-10). Other

factors originate laterally from the dorsal–ventral forebrain junction, as well as from basal forebrain structures themselves.

Do molecular studies identify how different cortical regions interact with thalamic neurons to establish specific functional modalities, such as vision and sensation? Moreover, once regional identity is established, can later developmental events modify it? It has been proposed that initially, there are no functional distinctions in the cortex but that they are induced by the ingrowth of extrinsic thalamic axons, which convey positional and functional specifications, the so-called “protocortex model.” However, in contrast, the abundant molecular evidence provided earlier suggests that intrinsic differences are established early in the neuroepithelium by molecular determinants that regulate areal specification, including the targeting of thalamic axons, termed the “protomap” model. Experimental tests indicate that neither model is entirely correct. Although there is early molecular regionalization of the cortex, the initial targeting of thalamic axons to the cortex is independent of these molecular differences. In the rodent, thalamic afferents first target to their usual cortical regions prenatally in the late embryo. However, once thalamic afferents reach the cortex, which occurs several days after birth, interactions of thalamic axon branches with local, regional cues lead to modifications of initial outgrowth and the establishment of connections that conform to areal molecular identities. Furthermore, the developing cortex exhibits a remarkable and unexpected level of flexibility in mediating modality-specific functions: In the ferret, surgical elimination of visual pathway (lateral geniculate nucleus) in postnatal pups results in the transfer of visual signaling to the auditory cortex, which successfully mediates vision! Thus the animal’s visual information is effectively processed by their auditory cortex.

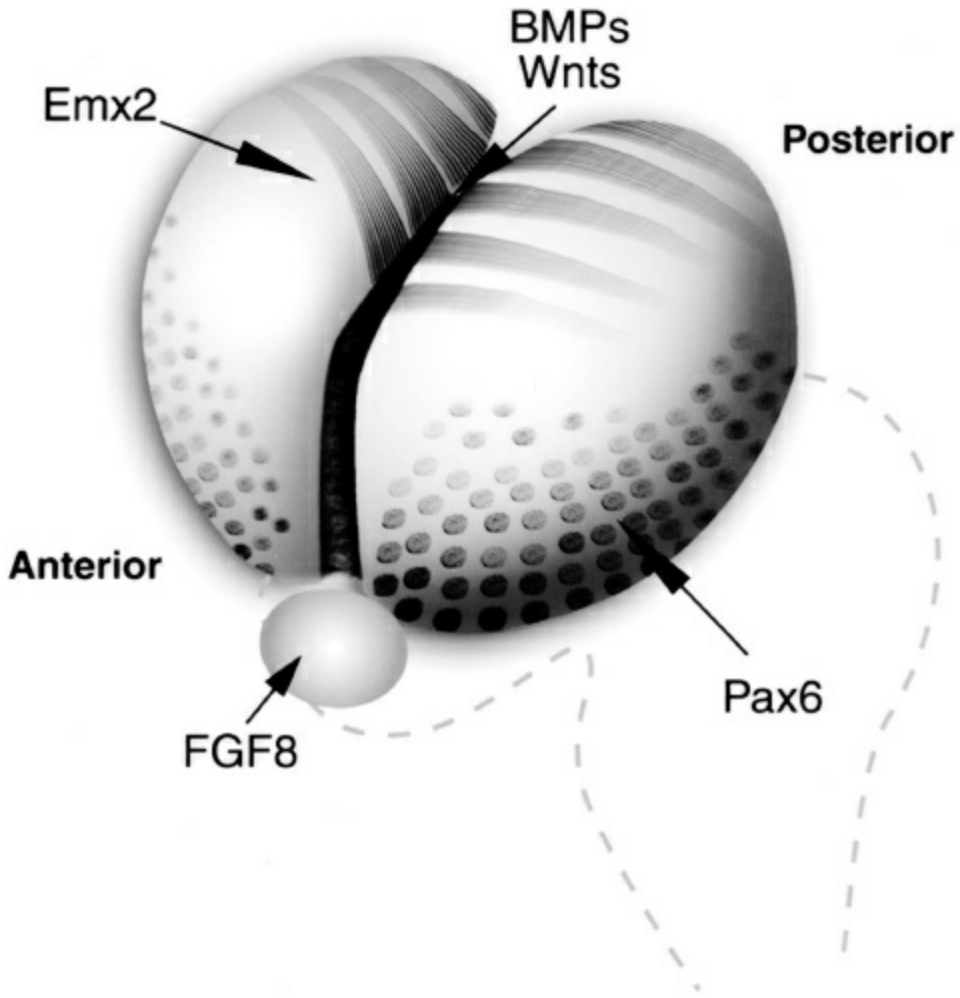

FIGURE 33-10
Patterning genes and signaling centers in the developing cerebral cortex. This schematic diagram shows a lateral–superior view of the two cerebral hemispheres of the embryonic mouse, sitting above the midbrain and hindbrain (*broken lines*). The anterior–lateral extent of *Pax6* gene expression is indicated by circles. The posterior–medial domain of *Emx2* expression is indicated by stripes. The genes exhibit continuous gradients of expression that decrease as they extend to opposite poles. The signaling factor fibroblast growth factor 8 (FGF8) is produced by and released from mesenchymal tissue in the anterior neural ridge, which regulates *Pax6* and *Emx2* expression. In the midline, bone morphogenetic proteins (BMPs) and Wingless-Int proteins (Wnts) are secreted from other signaling centers, including the roof plate and the cortical hems. (Courtesy of E. DiCicco-Bloom and K. Forgash.)

The Hippocampus. The hippocampus is a region of significant importance in schizophrenia, depression, autism, and other disorders, and defining mechanisms regulating hippocampal formation may provide clues to the developmental bases of these disorders. In mice, the hippocampus is located

in the medial wall of the telencephalic vesicle. Where it joins the roof plate, the future roof of the third ventricle, there is a newly defined signaling center, the cortical hem, which secretes BMPs, Wnts, and FGFs (see Fig. 33-10). Genetic experiments have defined patterning genes localized to the cortical hem and hippocampal primordia, whose deletions result in a variety of morphogenetic defects. In mice lacking Wnt3a, which is expressed in the cortical hem, the hippocampus is either completely missing or significantly reduced, whereas the neighboring cerebral cortex is mainly preserved. A similar phenotype is produced by deleting an intracellular factor downstream to Wnt receptor activation, the *Lef1* gene, suggesting that the Wnt3a-*Lef1* pathway is required for hippocampal cell specification or proliferation, issues remaining to be defined. When another cortical hem gene, *Lhx5,* is deleted, mice lack both the hem and neighboring choroid plexus, both sources of growth factors. However, in this case, the cortical hem cells may proliferate in excess, and the hippocampal primordia may be present but disorganized, exhibiting abnormalities in cell proliferation, migration, and differentiation. A related abnormality is observed with *Lhx2* mutation. Finally, a sequence of bHLH transcription factors plays roles in hippocampal neurogenesis: Dentate gyrus differentiation is defective in *NeuroD* and *Mash1* mutants. Significantly, expression of all these hippocampal patterning genes is regulated by factors secreted by anterior neural ridge, roof plate, and the cortical hem, including FGF8, Shh, BMPs, and Wnts. Moreover, the basal forebrain region secretes an EGF-related protein, transforming growth factor α (TGF-α), which can stimulate expression of the classical limbic marker protein, lysosomal-associated membrane protein (LAMP). These various signals and genes now serve as candidates for disruption in human diseases of the hippocampus.

The Basal Ganglia. Also, to the motor and cognitive functions, the basal ganglia take on new importance in neocortical function, since they appear to be the embryonic origin of virtually all adult GABA interneurons, reaching the neocortex through tangential migration. Gene expression studies have identified several transcription factors that appear in precursors originating in the ventral forebrain ganglionic eminences, allowing interneurons to be followed as they migrate dorsally into the cortical layers. Conversely, genetic deletion mutants exhibit diminished or absent interneurons, yielding results

consistent with other tracing techniques. These transcription factors, including *Pax6, Gsh2,* and *Nkx2.1,* establish boundaries between different precursor zones in the ventral forebrain VZ, through mechanisms involving mutual repression. As a simplified model, the medial ganglionic eminence (MGE) expresses Nkx2.1 primarily and gives rise to most GABA interneurons of the cortex and hippocampus, whereas the lateral ganglionic eminence (LGE) expresses *Gsh2* and generates GABA interneurons of the SVZ and olfactory bulb. The boundary between the ventral and dorsal forebrain then depends on LGE interaction with the dorsal neocortex, which expresses *Pax6.* When *Nkx2.1* is deleted, LGE transcription factor expression spreads ventrally into the MGE territory, and there is a 50 percent reduction in neocortical and striatal GABA interneurons.

In contrast, the deletion of *Gsh2* leads to ventral expansion of the dorsal cortical molecular markers and concomitant decreases in olfactory interneurons. Finally, *Pax6* mutation causes both MGE and LGE to spread laterally and into dorsal cortical areas, yielding increased interneuron migration. The final phenotypic changes are involved, as these factors exhibit unique and overlapping expression and interact to control cell fate.

Neuronal Specification. As indicated for basal ganglia, throughout the nervous system, transcription factors participate in decisions at multiple levels, including determining the generic neural cell, such as a neuron or glial cell, as well as neuron subtypes. *Mash1* can promote a neuronal fate over a glial fate as well as induce the GABA interneuron phenotype. However, another bHLH factor, *Olig1/2,* can promote oligodendrocyte development, whereas it promotes motor neuron differentiation elsewhere, indicating that the variety of factors expressed in a specific cell leads to combinatorial effects and thus diverse outcomes for cell differentiation. The bHLH inhibitory factor, *Id,* is expressed at the transition from somatosensory to the motor cortex, implying the roles of family members in areal characteristics. In the hippocampus, granule neuron fate is dependent on *NeuroD* and *Math1,* with deficient cell numbers when either one is deleted. The role of specific factors in cortical cell layer determination remains an area of active investigation but likely includes *Tbr1, Otx1,* and *Pax6.*

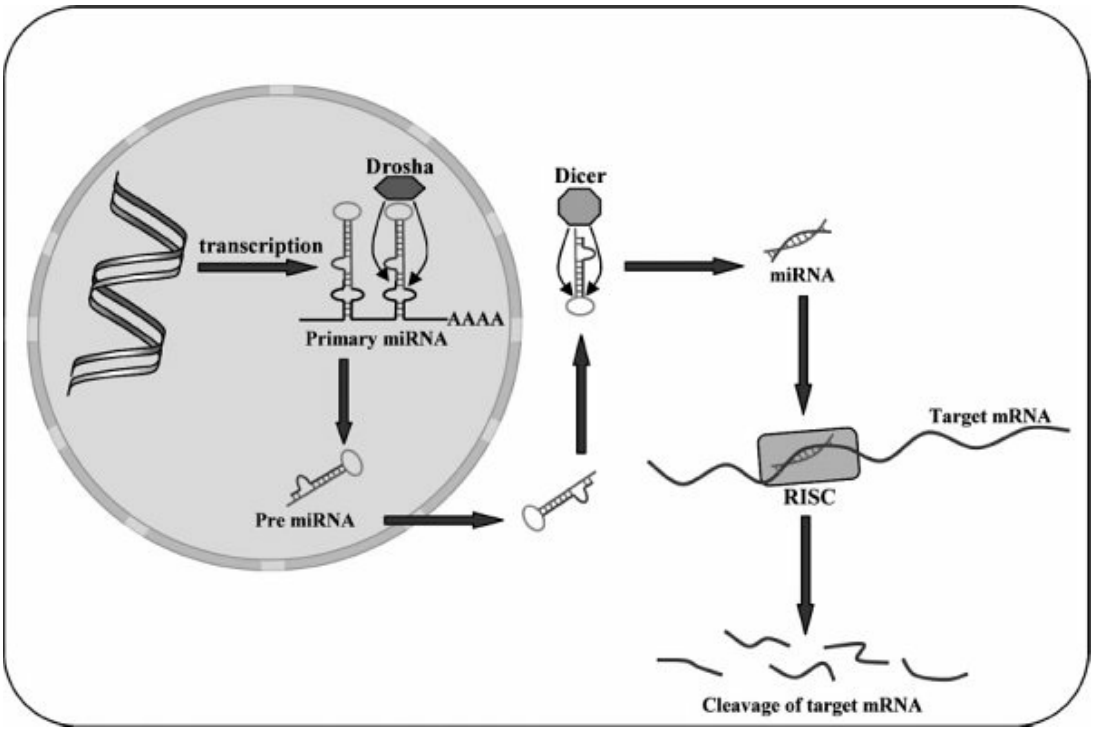

FIGURE 33-11
Processing and function of micro RNA (miRNA). After transcription, the primary miRNA forms a hairpin conformation. This structure allows the enzyme Drosha to cleave the transcript, producing a pre-miRNA that then exits the nucleus through nuclear pores. In the cytoplasm, Dicer cleaves the pre-miRNA stem loop, resulting in the formation of two complementary short RNA molecules. Only one of these molecules is integrated in the RNA-induced silencing complex (RISC) and serves as a guide strand that allows recognition and specificity for target RNA due to its sequence complementarity. After integration into the RISC complex, the miRNA matches with the complementary mRNA strand and induces mRNA duplex degradation by the argonaute protein, the catalytic enzyme of the RISC complex. (From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2009:55.)

A New Mechanism for Regulating Gene Expression: miRNAs

Over the last decade, a new mechanism for regulating messenger ribonucleic acid (mRNA) has been explored in a simple to complex organisms that involve microRNAs (miRNAs). We now know that miRNAs contribute not only to normal development and brain function but also to brain disorders, such as Parkinson and Alzheimer diseases, tauopathies, and brain cancer. miRNAs can affect the regulation of RNA transcription, alternative splicing, molecular modifications, or RNA translation. miRNAs are 21- to 23-nucleotide-long single-strand RNA molecules. Unlike mRNAs that encode

the instructions for ribosome complex translation into proteins, miRNAs are noncoding RNAs that are not translated but are instead processed to form loop structures. miRNAs exhibit a sequence that is partially complementary to one or several other cellular mRNAs. By binding to target mRNA transcripts, the miRNAs serve to interfere with their function, thereby downregulating the expression of these gene products. This gene silencing involves a complex mechanism: The larger miRNA primary transcript is first processed by the Microprocessor, an enzymatic complex consisting of the nuclease Drosha and the double-stranded RNA binding protein Pasha. The mature miRNA binds to its complementary RNA and then interacts with the endonuclease Dicer that is part of the RNA-induced silencing complex (RISC), resulting in the cleavage of the target mRNA and gene silencing (Fig. 33-11).

Currently, 475 miRNAs have been identified in humans, and their total number is estimated to be between 600 and 3,441. Potentially, up to 30 percent of all genes might be regulated by miRNAs, a whole new layer of molecular complexity. A connection between miRNAs and several brain diseases has already been made. For example, miR-133b, which is expressed explicitly in midbrain dopaminergic neurons, is deficient in midbrain tissue from patients with Parkinson disease. Furthermore, the miRNAs encoding miR-9, miR-124a, miR-125b, miR-128, miR-132, and miR-219 are abundantly represented in the fetal hippocampus, are differentially regulated in the aged brain, and are altered in Alzheimer disease hippocampus. Similar RNA species termed short-interfering RNAs (siRNAs) have been discovered in plants where they prevent the transcription of viral RNA. The mechanisms involved in these effects are closely related to those of miRNA. Thus siRNAs are now being used in both basic and clinical research to downregulate specific cellular gene products, thereby advancing the study of pathways involved in neurodevelopment and providing new selective tools to regulate disease-causing genes or therapeutic molecular targets.

Regulation of Neurodevelopment by Extracellular Factors

The interaction of extracellular factors with intrinsic genetic determinants controlling region-specific neurogenesis includes signals that regulate cell proliferation, migration, differentiation, and survival (Table 33-1). Patterning

genes control the expression of growth factor receptors and the molecular machinery of the cell division cycle. Extracellular factors are known to stimulate or inhibit the proliferation of VZ precursors and originate from the cells themselves, termed autocrine, neighboring cells/tissues, or paracrine, or from the general circulation, as in endocrine, all sources known to affect proliferation in the prenatal and postnatal developing brain. Although defined initially in cell culture, several mitogenic growth factors are now well-characterized in vivo, including those stimulating proliferation, such as basic FGF (bFGF), EGF, IGF-I, Shh, and signals inhibiting cell division, such as pituitary adenylate-cyclase–activating polypeptide (PACAP), GABA and glutamate, and members of the TGF-β superfamily. However, in addition to stimulating reentry of cells into the cell cycle, termed a mitogenic effect, extracellular signals also enhance proliferation by promoting survival of the mitotic population, a trophic action. Stimulation of both pathways is necessary to produce maximal cell numbers. These mitogenic and trophic mechanisms during development parallel those identified in carcinogenesis, reflecting roles of c-myc and bcl-2, respectively. Several of the neurotrophins, especially BDNF and neurotrophin-3 (NT3), promote the survival of mitotic precursors as well as the newly generated progeny.

Table 33-1
Regulation of Neurodevelopment by Extracellular Factors

The developmental significance of extracellular mitogens is demonstrated by the expression of the factors and their receptors in regions of neurogenesis. It is also demonstrated by the profound and permanent consequences of altering their activities during development. For example, by administering growth factors to developing embryos or pups, one can induce changes in proliferation in prenatal cortical VZ, postnatal cerebellar EGL, and hippocampal dentate gyrus that produce lifelong modifications in brain region population size and cell composition. Such changes may be relevant to structural differences observed in neuropsychiatric disorders, such as depression, schizophrenia, and autism. Precisely, in the cerebral cortex VZ of the embryonic rat, proliferation is controlled by promitogenic bFGF and antimitogenic PACAP, which are expressed as autocrine/paracrine signals. Positive and negative effects were shown in living embryos in utero by performing intracerebroventricular (ICV) injections of the factors or antagonists. ICV injection of bFGF produced a larger adult cortex composed of 87 percent more neurons, which employed glutamate, thus increasing the ratio of excitatory pyramidal neurons to GABA inhibitory neurons, which were unchanged.

Conversely, embryonic PACAP injection inhibited the proliferation of cortical precursors by 26 percent, reducing the number of labeled layer 5/6 neurons in the cortical plate 5 days later. A similar reduction was accomplished by genetically deleting promitogenic bFGF or leukocyte inhibitory factor (LIF)/ciliary neurotrophic factor (CNTF)/gp130 signaling, diminishing cortical size. Furthermore, the effects of mitogenic signals depended critically on the stage-specific program of regional development, since bFGF injection at later ages when gliogenesis predominates affected glial numbers selectively. Thus developmental dysregulation of mitogenic pathways due to genetic or environmental factors (hypoxia, maternal/fetal infection, or drug or toxicant exposure) will likely produce subtle changes in the size and composition of the developing cortex. Other signals likely to play proliferative roles include Wnt's, TGF-α, IGF-I, and BMPs. Although interactions between intrinsic cortical programs and extrinsic factors remain to be defined, a remarkable new study of mouse embryonic stem cells suggests that embryonic mammalian forebrain specification may be a developmentally ancestral intrinsic program that emerges in the absence of extrinsic signals. In specific culture conditions that block endogenous Shh signaling, mouse embryonic stem cells can sequentially generate the various types of neurons that display the most salient features of genuine cortical pyramidal neurons. When grafted into the cerebral cortex, these cells differentiate into neurons that project to select cortical (visual and limbic regions) and subcortical targets, corresponding to a wide range of pyramidal layer neurons. Insight into precision control of neuronal differentiation will open new avenues to perform neuronal grafts in humans for cellular replacement in various acquired and neurodegenerative diseases.

Similar to the cerebral cortex, later generated populations of granule neurons, such as in the cerebellum and hippocampal dentate gyrus, are also sensitive to growth factor manipulation, which is especially relevant to therapies administered intravenously to premature and newborn infants in the neonatal nursery. Like in humans, cerebellar granule neurons are produced postnatally in rats, but for only 3 weeks, whereas in both species, dentate gyrus neurons are produced throughout life. Remarkably, a single peripheral injection of bFGF into newborn rat pups rapidly crossed into the cerebrospinal fluid (CSF) and stimulated proliferation in the cerebellar EGL by 30 percent as well as hippocampal dentate gyrus by twofold by 8 hours,

consistent with an endocrine mechanism of action. The consequence of mitogenic stimulation in the cerebellum was a 33 percent increase in the number of internal granule layer neurons and a 22 percent larger cerebellum. In the hippocampus, mitotic stimulation elicited by a single bFGF injection increased the absolute number of dentate gyrus granule neurons by 33 percent at 3 weeks, defined stereologically, producing a 25 percent larger hippocampus containing more neurons and astrocytes, a change that persisted lifelong. Conversely, genetic deletion of bFGF resulted in smaller cerebellum and hippocampus at birth and throughout life, indicating that levels of the growth factor were critical for normal brain region formation. Other proliferative signals regulating cerebellar granule neurogenesis include Shh and PACAP, the disruption of which contributes to human medulloblastoma, whereas in the hippocampus, the Wnt family may be involved.

Clinical Implications. There are several clinical implications of these surprising growth factor effects observed in newborns. First, we may need to investigate possible neurogenetic effects of therapeutic agents we administer in the newborn nursery for long-term consequences. Second, because bFGF is as effective in stimulating adult neurogenesis (see subsequent text) as in newborns because of specific transport across the mature BBB, there is the possibility that other protein growth factors are also preferentially transported into the brain and alter ongoing neurogenesis. Indeed, in rats, IGF-I also stimulates mature hippocampal dentate gyrus neurogenesis. Third, other therapeutics cross the BBB efficiently due to their lipid solubility, such as steroids, which inhibit neurogenesis across the age spectrum. Steroids are frequently used perinatally to promote lung maturation and treat infections and trauma, but effects on human brain formation have not been examined. Fourth, it is well known that neurologic development may be delayed in children who experience a severe systemic illness that is associated with numerous inflammatory cytokines. One may wonder to what degree this reflects an interference with neurogenesis and concomitant processes, potentially producing long-term differences in cognitive and motor functional development. Finally, maternal infection during pregnancy is a known risk factor for schizophrenia, and cytokines that cross the placental barrier may directly affect fetal brain cell proliferation and differentiation as well as cell migration, target selection, and synapse maturation, as shown in animal

models, eventually leading to multiple brain and behavioral abnormalities in the adult offspring.

Cell Migration

Throughout the nervous system, newly generated neurons naturally migrate away from proliferative zones to achieve final destinations. If this process is disrupted, abnormal cell localization and function result. In humans, more than 25 syndromes with disturbed neuronal migration have been described. As noted earlier, neurons migrate in both radial and tangential fashions during development and may establish cell layers that are inside-to-outside, or the reverse, according to region. In the developing cerebral cortex, the most well-characterized mechanism is radial migration from underlying VZ to appropriate cortical layers in an inside-to-outside fashion. Also, however, the inhibitory GABA interneurons that are generated in ventrally located medial ganglionic eminences reach the cortex through tangential migration in the intermediate zone along with axonal processes or other neurons. The neurons in the developing cerebellum also exhibit both radial and tangential migration. Purkinje cells leave the fourth ventricle VZ and exhibit radial migration, whereas other precursors from the rhombic lip migrate tangentially to cover the cerebellar surface, establishing the EGL, a secondary proliferative zone. From EGL, newly generated granule cells migrate radially inward to create the internal granule cell layer. Finally, granule interneurons of the olfactory bulb exhibit a different kind of migration, originating in the SVZ of the lateral ventricles overlying the striatum. These neuroblasts divide and migrate simultaneously in the rostral migratory stream in transit to the bulb, on a path comprising chains of cells that support forward movements. The most commonly recognized disorders of human neuronal migration are the extensive lissencephalies (see subsequent text), although incomplete migration of more restricted neuron aggregates (heterotopias) frequently underlies focal seizure disorders.

Animal models have defined molecular pathways involved in neuronal migration. Cell movement requires signals to start and stop migration, adhesion molecules to guide migration, and functional cytoskeleton to mediate cell translocation. The best-characterized mouse model of aberrant neuronal migration is reeler, a spontaneous mutant in which cortical neuron

laminar position is inverted, being generated in outside-to-inside fashion. Reelin is a large, secreted extracellular glycoprotein produced embryonically by the earliest neurons in the cortical preplate, Cajal–Retzius cells, and hippocampus and cerebellum. Molecular and genetic analysis has established a signaling sequence in reelin activity that includes at least two receptors, the very low-density lipoprotein receptor (VLDLR) and the apoprotein E receptor 2 (ApoER2), and the intracellular adapter protein, disabled 1 (Dab1), initially identified in the scrambler mutant mouse, a reelin phenocopy. Current thoughts consider the reelin system as one mediator of radial glia-guided neuron migration, although its specific functions in starting or stopping migration remain controversial. The roles of the VLDL and ApoE2 receptors are intriguing for their possible contributions to Alzheimer disease risk. Recent studies have found human reelin gene (*RELN*) mutations associated with autosomal recessive lissencephaly with cerebellar hypoplasia, exhibiting a markedly thickened cortex with pachygyria, abnormal hippocampal formations, and severe cerebellar hypoplasia with absent folia. Additional studies suggest that reelin polymorphisms may contribute to ASD risk as well.

Concerning cytoskeletal proteins, studies of the filamentous fungus *Aspergillus nidulans* surprisingly provided insight into the molecular machinery underlying the human migration disorder, Miller–Dieker syndrome, lissencephaly associated with abnormal chromosome 17q13.3. Lissencephaly is a diverse disorder characterized by a smooth cortical surface lacking in gyri and sulci, with markedly reduced brain surface area. The absence of convolutions results from a migration defect: the majority of neurons fail to reach their final destinations. In classical lissencephaly (type I), the cerebral cortex is thick and usually four-layered, whereas, in cobblestone lissencephaly (type II), the cortex is chaotically organized with a partly smooth and partly pebbled surface and deficient lamination. The most severely affected parts of the brain are the cerebral cortex and hippocampus, with the cerebellum less affected. In fungus, the gene *NudF* was found to be essential for intracellular nuclear distribution, a translocation process also involved in mammalian cell migration. The human homolog of *NudF* is LIS-1 or PAFAH1B1, a mutation of which accounts for up to 60 percent of lissencephaly cases of type I pathology. The LIS-1 gene product interacts with microtubules and related motor components dynein and dynactin as well

as doublecortin (DCX), which may regulate microtubule stability. Mutations in the DCX gene result in X-linked lissencephaly in males and bands of heterotopic neurons in white matter in females, appearing as a “double cortex” on imaging studies, producing severe mental retardation and epilepsy. Other migratory defects occur when proteins associated with the actin cytoskeleton are affected, such as a mutation in the filamin 1 gene responsible for periventricular nodular heterotopias in humans and mutations of a regulatory phosphokinase enzyme, the CDK5/p35 complex.

Cell migration also depends on molecules mediating cellular interactions, which provide cell adhesion to establish neuron–neuron and neuron–glia relationships or induce attraction or repulsion. Astrotactin is a major glial protein involved in neuronal migration on radial glial processes, whereas neuregulins and their receptors, ErbB2-4, play roles in neuronal–glial migratory interactions. Recent genetic studies associate neuregulin polymorphisms with schizophrenia, suggesting that this developmental disease may depend on altered oligodendrocyte numbers and activities and synaptic functions. Furthermore, some work suggests that early appearing neurotransmitters themselves, GABA and glutamate, and platelet-derived growth factor (PDGF) regulate migration speed. In contrast to radial migration from cortical VZ, GABA interneurons generated in ganglionic eminences employ different mechanisms to leave the ventral forebrain and migrate dorsally into the cerebral cortex. Several signaling systems have been identified, including the Slit protein and Robo receptor, the semaphorins and their neuropilin receptors, and hepatocyte growth factor and its c-Met receptor, all of which appear to repel GABA interneurons from the basal forebrain, promoting tangential migration into the cortex. Significantly, the c-Met receptor has recently been associated with ASDs, suggesting that altered GABA interneuron migration into the cortex and deficits in inhibitory signaling may contribute to the phenotype, including seizures and abnormal cognitive processing. Finally, several human forms of congenital muscular dystrophy with severe brain and eye migration defects result from gene mutations in enzymes that transfer mannose sugars to serine/threonine -OH groups in glycoproteins, thereby interrupting interactions with several extracellular matrix molecules and producing type II cobblestone lissencephalies.

Differentiation and Neuronal Process Outgrowth

After newly produced neurons and glial cells reach their final destinations, they differentiate into mature cells. For neurons, this involves outgrowth of dendrites and extension of axonal processes, the formation of synapses, and the production of neurotransmitter systems, including receptors and selective reuptake sites. Most axons will become insulated by myelin sheaths produced by oligodendroglial cells. Many of these events occur with a peak period from 5 months of gestation onward. During the first several years of life, many neuronal systems exhibit exuberant process growth and branching, which is later decreased by selective "pruning" of axons and synapses, dependent on experience. In contrast, myelination continues for several years after birth and into adulthood.

Although there is tremendous synapse plasticity in the adult brain, a fundamental feature of the nervous system is the point-to-point or topographic mapping of one neuron population to another. During development, neurons extend axons to innervate diverse distant targets, such as the cortex and spinal cord. The structure that recognizes and responds to cues in the environment is the growth cone, located at the axon tip. The axonal process is structurally supported by microtubules that are regulated by numerous microtubule-associated proteins (MAPs), whereas the terminal growth cone exhibits a transition to actin-containing microfilaments. The growth cone has rod-like extensions called filopodia that bear receptors for specific guidance cues present on cell surfaces and in the extracellular matrix. Interactions between filopodial receptors and environmental cues cause growth cones to move forward, turn, or retract. Recent studies have identified the actin-modulating proteins and kinases involved in rapid growth cone movements, such as LIMK kinase that causes the language phenotype associated with Williams syndrome. Perhaps surprising is that activation of growth cone receptors leads to local mRNA translation to produce synaptic proteins, whereas traditional concepts assumed that all proteins were transported to axon terminals from distant neuronal cell somas. The region-specific expression of extracellular guidance molecules, such as cadherins, regulated by patterning genes *Pax6* and *Emx2*, results in the highly directed outgrowth of axons, termed axonal pathfinding. These molecules affect the direction, speed, and fasciculation of axons, acting through either positive or

negative regulation. Guidance molecules may be soluble extracellular factors or may be bound to extracellular matrix or cell membranes. In the latter class of signal is the newly discovered family of transmembrane proteins, the ephrins. Ephrins act via the largest known family of tyrosine kinase receptors in the brain, Eph receptors, and play a significant role in topographic mapping between neuron populations and their targets. Ephrins frequently serve as chemorepellent cues, negatively regulating growth by preventing developing axons from entering incorrect target fields. For example, the optic tectum expresses ephrins A2 and A5 in a gradient that decreases along the posterior to the anterior axis, whereas innervating retinal ganglion cells express a gradient of Eph receptors. Ganglion cell axons from the posterior retina, which possess high Eph A3 receptor levels, will preferentially innervate the anterior tectum because the low-level ephrin expression does not activate the Eph kinase that causes growth cone retraction. In the category of soluble molecules, netrins serve primarily as chemoattractant proteins secreted, for instance, by the spinal cord floor plate to stimulate spinothalamic sensory interneurons to grow into the anterior commissure. In contrast, Slit is a secreted chemorepulsive factor that, through its roundabout (Robo) receptor, regulates midline crossing and axonal fasciculation and pathfinding.

The Neurodevelopmental Basis of Psychiatric Disease

An increasing number of neuropsychiatric conditions are considered to originate during brain development, including schizophrenia, depression, autism, and ADHD. Defining when a condition begins helps direct attention to underlying pathogenic mechanisms. The term neurodevelopmental suggests that the brain is abnormally formed from the very beginning due to disruption of fundamental processes, in contrast to a normally formed brain that is injured secondarily or that undergoes degenerative changes. However, the value of the term neurodevelopmental needs to be reconsidered because of different use by clinicians and pathologists. Also, given that the same molecular signals function in both development and maturity, altering an early ontogenetic process by changes in growth factor signaling, for instance, probably means that other adult functions exhibit ongoing dysregulation as well. For example, clinical researchers of schizophrenia consider the disorder

neurodevelopmental because at the time of onset and diagnosis, the prefrontal cortex and hippocampus are smaller and ventricles enlarged already at adolescent presentation.

In contrast, the neuropathologist uses the term neurodevelopmental for specific morphologic changes in neurons. If a brain region exhibits a normal cytoarchitecture, but with neurons of smaller than the normal diameter, reminiscent of “immature” stages, then this may be considered an arrest of development. However, if the same cellular changes are accompanied by inflammatory signs, such as gliosis and white blood cell infiltrate, then this is termed neurodegeneration. These morphologic and cellular changes may no longer be adequate to distinguish disorders that originate from development versus adulthood, especially given the roles of glial cells, including astrocytes, oligodendrocytes, and microglia, as sources of neurotrophic support during both periods of life. Thus abnormalities in glial cells may occur in both epochs to promote disease or act as mechanisms of repair. Many neurodegenerative processes, such as in Alzheimer and Parkinson diseases, are associated with microglial cells.

On the other hand, neuronal dysfunction in adulthood, such as cell shrinkage, may occur without inflammatory changes. In animal models, interruption of BDNF neurotrophic signaling in the adult brain results in neuron and dendrite atrophy in the cerebral cortex without eliciting glial cell proliferation. Thus finding small neurons without gliosis in the brains of patients with schizophrenia or autism does not necessarily mean that the condition is only or primarily developmental in origin. In turn, several etiologic assumptions about clinical brain conditions may require reexamination.

Because the same processes that mediate development, including neurogenesis, gliogenesis, axonal growth and retraction, synaptogenesis, and cell death, also function during adulthood, a new synthesis has been proposed. All of these processes, although perhaps in more subtle forms, contribute to adaptive and pathologic processes. Successful aging of the nervous system may require precise regulation of these processes, allowing the brain to adapt appropriately and counteract the numerous intrinsic and extrinsic events that could potentially lead to neuropathology. For example, adult neurogenesis and synaptic plasticity are necessary to maintain neuronal circuitry and ensure proper cognitive functions. Programmed cell death is

crucial to prevent tumorigenesis that can occur as cells accumulate mutations throughout life. Thus dysregulation of these ontogenetic processes in adulthood will lead to disruption of brain homeostasis, expressing itself as various neuropsychiatric diseases.

Schizophrenia. The neurodevelopmental hypothesis of schizophrenia postulates that etiologic and pathogenetic factors occurring before the formal onset of the illness, that is, during gestation, disrupt the course of normal development. These subtle early alterations in specific neurons, glia, and circuits confer vulnerability to other later developmental factors, ultimately leading to malfunctions. Schizophrenia is a multifactorial disorder, including both genetic and environmental factors. Clinical studies using risk assessment have identified some relevant factors, including prenatal and birth complications (hypoxia, infection, or substance and toxicant exposure), family history, body dysmorphia, especially structures of neural crest origin, and presence of mild premorbid deficits in social, motor, and cognitive functions. These risk factors may affect ongoing developmental processes such as experience-dependent axonal and dendritic production, programmed cell death, myelination, and synaptic pruning. An intriguing animal model using human influenza-induced pneumonia of pregnant mice shows that the inflammatory cytokine response produced by the mother may directly affect the offspring's brain development, with no evidence of the virus in the fetus or placenta.

Neuroimaging and pathology studies identify structural abnormalities at disease presentation, including smaller prefrontal cortex and hippocampus and enlarged ventricles, suggesting abnormal development. More severely affected patients exhibit a more significant number of affected regions with more considerable changes. In some cases, ventricular enlargement and cortical gray matter atrophy increase with time. These ongoing progressive changes should lead us to reconsider the potential role of active degeneration in schizophrenia, whether due to the disease or its consequences, such as stress or drug treatment. However, classic signs of neurodegeneration with inflammatory cells are not present.

Structural neuroimaging strongly supports the conclusion that the hippocampus in schizophrenia is significantly smaller, perhaps by 5 percent. In turn, brain morphology has been used to assess the etiologic contributions

of genetic and environmental factors. Comparisons of concordance for schizophrenia in monozygotic and dizygotic twins support roles for both factors. Among monozygotic twins, only 40 to 50 percent of both twins have the illness, indicating that the genetic constitution alone does not ensure disease and suggesting that the embryonic environment also contributes. Neuroimaging, pharmacologic, and pathologic studies suggest that some genetic factors allow for susceptibility and that secondary insults, such as birth trauma or perinatal viral infection, provide the other. This model is consistent with imaging studies showing small hippocampus in both affected and unaffected monozygotic twins.

Moreover, healthy, genetically at-risk individuals show hippocampal volumes (smaller) more similar to affected probands than normal controls. Thus hippocampal volume reduction is not pathognomonic of schizophrenia but instead may represent a biologic marker of genetic susceptibility. It is not difficult to envision roles for altered developmental regulators in producing a smaller hippocampus, which in turn limits functional capacity. A smaller hippocampus may result from subtle differences in the levels of transcription factors, such as *NeuroD, Math1,* or *Lhx,* signaling by Wnt3a and downstream mediator *Lef1,* or proliferative control mediated by bFGF, the family members of which exhibit altered expression levels in schizophrenia brain samples. Such genetic limitations may only become manifest following another developmental challenge, such as gestational infection, stressors, or toxicant exposure.

A regional locus of schizophrenia pathology remains uncertain but may include the hippocampus, entorhinal cortex, multimodal association cortex, limbic system, amygdala, cingulate cortex, thalamus, and medial temporal lobe. Despite size reductions in specific regions, attempts to define changes in cell numbers have been unrewarding since most studies do not quantify the entire cell population but assess only regional cell density. Without assessing a region’s total volume, cell density measures alone are limited in revealing population size. Most studies have found no changes in cell density in diverse regions. A single study successfully examining total cell number in the hippocampus found normal neuron density and a 5 percent volume reduction on the left and 2 percent on the right, yielding no significant change in total cell number.

In contrast to total neuron numbers, using neuronal cell-type–specific

markers, many studies have found a decreased density of nonpyramidal GABA interneurons in the cortex and hippocampus. In particular, parvalbumin-expressing interneurons are reduced, whereas calretinin-containing cells are normal, suggesting a deficiency of an interneuron subtype. These morphometric data are supported by molecular evidence for decreased GABA neurons, including reduced mRNA and protein levels of the GABA-synthesizing enzyme, GAD67, in the cortex and hippocampus. Another product of the adult GABA-secreting neurons, reelin, which initially appears in Cajal–Retzius cells in the embryonic brain, is reduced 30 to 50 percent in schizophrenia and bipolar disorder with psychotic symptoms. Such a deficiency, leading to diminished GABA signaling, may underlie a potential compensatory increase in $GABA_A$ receptor binding detected in hippocampal CA 2 to 4 fields by both pyramidal and nonpyramidal neurons, apparently selective since benzodiazepine binding is unchanged. More generally, deficiency in a subpopulation of GABA interneurons raises intriguing new possibilities for schizophrenia etiology. As indicated in the preceding gene patterning section, different subpopulations of forebrain GABA interneurons originate from distinct precursors located in the embryonic basal forebrain. Thus cortical and hippocampal GABA interneurons may derive primarily from the MGE under control of the patterning gene *Nkx2.1,* whereas SVZ and olfactory neurons derive from *Gsh2*-expressing LGE precursors.

Furthermore, the timing and sequence of GABA interneuron generation may depend on a regulatory network, including *Mash1, Dlx1/2,* and *Dlx5/6,* all gene candidates for schizophrenia risk. Indeed, *DLX1* gene expression is reduced in the thalamus of patients with psychosis. Thus abnormal regulation of these factors may diminish selectively GABA interneuron formation, which in turn may represent a genetically determined vulnerability and may contribute to diminished regional brain size or function.

The most compelling neuropathologic evidence for a developmental basis is the finding of aberrantly localized or clustered neurons, especially in lamina II of the entorhinal cortex and in the white matter underlying prefrontal cortex and temporal and parahippocampal regions. These abnormalities represent alterations of developmental neuronal migration, survival, and connectivity. Also, in the hippocampus and neocortex,

pyramidal neurons appear smaller in many studies, exhibiting fewer dendritic arborizations and spines with reduced neuropil, findings that are associated with reductions in neuronal molecules, including MAP2, spinophilin, synaptophysin, and SNAP25. Although the genes associated with schizophrenia are reviewed extensively in other chapters, worth mentioning here is a particularly intriguing candidate gene, *DISC1*, whose protein has roles during development, including regulating cell migration, neurite outgrowth, and neuronal maturation as well as in the adult brain, where it modulates cytoskeletal function, neurotransmission, and synaptic plasticity. DISC1 protein interacts with many other proteins intimately involved in neuronal cell migration and forms a protein complex with Lis1 and NudEL that is downstream of reelin signaling.

Autism Spectrum Disorders. Another condition that is neurodevelopmental in origin is ASDs, a complex and heterogeneous group of disorders characterized by abnormalities in social interaction and communication and the presence of restricted or repetitive interests and activities. In the last edition of DSM (DSM-IV), the ASDs included classic autistic disorder, Asperger syndrome, and pervasive developmental disorder not otherwise specified. These three disorders were grouped due to their common occurrence in families, indicating related genetic factors and shared signs and symptoms. Recent conceptualizations of ASDs propose that there are multiple “autisms” differing in underlying pathogenetic mechanisms and manifestations. The different core symptom domains (or other endophenotypes) will likely be more heritable than the syndromic diagnosis, which was constructed to be inclusive. The broad diversity of ASD signs and symptoms reflects the multiplicity of abnormalities observed in pathologic and functional studies and includes both forebrain and hindbrain regions. Forebrain neurons in the cerebral cortex and limbic system play critical roles in social interaction, communication, and learning and memory. For example, the amygdala, which connects to prefrontal and temporal cortices and fusiform gyrus, plays a prominent role in social and emotional cognition. In ASDs, the amygdala and fusiform gyrus demonstrate abnormal activation during facial recognition and emotional attribution tasks. Some investigators hypothesize that ASDs reflect dysfunctions in specific neural networks, such as the social network.

On the other hand, neurophysiologic tests of evoked cortical potentials and oculomotor responses indicate a standard perception of primary sensory information but disturbed higher cognitive processing. The functional impairments in higher-order cognitive processing and neocortical circuitry suggest a developmental disorder involving synaptic organization, a mechanism that may be uniformly present throughout the brain, a model in distinct contrast to abnormalities of specific neural networks. The earlier reference to the expression of Wnt3a in cells that migrated widely during development and appear in auditory systems is one example of how developmental changes may affect single functional networks. In contrast, changes in common and widely expressed synaptic molecules, such as the neuroligins, would represent the other mechanism.

The most important recent discovery in ASD pathogenesis has been the widely reported and replicated brain growth phenotype: The brain starts with, most likely, average size at birth increases in volume at an accelerated rate by the end of the first year compared to the typically developing child, and this process continues from ages 2 to 4 years. These data derive from both neuroimaging studies as well as measures of head circumference performed by multiple labs. It is not known whether this reflects an acceleration of normal developmental processes or a disease-specific aberration in postnatal development, including changes in cell numbers, neuronal processes, synapse formation, and modifications, or glial cell dysfunction, to name a few. The most prominent differences are observed in the frontal and parietal cortex, cerebellar hemispheres, as well as the amygdala. These findings are also consistent with recent reports of macrocephaly in up to ~20 percent of ASD cases in brain and DNA banks. These findings raise many questions to be addressed by developmental neuroscientists.

Functional neuroimaging studies indicate broad forebrain but also cerebellar dysfunctions in ASD, and classical pathologic studies have suggested abnormalities restricted to limbic and cerebellar structures. However, classical studies were hampered by small sample sizes, poor control for comorbidities such as epilepsy and mental retardation that affect neuroanatomy, and the use of tissue cell density measures as opposed to unbiased stereologic methods to estimate regional neuron numbers. Although previous studies described increased densities of small neurons in interconnecting limbic nuclei, including CA fields, septum, mammillary

bodies, and amygdala, these results have not been replicated by other laboratories. In contrast, the most consistent neuropathology has been observed in the cerebellum (21 of 29 brains), showing reductions in the number of Purkinje neurons without signs of acquired postnatal lesions, such as gliosis, empty baskets, and retrograde loss of afferent inferior olive neurons, suggesting prenatal origins.

A more recent study identifies widespread and nonuniform abnormalities, suggesting dysregulation of many processes, including neuron proliferation, migration, survival, organization, and programmed cell death. Four of six brains were macrocephalic, consistent with an increased size defined by numerous pathology and neuroimaging studies. In the cerebral cortex, there was thickened or diminished gray matter, disorganized laminar patterns, misoriented pyramidal neurons, ectopic neurons in both superficial and deep white matter, and increased or decreased neuron densities. This evidence of abnormal cortical neurogenesis and migration accords well with the deficits in cognitive functions. In the brainstem, neuronal disorganization appeared as discontinuous and malpositioned neurons in olivary and dentate nuclei, ectopic neurons in medulla and cerebellar peduncles, and aberrant fiber tracts. There were widespread patchy or diffuse decreases of Purkinje neurons, sometimes associated with increased Bergmann glia, or ectopic Purkinje neurons in the molecular layer. Hippocampal neuronal atrophy was not observed, and quantitative stereology found no consistent change in neuron density or number. Moreover, a single recent neuropathologic study using multiple immunologic indices has reported increased levels of immune cytokines in the CSF of patients and brain tissues as well as astrocytes expressing high levels of glial fibrillary acidic protein in the frontal and cingulated cortex, white matter, and cerebellum, all suggesting potential immune activation without evidence of an inflammatory process. We await confirmation of these critical findings.

Although seemingly incompatible, these various data support a model of developmental abnormalities occurring at different times, altering regions according to specific schedules of neurogenesis and differentiation. It is notable that a similar range of abnormalities was found in classical studies but was excluded since these abnormalities did not occur in every brain examined. Moreover, in 15 children exposed to the teratogen thalidomide during days 20 to 24 of gestation, when cranial and Purkinje neurogenesis

occurs in the brainstem, four cases exhibited autism. Based on these data, autism is associated with insults at 3 weeks for thalidomide, 12 weeks when inferior olivary neurons are migrating, and ~30 weeks when olivary axons make synapses with Purkinje cells. These diverse abnormalities in cell production, survival, migration, organization, and differentiation in both the hindbrain and forebrain indicate disturbed brain development over a range of stages. Recent genetic studies have defined two genetic polymorphisms associated reproducibly with ASD in several datasets, both of which influence brain developmental processes. The first is *ENGRAILED-2*, the cerebellar patterning gene whose dysregulation causes deficits in Purkinje and granule neurons in animal models and acts to control proliferation and differentiation. The second is the hepatocyte growth factor receptor *cMET*, whose function affects tangential migration of GABA interneurons from the ventral forebrain ganglionic eminences, potentially leading to imbalances of excitatory and inhibitory neurotransmission.

Furthermore, although the cellular derangements may be directly responsible for the core symptoms of autism, there is an alternative hypothesis: Disturbed regulation of developmental processes produces an as-yet-unidentified biochemical, cellular lesion that may be associated with autism. This proposal is supported by the currently known genetic causes of autism that account for 10 percent of cases, including tuberous sclerosis, neurofibromatosis, Smith–Lemli–Opitz syndrome, Rett syndrome, and fragile X mental retardation. These genetic etiologies interfere with cell proliferation control, cholesterol biosynthesis and Shh function, and synaptic and dendrite protein translation and function, fundamental processes in the sequence of development. An intriguing potential link in these monogenetic causes of autism symptoms is their participation in protein synthesis in the synapse, mainly as regulated via the PI3K/Akt signaling pathway and the mammalian target of rapamycin (mTOR) complex, an area of active research.

The Remarkable Discovery of Adult Neurogenesis

In the last decade, there has been a fundamental shift in paradigm regarding the limits of neurogenesis in the brain, with important implications for neural plasticity, mechanisms of disease etiology and therapy, and possibilities of repair. Until recently, it has generally been maintained that we do not produce

new neurons in the brain after birth (or soon after that, considering cerebellar EGL); thus, brain plasticity and repair depend on modifications of a numerically static neural network. We now have strong evidence to the contrary: new neurons are generated throughout life in certain regions, well documented across the phylogenetic tree, including birds, rodents, primates, and humans. As an area of intense interest and investigation, we may expect rapid progress over the next two decades, likely altering models described herein.

The term neurogenesis has been used inconsistently in different contexts, indicating sequential production of neural elements during development, first neurons then glial cells, but frequently connoting only neuron generation in the adult brain, in contrast to gliogenesis. For this discussion, we use the first, more general meaning, and distinguish cell types as needed. The first evidence of mammalian neurogenesis in the adult hippocampus was reported in the 1960s in which ^{3}H-thymidine-labeled neurons were documented. As a standard marker for cell production, these studies used nuclear incorporation of ^{3}H-thymidine into newly synthesized DNA during chromosome replication, which occurs before cells undergo division. After a delay, cells divide, producing two ^{3}H-thymidine-labeled progeny. Cell proliferation is defined as an absolute increase in cell number, which occurs only if cell production is not balanced by cell death. Because there is currently little evidence for a progressive increase in brain size with age, except perhaps for rodent hippocampus, most neurogenesis in the adult brain is compensated for by cell loss. More recent studies of neurogenesis employ the more convenient thymidine analog BrdU, which can be injected into living animals and then detected by immunohistochemistry.

During embryonic development, neurons are produced from almost all regions of the ventricular neuroepithelium. Neurogenesis in the adult, however, is mostly restricted to two regions: the SVZ lining the lateral ventricles and a narrow proliferative zone underlying the dentate gyrus granule layer (subgranular zone) in the hippocampus. In mice, rodents, and monkeys, newly produced neurons migrate from the SVZ in an anterior direction into the olfactory bulb to become GABA interneurons. The process has been elegantly characterized at both ultrastructural and molecular levels. In the SVZ, the neuroblasts (A cells) on their way to the olfactory bulb create chains of cells and migrate through a scaffold of glial cells supplied by

slowly dividing astrocytes (B cells). Within this network of cell chains, there are groups of rapidly dividing neural precursors (C cells). Evidence suggests that the B cells give rise to the C cells, which in turn develop into the A cells, the future olfactory bulb interneurons. The existence of a sequence of precursors with progressively restricted abilities to generate diverse neural cell types makes defining mechanisms that regulate adult neurogenesis in vivo a significant challenge.

As in the developing brain, adult neurogenesis is also subject to regulation by extracellular signals that control precursor proliferation and survival and, in many cases, the very same factors. After the initial discovery of adult neural stem cells generated under EGF stimulation, other regulatory factors were defined, including bFGF, IGF-I, BDNF, and LIF/CNTF. Although the hallmark of neural stem cells includes the capacity to generate neurons, astrocytes, and oligodendroglia, termed multipotentiality, specific signals appear to produce relatively different profiles of cells that may migrate to distinct sites. Intraventricular infusion of EGF promotes primarily gliogenesis in the SVZ, with cells migrating to the olfactory bulb, striatum, and corpus callosum, whereas bFGF favors the generation of neurons destined for the olfactory bulb. Both factors appear to stimulate mitosis directly, with differential effects on the cell lineage produced. In contrast, BDNF may increase neuron formation in SVZ as well as striatum and hypothalamus, though effects may be primarily through promoting survival of newly generated neurons that otherwise undergo cell death. Finally, CNTF and related LIF may promote gliogenesis or support the self-renewal of adult stem cells rather than enhancing a specific cell category.

Remarkably, in addition to direct intraventricular infusions, adult neurogenesis is also affected by peripheral levels of growth factors, hormones, and neuropeptides. Peripheral administration of both bFGF and IGF-I stimulate neurogenesis, increasing selectively mitotic labeling in the SVZ and hippocampal subgranular zone, respectively, suggesting that there are specific mechanisms for factor transport across the BBB. Of interest, elevated prolactin levels, induced by peripheral injection or natural pregnancy, stimulate proliferation of progenitors in the mouse SVZ, leading to increased olfactory bulb interneurons, potentially playing roles in learning new infant scents. This process may be relevant to changes in prolactin seen in psychiatric disease. Conversely, in behavioral paradigms of social stress,

such as territorial challenge by male intruders, activation of the hypothalamic–pituitary–adrenal (HPA) axis with increased glucocorticoids leads to reduced neurogenesis in the hippocampus, apparently through local glutamate signaling. Inhibition is also observed after peripheral opiate administration, a model for substance abuse. Thus neurogenesis may be one target process affected by changes of hormones and neuropeptides associated with several psychiatric conditions.

The discovery of adult neurogenesis naturally leads to questions about whether new neurons can integrate into the complex cytoarchitecture of the mature brain and speculation about its functional significance, if any. In rodents, primates, and humans, new neurons are generated in the dentate gyrus of the hippocampus, an area important for learning and memory. Some adult-generated neurons in humans have been shown to survive for at least 2 years. Furthermore, newly generated cells in the adult mouse hippocampus indeed elaborate extensive dendritic and axonal arborizations appropriate to the neural circuit and display functional synaptic inputs and action potentials. From a functional perspective, the generation or survival of new neurons correlates strongly with multiple instances of behavioral learning and experience. For example, the survival of newly generated neurons is markedly enhanced by hippocampal-dependent learning tasks and by an enriched, behaviorally complex environment. Of perhaps greater importance, a reduction in dentate gyrus neurogenesis impairs the formation of trace memories, that is when an animal must associate stimuli that are separated in time, a hippocampal-dependent task. Finally, in songbirds, neurogenesis is activity-dependent and is increased by foraging for food and learning a new song, whether it occurs seasonally or is induced by steroid hormone administration.

From clinical and therapeutic perspectives, fundamental questions are whether changes in neurogenesis contribute to disease and whether newly formed neurons undergo migration to and integration into regions of injury, replacing dead cells and leading to functional recovery. A neurogenetic response has now been shown for multiple conditions in the adult, including brain trauma, stroke, and epilepsy. For instance, ischemic stroke in the striatum stimulates adjacent SVZ neurogenesis, with neurons migrating to the injury site. Furthermore, in a highly selective paradigm not involving local tissue damage, degeneration of layer three cortical neurons elicited SVZ

neurogenesis and cell replacement. These studies raise the possibility that newly produced neurons typically participate in recovery and may be stimulated as a novel therapeutic strategy. However, in contrast to potential reconstructive functions, neurogenesis may also play roles in pathogenesis: In a kindling model of epilepsy, newly generated neurons were found to migrate to incorrect positions and participate in aberrant neuronal circuits, thereby reinforcing the epileptic state.

Conversely, reductions in neurogenesis may contribute to several conditions that implicate dysfunction or degeneration of the hippocampal formation. Dentate gyrus neurogenesis is inhibited by increased glucocorticoid levels observed in aged rats. It can be reversed by steroid antagonists and adrenalectomy, observations potentially relevant to the correlation of elevated human cortisol levels with reduced hippocampal volumes, and the presence of memory deficits. Similarly, stress-induced increases in human glucocorticoids may contribute to decreased hippocampal volumes seen in schizophrenia, depression, and PTSD.

A potential role for altered neurogenesis in disease has gained the most support in recent studies of depression. Several studies in animals and humans suggest a correlation of decreased hippocampal size with depressive symptoms, whereas clinically significant antidepressant therapy elicits increased hippocampal volume and enhanced neurogenesis, with causal relationships still being defined. For example, postmortem and brain imaging studies indicate cell loss in corticolimbic regions in bipolar disorder and major depression. Significantly, mood stabilizers, such as lithium and valproic acid, as well as antidepressants and ECT, activate intracellular pathways that promote neurogenesis and synaptic plasticity. Furthermore, in a useful primate model, the adult tree shrew, the chronic psychosocial stress model of depression elicited ~15 percent reductions in brain metabolites and a 33 percent decrease in neurogenesis (BrdU mitotic labeling), effects that were prevented by coadministration of antidepressant, tianeptine. More importantly, although stress exposure elicited small reductions in hippocampal volumes, stressed animals treated with antidepressants exhibited increased hippocampal volumes. Similar effects have been found in rodent models of depression.

Also, to the previous structural relationships, recent evidence has begun defining the roles of relevant neurotransmitter systems to antidepressant

effects on behavior and neurogenesis. In a most exciting finding, a causal link between antidepressant-induced neurogenesis and a positive behavioral response has been demonstrated. In the serotonin 1A receptor null mouse, fluoxetine, a selective serotonin reuptake inhibitor [SSRI], produced neither enhanced neurogenesis nor behavioral improvement. Furthermore, when hippocampal neuronal precursors were selectively reduced (85 percent) by X-irradiation, neither fluoxetine nor imipramine induced neurogenesis or behavioral recovery. Finally, one study using hippocampal cultures from normal and mutant rodents strongly supports a neurogenetic role for endogenous NPY, which is contained in dentate gyrus hilar interneurons. NPY stimulates precursor proliferation selectively via the Y1 (not Y2 or Y5) receptor, a finding consistent with the receptor-mediating antidepressive effects of NPY in animal models and the impact of NPY levels on both hippocampal-dependent learning and responses to stress. In aggregate, these observations suggest that volume changes observed with human depression and therapy may directly relate to alterations in ongoing neurogenesis. More generally, the discovery of adult neurogenesis has led to significant changes in our perspectives on the regenerative capacities of the human brain.

NEUROPHYSIOLOGY AND NEUROCHEMISTRY

The study of chemical interneuronal communication is called neurochemistry, and in recent years there has been an explosion of knowledge in understanding chemical transmission between neurons and the receptors affected by those chemicals. It also influences our understanding of brain physiology. This section chapter focuses on the complex heterogeneity of both these areas to help explain the complexity of thoughts, feelings, and behaviors that make up the human experience.

Monoamine Neurotransmitters

The monoamine neurotransmitters and acetylcholine have been historically implicated in the pathophysiology and treatment of a wide variety of neuropsychiatric disorders. Each monoamine neurotransmitter system modulates many different neural pathways, which themselves subserve multiple behavioral and physiologic processes. Conversely, each CNS neurobehavioral process is likely modulated by multiple interacting

neurotransmitter systems, including monoamines.

This complexity poses a significant challenge to understanding the precise molecular, cellular, and systems-level pathways through which various monoamine neurotransmitters affect neuropsychiatric disorders. However, recent advances in human genetics and genomics, as well as in experimental neuroscience, have shed light on this question. Molecular cloning has identified a large number of genes that regulate monoaminergic neurotransmissions, such as the enzymes, receptors, and transporters that mediate the synthesis, cellular actions, and cellular reuptake of these neurotransmitters, respectively. Human genetics studies have provided evidence of tantalizing links between allelic variants in specific monoamine-related genes and psychiatric disorders and trait abnormalities. In contrast, the ability to modify gene function and cellular activity in experimental animals has clarified the roles of specific genes and neural pathways in mediating behavioral processes.

Monoamines act on target cells by binding to specific cell-surface receptors. There are multiple receptor subtypes for each monoamine, which are expressed in diverse regions and subcellular locales and which engage a variety of intracellular signaling pathways. This panoply of receptors thus allows each monoamine neurotransmitter to modulate target cells in many ways; the same molecule may activate some cells while inhibiting others, depending on which receptor subtype is expressed by each cell. The various monoamines are discussed below.

Serotonin. Although only one in a million CNS neurons produces serotonin, these cells influence virtually all aspects of CNS function. The cell bodies of these serotonergic neurons are clustered in the midline raphe nuclei of the brainstem; the rostral raphe nuclei send ascending axonal projections throughout the brain, whereas the descending caudal raphe nuclei send projections into the medulla, cerebellum, and spinal cord (Fig. 33-12). The descending serotonergic fibers that innervate the dorsal horn of the spinal cord have been implicated in the suppression of nociceptive pathways, a finding that may relate to the pain-relieving effects of some antidepressants. The tonic firing of CNS serotonin neurons varies across the sleep–wake cycle, with an absence of activity during rapid eye movement (REM) sleep. Increased serotonergic firing is observed during rhythmic motor behaviors

and suggests that serotonin modulates some forms of motor output.

Most serotonergic innervation of the cortex and limbic system arises from the dorsal and median raphe nuclei in the midbrain; the serotonergic neurons in these areas send projections through the medial forebrain bundle into target forebrain regions. The median raphe provides most of the serotonergic fibers that innervate the limbic system, whereas the dorsal raphe nucleus provides most of the serotonergic fibers that innervate the striatum and thalamus.

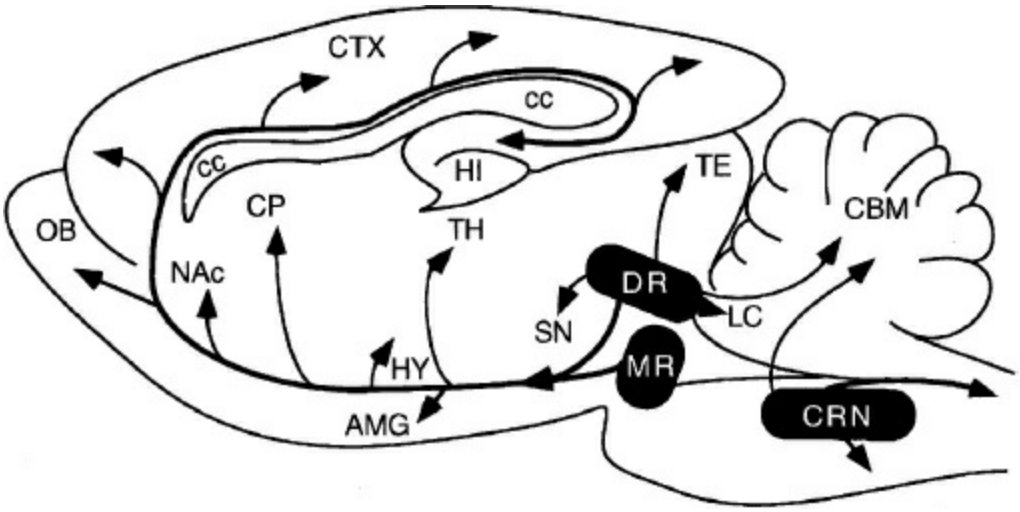

FIGURE 33-12
Brain serotonergic pathways (in rats). Serotonergic neurons are located in brainstem midline raphe nuclei and project throughout the neuraxis. (There is an approximate similarity between monoamine pathways in rats and in humans.) AMG, amygdala; CBM, cerebellum; cc, corpus callosum; CP, caudate putamen; CRN, caudal raphe nuclei; CTX, neocortex; DR, dorsal raphe nucleus; HI, hippocampus; HY, hypothalamus; LC, locus ceruleus; MR, median raphe nucleus; NAc, nucleus accumbens; OB, olfactory bulb; SN, substantia nigra; TE, tectum; TH, thalamus; TM, tuberomammillary nucleus of hypothalamus. (From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2009:65.)

Also, to the different target fields of these serotonergic nuclei, there are cellular differences between their constituent neurons. Dorsal raphe serotonergic fibers are fine, with small vesicle-coated swellings called varicosities, whereas median raphe fibers have large spherical or beaded varicosities. It is unclear to what extent serotonin acts as a true synaptic or "private" neurotransmitter versus action as a local endocrine hormone or "social transmitter," or whether its roles differ depending on the fiber type from which it is released. These fibers show differential sensitivity to the

neurotoxic effects of the amphetamine analog 3,4-methylenedioxy-methamphetamine (MDMA, “ecstasy”), which lesions the fine axons of the dorsal raphe while sparing the thick beaded axons of the median raphe. The significance of these morphologic differences is unclear, although recent work has identified functional differences between the serotonergic neurons of the dorsal and median raphe nuclei.

Dopamine. Dopamine neurons are more widely distributed than those of other monoamines, residing in the midbrain substantia nigra and ventral tegmental area (VTA) and the periaqueductal gray, hypothalamus, olfactory bulb, and retina. In the periphery, dopamine is found in the kidney, where it functions to produce renal vasodilation, diuresis, and natriuresis. Three dopamine systems are highly relevant to psychiatry: The nigrostriatal, mesocorticolimbic, and tuberohypophyseal system (Fig. 33-13). Degeneration of the nigrostriatal system causes Parkinson disease and has led to an intense research focus on the development and function of dopamine neurons in the midbrain substantia nigra nuclei. Dopamine cell bodies in the pars compacta division of this region send ascending projections to the dorsal striatum (especially to the caudate and putamen) and thereby modulate motor control. The extrapyramidal effects of antipsychotic drugs are thought to result from the blockade of these striatal dopamine receptors.

The midbrain VTA lies medial to the substantia nigra and contains dopaminergic neurons that give rise to the mesocorticolimbic dopamine system. These neurons send ascending projections that innervate limbic structures, such as the nucleus accumbens and amygdala; the mesoaccumbens pathway is a central element in the neural representation of reward, and intense research has been devoted to this area in recent years. All known drugs of abuse activate the mesoaccumbens dopamine pathway, and plastic changes in this pathway are thought to underlie drug addiction. The mesolimbic projection is believed to be a significant target for the antipsychotic properties of dopamine receptor antagonist drugs in controlling the positive symptoms of schizophrenia, such as hallucinations and delusions.

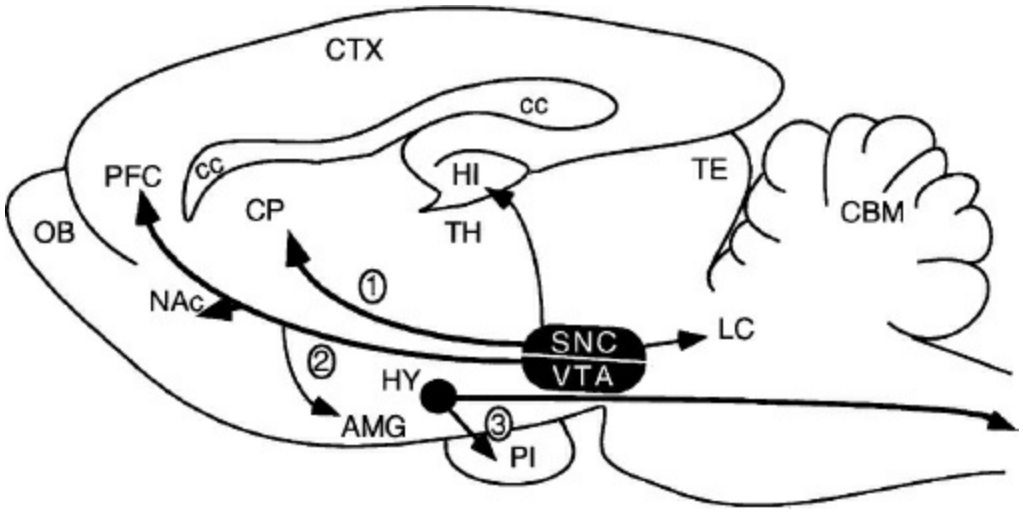

FIGURE 33-13
Brain dopaminergic pathways (in rats). The three principal dopaminergic pathways: (*1*) nigrostriatal pathway, (*2*) mesocorticolimbic pathway, and (*3*) tuberohypophyseal pathway. AMG, amygdala; CBM, cerebellum; cc, corpus callosum; CP, caudate putamen; CTX, neocortex; HI, hippocampus; HY, hypothalamus; LC, locus ceruleus; NAc, nucleus accumbens; OB, olfactory bulb; PFC, prefrontal cortex; PI, pituitary; SNC, substantia nigra pars compacta; TE, tectum; TH, thalamus; VTA, ventral tegmental area. (From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2009:66.)

VTA dopamine neurons also project to cortical structures, such as the prefrontal cortex, and modulate working memory and attention; decreased activity in this pathway is proposed to underlie negative symptoms of schizophrenia. Thus antipsychotic drugs that decrease positive symptoms by blocking dopamine receptors in the mesolimbic pathway may simultaneously worsen these negative symptoms by blocking similar dopamine receptors in the mesocortical pathway. The decreased risk of extrapyramidal side effects seen with clozapine (Clozaril; vs. other typical antipsychotic medications) is thought to be due to its relatively selective effects on this mesocortical projection. The tuberohypophyseal system consists of dopamine neurons in the hypothalamic arcuate and paraventricular nuclei that project to the pituitary gland and thereby inhibit prolactin release. Antipsychotic drugs that block dopamine receptors in the pituitary may thus disinhibit prolactin release and cause galactorrhea.

Norepinephrine and Epinephrine. The postganglionic sympathetic neurons of the ANS release norepinephrine, resulting in widespread

peripheral effects, including tachycardia and elevated blood pressure. The adrenal medulla releases epinephrine, which produces similar effects; epinephrine-secreting pheochromocytoma tumors produce bursts of sympathetic activation, central arousal, and anxiety.

Norepinephrine-producing neurons are found within the brain in the pons and medulla in two major clusterings: The locus ceruleus (LC) and the lateral tegmental noradrenergic nuclei (Fig. 33-14). Noradrenergic projections from both of these regions extensively ramify as they project throughout the neuraxis. In humans, the LC is found in the dorsal portion of the caudal pons and contains approximately 12,000 tightly packed neurons on each side of the brain. These cells provide the central noradrenergic projections to the neocortex, hippocampus, thalamus, and midbrain tectum. The activity of LC neurons varies with the animal's level of wakefulness. Firing rates are responsive to novel or stressful stimuli, with the largest responses to stimuli that disrupt ongoing behavior and reorient attention. Altogether, physiologic studies indicate a role for this structure in the regulation of arousal state, vigilance, and stress response. The projections from lateral tegmental nucleus neurons, which are loosely scattered throughout the ventral pons and medulla, partially overlap those of the LC. Fibers from both cell groups innervate the amygdala, septum, and spinal cord. Other regions, such as the hypothalamus and lower brainstem, receive adrenergic inputs predominantly from the lateral tegmental nucleus. The relatively few neurons that utilize epinephrine as a neurotransmitter are located in the caudal pons and medulla, intermingled with noradrenergic neurons. Projections from these groups ascend to innervate the hypothalamus, LC, and visceral efferent and afferent nuclei of the midbrain.

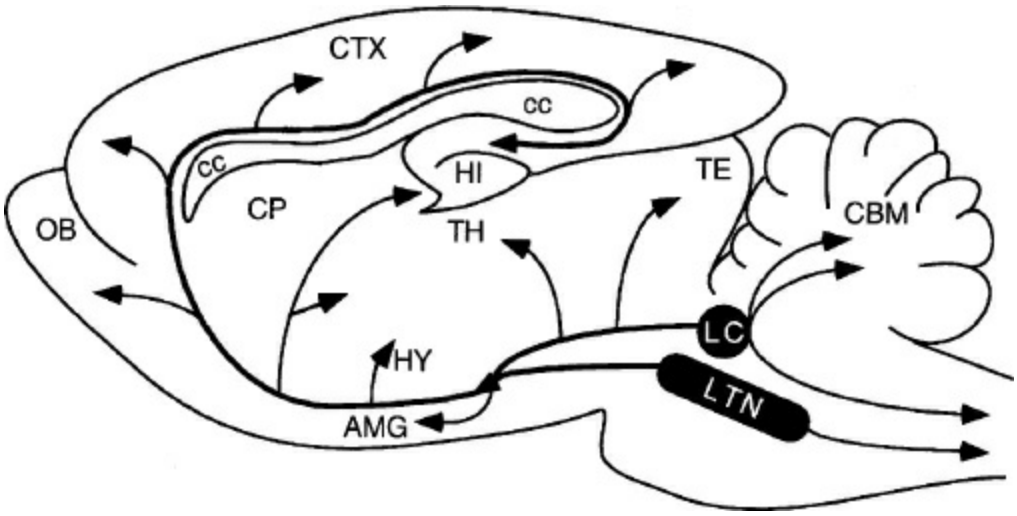

FIGURE 33-14
Brain noradrenergic pathways (in rats). Projections of noradrenergic neurons located in the locus ceruleus (LC) and lateral tegmental noradrenergic nuclei (LTN). AMG, amygdala; CBM, cerebellum; cc, corpus callosum; CP, caudate putamen; CTX, neocortex; HI, hippocampus; HY, hypothalamus; OB, olfactory bulb; TE, tectum; TH, thalamus. (From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2009:66.)

Histamine. Histamine is perhaps best known for its role in allergies. It is an inflammatory mediator stored in mast cells and released upon cellular interaction with allergens. Once released, histamine causes vascular leakage and edema and other facial and topical allergy symptoms. In contrast, central histaminergic neural pathways have only more recently been characterized by immunocytochemistry using antibodies to the synthetic enzyme histidine decarboxylase and histamine. Histaminergic cell bodies are located within a region of the posterior hypothalamus termed the tuberomammillary nucleus. The activity of tuberomammillary neurons is characterized by firing that varies across the sleep–wake cycle, with the highest activity during the waking state, slowed firing during slow-wave sleep, and absence of firing during REM sleep. Histaminergic fibers project diffusely throughout the brain and spinal cord (Fig. 33-15). Ventral ascending projections course through the medial forebrain bundle and then innervate the hypothalamus, diagonal band, septum, and olfactory bulb. Dorsal ascending projections innervate the thalamus, hippocampus, amygdala, and rostral forebrain. Descending projections travel through the central midbrain gray to the dorsal hindbrain and spinal cord. The fibers have varicosities that are seldom

associated with classical synapses, and histamine has been proposed to act at a distance from its sites of release, like a local hormone. The hypothalamus receives the densest histaminergic innervation, consistent with a role for this transmitter in the regulation of autonomic and neuroendocrine processes. Also, muscular histaminergic innervation is seen in monoaminergic and cholinergic nuclei.

Acetylcholine. Within the brain, the axonal processes of cholinergic neurons may either project to distant brain regions (projection neurons) or contact local cells within the same structure (interneurons). Two large clusters of cholinergic projection neurons are found within the brain: The basal forebrain complex and the mesopontine complex (Fig. 33-16). The basal forebrain complex provides most of the cholinergic innervation to the nonstriatal telencephalon. It consists of cholinergic neurons within the nucleus basalis of Meynert, the horizontal and vertical diagonal bands of Broca, and the medial septal nucleus. These neurons project to widespread areas of the cortex and amygdala, to the anterior cingulate gyrus and olfactory bulb, and the hippocampus, respectively. In Alzheimer disease, there is significant degeneration of neurons in the nucleus basalis, leading to a substantial reduction in cortical cholinergic innervation. The extent of neuronal loss correlates with the degree of dementia, and the cholinergic deficit may contribute to the cognitive decline in this disease, consistent with the beneficial effects of drugs that promote acetylcholine signaling in this disorder.

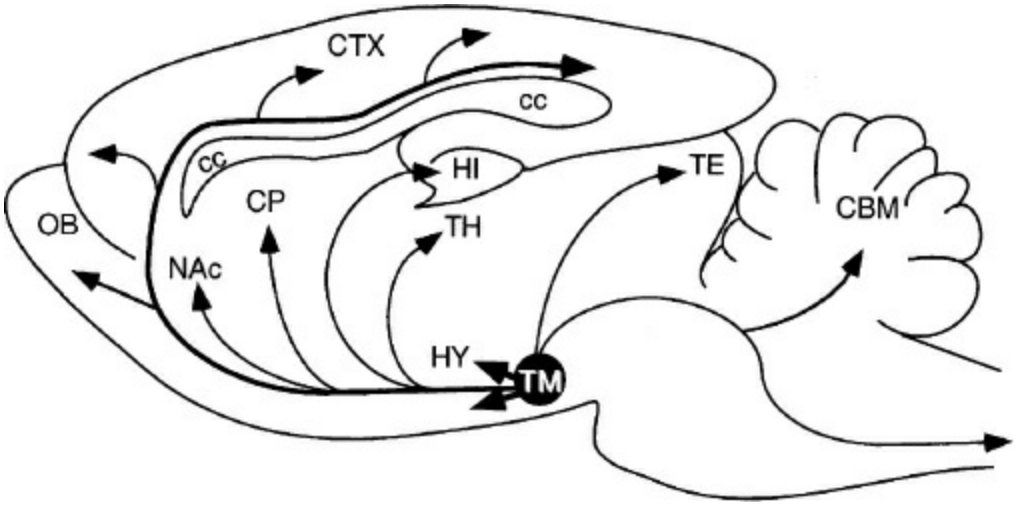

FIGURE 33-15

Brain histaminergic pathways (in rats). Histaminergic neurons are located in the tuberomammillary nucleus of the caudal hypothalamus (TM) and project to the hypothalamus (HY) and more distant brain regions. FIGURE 33-16
Brain cholinergic projection pathways (in rats). The majority of cholinergic projection neurons are located in the basal forebrain complex (BFC) and the mesopontine complex (MPC). AMG, amygdala; CBM, cerebellum; cc, corpus callosum; CP, caudate putamen; CTX, neocortex; HI, hippocampus; HY, hypothalamus; LC, locus ceruleus; NAc, nucleus accumbens; OB, olfactory bulb; SN, substantia nigra; TE, tectum; TH, thalamus. (From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2009:67.)

The mesopontine complex consists of cholinergic neurons within the pedunculopontine and laterodorsal tegmental nuclei of the midbrain and pons and provides cholinergic innervation to the thalamus and midbrain areas (including the dopaminergic neurons of the VTA and substantia nigra) and descending innervation to other brainstem regions such as the LC, dorsal raphe, and cranial nerve nuclei. In contrast to central serotonergic, noradrenergic, and histaminergic neurons, cholinergic neurons may continue to fire during REM sleep and have been proposed to play a role in REM sleep induction. Acetylcholine is also found within interneurons of several brain regions, including the striatum. The modulation of striatal cholinergic transmission has been implicated in the antiparkinsonian actions of

anticholinergic agents. Within the periphery, acetylcholine is a prominent neurotransmitter, located in motoneurons innervating skeletal muscle, preganglionic autonomic neurons, and postganglionic parasympathetic neurons. Peripheral acetylcholine mediates the characteristic postsynaptic effects of the parasympathetic system, including bradycardia and reduced blood pressure, and enhanced digestive function.

Monoamine Synthesis, Storage, and Degradation

Also, to neuroanatomic similarities, monoamines are synthesized, stored, and degraded in similar ways (Fig. 33-17). Monoamines are synthesized within neurons from common amino acid precursors (Fig. 33-17, step 1) and taken up into synaptic vesicles by way of a vesicular monoamine transporter (Fig. 33-17, step 2). On stimulation, vesicles within nerve terminals fuse with the presynaptic terminal and release the neurotransmitter into the synaptic cleft (Fig. 33-17, step 3). Once released, the monoamines interact with postsynaptic receptors to alter the function of postsynaptic cells (Fig. 33-17, step 4), and they may also act on presynaptic autoreceptors on the nerve terminal to suppress further release (Fig. 33-17, step 5). Also, released monoamines may be taken back up from the synaptic cleft into the nerve terminal by plasma membrane transporter proteins (Fig. 33-17, step 6), a process known as reuptake. Reuptake plays an essential role in limiting the total magnitude and temporal duration of monoamine signaling. Once monoamines are taken up, they may be subject to enzymatic degradation (Fig. 33-17, step 7), or they may be protected from degradation by uptake into vesicles. The processing of acetylcholine differs from this scheme and is described later in this section.

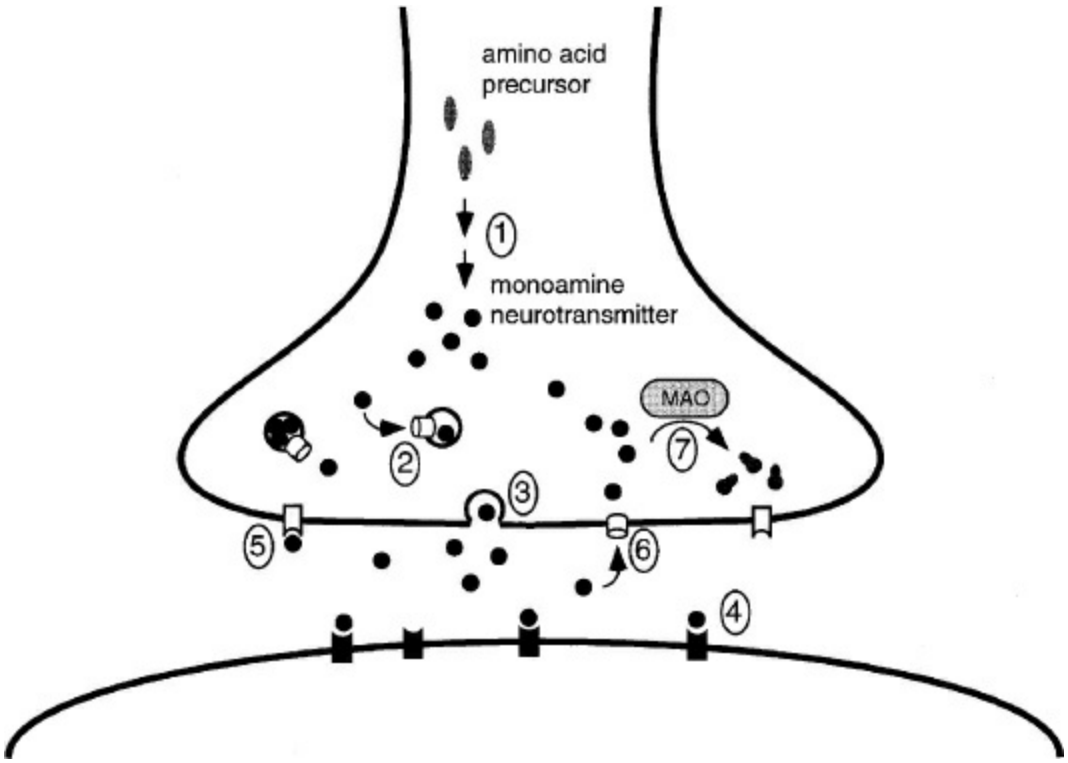

FIGURE 33-17

Serotonin

The CNS contains less than 2 percent of the serotonin in the body; peripheral serotonin is located in platelets, mast cells, and enterochromaffin cells. More than 80 percent of all the serotonin in the body is found in the gastrointestinal system, where it modulates motility and digestive functions. Platelet serotonin promotes aggregation and clotting through a most unusual mechanism: The covalent linkage of serotonin molecules to small GTP-binding proteins, which can then activate these proteins, is a process termed "serotonylation." Peripheral serotonin cannot cross the BBB, so serotonin is synthesized within the brain as well. Serotonin is synthesized from the amino acid tryptophan, which is derived from the diet. The rate-limiting step in serotonin synthesis is the hydroxylation of tryptophan by the enzyme tryptophan hydroxylase to form 5-hydroxytryptophan (4-HT) (Fig. 33-18). Two isoforms of tryptophan hydroxylase exist—one isoform is found mainly in the periphery, whereas the second isoform is restricted to the CNS.

Under normal circumstances, tryptophan concentration is rate-limiting in serotonin synthesis. Therefore, much attention has focused on the factors that determine tryptophan availability. Unlike serotonin, tryptophan is taken up into the brain by way of a saturable active carrier mechanism. Because tryptophan competes with other large neutral amino acids for transport, brain uptake of this amino acid is determined both by the amount of circulating tryptophan and by the ratio of tryptophan to other large neutral amino acids. This ratio may be elevated by carbohydrate intake, which induces insulin release and the uptake of many sizeable neutral amino acids into peripheral tissues.

Conversely, high-protein foods tend to be relatively low in tryptophan, thus lowering this ratio. Moreover, the administration of specialized low tryptophan diets produces significant declines in brain serotonin levels. After tryptophan hydroxylation, 5-hydroxytryptophan is rapidly decarboxylated by aromatic amino acid decarboxylase (an enzyme also involved in dopamine synthesis) to form serotonin.

The first step in the degradation of serotonin is mediated by monoamine oxidase type A (MAO_A), which oxidizes the amino group to form an aldehyde. MAO_A is located in mitochondrial membranes and is nonspecific in its substrate specificity; in addition to serotonin, it oxidizes norepinephrine. The elevation of serotonin levels by MAO inhibitors (MAOIs) is believed to underlie the antidepressant efficacy of these drugs. After oxidation by MAO_A, the resulting aldehyde is further oxidized to 5-hydroxyindoleacetic acid (5-HIAA). Levels of 5-HIAA are often measured as a correlate of serotonergic system activity, although the relationship of these levels to serotonergic neuronal activity remains unclear.

Catecholamines. The catecholamines are synthesized from the amino acid tyrosine, which is taken up into the brain via an active transport mechanism (Fig. 33-19). Within catecholaminergic neurons, tyrosine hydroxylase catalyzes the addition of a hydroxyl group to the meta position of tyrosine, yielding L-dopa. This rate-limiting step in catecholamine synthesis is subject to inhibition by high levels of catecholamines (end-product inhibition). Because tyrosine hydroxylase usually is saturated with substrate, manipulation of tyrosine levels does not readily affect the rate of catecholamine synthesis. Once formed, L-dopa is rapidly converted to dopamine by dopa decarboxylase, which is located in the cytoplasm. It is now recognized that this enzyme acts not only on L-dopa but also on all naturally occurring aromatic L-amino acids, including tryptophan, and thus it is more appropriately termed aromatic amino acid decarboxylase. In noradrenergic and adrenergic neurons, dopamine is actively transported into

storage vesicles, where it is oxidized by dopamine β-hydroxylase to form norepinephrine. In adrenergic neurons and the adrenal medulla, norepinephrine is converted to epinephrine by phenylethanolamine *N*-methyltransferase (PNMT), which is located within the cytoplasmic compartment.

Synthesis of catecholamines. (From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2009:69.)

Two enzymes that play significant roles in the degradation of catecholamines are monoamine oxidase and catechol-*O*-methyltransferase (COMT). MAO is located on the outer membrane of mitochondria, including those within the terminals of adrenergic fibers, and oxidatively deaminates catecholamines to their corresponding aldehydes. Two MAO isozymes with differing substrate specificities have been identified: MAO_A, which preferentially deaminates serotonin and norepinephrine, and MAO type B (MAO_B), which deaminates dopamine, histamine, and a broad spectrum of phenylethylamines. Neurons contain both MAO isoforms. The blockade of monoamine catabolism by MAO inhibitors produces elevations in brain monoamine levels. MAO is also found in peripheral tissues such as the gastrointestinal tract and liver, where it prevents the accumulation of toxic amines. For example, peripheral MAO degrades dietary tyramine, an amine that can displace norepinephrine from sympathetic postganglionic nerve endings, producing hypertension if tyramine is present in sufficient quantities. Thus patients treated with MAO inhibitors are cautioned to avoid pickled and fermented foods that typically have high levels of tyramine. Catechol-O-methyltransferase (COMT) is located in the cytoplasm and is widely distributed throughout the brain and peripheral tissues, although little to none is found in adrenergic neurons. It has a broad substrate specificity, catalyzing the transfer of methyl groups from *S*-adenosyl methionine to the *m*-hydroxyl group of most catechol compounds. The catecholamine metabolites produced by these and other enzymes are frequently measured as indicators of the activity of catecholaminergic systems. In humans, the predominant metabolites of dopamine and norepinephrine are homovanillic acid (HVA) and 3-methoxy-4-hydroxyphenylglycol (MHPG), respectively.

Histamine. As is the case for serotonin, the brain contains only a small portion of the histamine found in the body. Histamine is distributed throughout most tissues of the body, predominantly in mast cells. Because it does not readily cross the BBB, it is believed that histamine is synthesized

within the brain. In the brain, histamine is formed by the decarboxylation of the amino acid histidine by a specific L-histidine decarboxylase. This enzyme is not typically saturated with substrate, so synthesis is sensitive to histidine levels. This is consistent with the observation that the peripheral administration of histidine elevates brain histamine levels. Histamine is metabolized in the brain by histamine *N*-methyltransferase, producing methylhistamine. In turn, methylhistamine undergoes oxidative deamination by MAO_B.

Acetylcholine. Acetylcholine is synthesized by the transfer of an acetyl group from acetyl coenzyme A (ACoA) to choline in a reaction mediated by the enzyme choline acetyltransferase (ChAT). The majority of choline within the brain is transported from the blood rather than being synthesized de novo. Choline is taken up into cholinergic neurons by a high-affinity active transport mechanism, and this uptake is the rate-limiting step in acetylcholine synthesis. The rate of choline transport is regulated, such that increased cholinergic neural activity is associated with enhanced choline uptake. After synthesis, acetylcholine is stored in synaptic vesicles through the action of a vesicular acetylcholine transporter. After vesicular release, acetylcholine is rapidly broken down by hydrolysis by acetylcholinesterase, located in the synaptic cleft. Much of the choline produced by this hydrolysis is then taken back into the presynaptic terminal via the choline transporter. Although acetylcholinesterase is primarily in cholinergic neurons and synapses, a second class of cholinesterase, butyrylcholinesterase, is primarily in the liver and plasma as well as in glia. In the treatment of Alzheimer disease, strategies aimed at enhancing cholinergic function, primarily through the use of cholinesterase inhibitors to prevent usual degradation of acetylcholine, have shown moderate efficacy in ameliorating cognitive dysfunction as well as behavioral disturbances. Cholinesterase inhibitors are also used in the treatment of myasthenia gravis, a disease characterized by weakness due to blockade of neuromuscular transmission by autoantibodies to acetylcholine receptors.

Transporters. A great deal of progress has been made in the molecular characterization of the monoamine plasma membrane transporter proteins. These membrane proteins mediate the reuptake of synaptically released

monoamines into the presynaptic terminal. This process also involves cotransport of Na^+ and Cl^- ions and is driven by the ion concentration gradient generated by the plasma membrane Na^+/K^+ ATPase. Monoamine reuptake is an essential mechanism for limiting the extent and duration of activation of monoaminergic receptors. Reuptake is also a primary mechanism for replenishing terminal monoamine neurotransmitter stores. Moreover, transporters serve as molecular targets for several antidepressant drugs, psychostimulants, and monoaminergic neurotoxins. Whereas transporter molecules for serotonin (SERT), dopamine (DAT), and norepinephrine (NET) have been well characterized, transporters selective for histamine and epinephrine have not been demonstrated.

Among drugs of abuse, cocaine binds with high affinity to all three known monoamine transporters, although the stimulant properties of the drug have been attributed primarily to its blockade of DAT. This view has been recently supported by the absence of cocaine-induced locomotor stimulation in a strain of mutant mice engineered to lack this molecule. Psychostimulants produce a paradoxical locomotor suppression in these animals that has been attributed to their blockade of the serotonin transporter. The rewarding properties of cocaine have also been attributed primarily to dopamine transporter inhibition, although other targets mediate these effects as well since cocaine still has rewarding effects in mice lacking the dopamine transporter. It appears that serotonergic as well as dopaminergic mechanisms, may be involved. Transporters may also provide routes that allow neurotoxins to enter and damage monoaminergic neurons; examples include the dopaminergic neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) and the serotonergic neurotoxin MDMA.

Vesicular Monoamine Transporter. Also, to the reuptake of monoamines into the presynaptic nerve terminal, a second transport process serves to concentrate and store monoamines within synaptic vesicles. The transport and storage of monoamines in vesicles may serve several purposes: (1) to enable the regulated release of the transmitter under appropriate physiologic stimulation, (2) to protect monoamines from degradation by MAO, and (3) to protect neurons from the toxic effects of free radicals produced by the oxidation of cytoplasmic monoamines. In contrast with the plasma membrane transporters, a single type of vesicular monoamine

transporter is believed to mediate the uptake of monoamines into synaptic vesicles within the brain. Consistent with this, blockade of this vesicular monoamine transporter by the antihypertensive drug reserpine (Serpasil) has been found to deplete brain levels of serotonin, norepinephrine, and dopamine and to increase the risk of suicide and affective dysfunction.

Receptors

Ultimately, the effects of monoamines on CNS function and behavior depend on their interactions with receptor molecules. The binding of monoamines to these plasma membrane proteins initiates a series of intracellular events that modulate neuronal excitability. Unlike the transporters, multiple receptor subtypes exist for each monoamine neurotransmitter (Table 33-2).

Serotonin Receptors. The 5-hydroxytryptophan type 1 (5-HT_1) receptors comprise the largest serotonin receptor subfamily, with human subtypes designated 5-HT_{1A}, 5-HT_{1B}, 5-HT_{1D}, 5-HT_{1E}, and 5-HT_{1F}. All five 5-HT_1 receptor subtypes display intronless gene structures, high affinities for serotonin, and adenylate cyclase inhibition. The most intensively studied of these has been the 5-HT_{1A} receptor. This subtype is found on postsynaptic membranes of forebrain neurons, primarily in the hippocampus, cortex, and septum, and on serotonergic neurons, where it functions as an inhibitory somatodendritic autoreceptor. There is a significant interest in the 5-HT_{1A} receptor as a modulator of both anxiety and depression. The downregulation of 5-HT_{1A} autoreceptors by the chronic administration of serotonin reuptake inhibitors has been implicated in their antidepressant effects, and SSRIs may produce some behavioral effects via increases in hippocampal neurogenesis mediated by postsynaptic 5-HT_{1A} receptor activation. Also, partial 5-HT_{1A} receptor agonists such as buspirone display both anxiolytic and antidepressant properties.

Much recent attention has focused on the contributions of 5-$HT_{2A/C}$ receptors to the actions of atypical antipsychotic drugs such as clozapine, risperidone, and olanzapine. Analysis of the receptor-binding properties of these drugs has led to the hypothesis that 5-HT_{2A} receptor blockade correlates with the therapeutic effects of atypical antipsychotics. The 5-HT_{2A}

receptor also influences working memory, which is likely impaired in schizophrenia.

The 5-HT_{2C} receptor is expressed at high levels in many CNS regions, including the hippocampal formation, prefrontal cortex, amygdala, striatum, hypothalamus, and choroid plexus. Stimulation of 5-HT_{2C} receptors has been proposed to produce anxiogenic effects as well as anorectic effects, which may result from interactions with the hypothalamic melanocortin and leptin pathways. 5-HT_{2C} receptors may also play a role in the weight gain and development of type 2 diabetes mellitus associated with atypical antipsychotic treatment. Indeed, a line of mice lacking this receptor subtype exhibits an obesity syndrome associated with overeating and enhanced seizure susceptibility, suggesting that this receptor regulates neuronal network excitability. A variety of antidepressant and antipsychotic drugs antagonize 5-HT_{2C} receptors with high affinity.

Conversely, hallucinogens such as lysergic acid diethylamide (LSD) display agonist activity at 5-HT_2 (and other) serotonin receptor subtypes. 5-HT_{2C} receptor transcripts also undergo RNA editing, producing isoforms of the receptor with significantly altered basal versus serotonin-induced activity. Alterations in 5-HT_{2C} receptor mRNA editing have been found in the brains of suicide victims with a history of major depression, and SSRIs have been shown to alter these editing patterns.

Dopamine Receptors. In 1979, it was recognized that the actions of dopamine are mediated by more than one receptor subtype. Two dopamine receptors, termed D_1 and D_2, were distinguished based on differential binding affinities of a series of agonists and antagonists, distinct effector mechanisms, and distinct distribution patterns within the CNS. It was subsequently found that the therapeutic efficacy of antipsychotic drugs correlated strongly with their affinities for the D_2 receptor, implicating this subtype as an essential site of antipsychotic drug action. Recent molecular cloning studies have identified three additional dopamine receptor genes encoding the D_3, D_4, and

D_5 dopamine receptors. Based on their structure, pharmacology, and primary effector mechanisms, the D_3 and D_4 receptors are considered to be "D_2-like," and the D_5 receptor "D_1-like." The functional roles of the recently discovered subtypes remain to be definitively elucidated.

The D_1 receptor was initially distinguished from the D_2 subtype by its high affinity for the antagonist SCH 23390 and relatively low affinity for butyrophenones such as haloperidol (Haldol). Whereas D_1 receptor activation stimulates cyclic adenosine monophosphate (cAMP) formation, D_2 receptor stimulation produces the opposite effect.

Adrenergic Receptors. As for the α_1 receptors, the functions of α_2 receptor subtypes (designated α_{2A}, α_{2B}, and α_{2C}) have been challenging to determine due to a lack of selective agonists and antagonists; α_2 receptors display both presynaptic autoreceptor and postsynaptic actions, and all appear to inhibit the cAMP formation and to activate potassium channels with resultant membrane hyperpolarization. These receptors regulate neurotransmitter release from peripheral sympathetic nerve endings. The stimulation of central α_2 autoreceptors (likely the α_{2A} subtype) inhibits firing of the noradrenergic neurons of the LC, which are implicated in arousal states. This mechanism has been proposed to underlie the sedative effects of the α_2 receptor agonist clonidine (Catapres). Also, the stimulation of brainstem α_2 receptors has been proposed to reduce sympathetic and to augment parasympathetic nervous system activity. This action may relate to the utility of clonidine in lowering blood pressure and in suppressing the sympathetic hyperactivity associated with opiate withdrawal. Activation of α_2 receptors inhibits the activity of serotonin neurons of the dorsal raphe nucleus, whereas activation of local α_1 receptors stimulates the activity of these neurons, and this is thought to be a significant activating input to the serotonergic system.

Histamine Receptors. Histaminergic systems have been proposed to modulate arousal, wakefulness, feeding behavior, and neuroendocrine responsiveness. Four histaminergic receptor subtypes have been identified

and termed H_1, H_2, H_3, and H_4. The H_4 receptor was identified recently and is detected predominantly in the periphery, in regions such as the spleen, bone marrow, and leukocytes. The other three histamine receptors have a prominent expression in the CNS. H_1 receptors are expressed throughout the body, particularly in the smooth muscle of the gastrointestinal tract and bronchial walls, as well as on vascular endothelial cells. H_1 receptors are widely distributed within the CNS, with exceptionally high levels in the thalamus, cortex, and cerebellum. H_1 receptor activation is associated with G_q activation and stimulation of phosphoinositide turnover and tends to increase excitatory neuronal responses. These receptors are the targets of classical antihistaminergic agents used in the treatment of allergic rhinitis and conjunctivitis. The sedative effects of these compounds derive from their actions in the CNS and implicate histamine in the regulation of arousal and the sleep–wake cycle. Accordingly, a line of mutant mice lacking histamine displays deficits in waking and attention. Also, the sedation and weight gain produced by several antipsychotic and antidepressant drugs have been attributed to H_1 receptor antagonism. Conversely, H_1 receptor agonists stimulate arousal and suppress food intake in animal models.

Cholinergic Receptors. M1 receptors are the most abundantly expressed muscarinic receptors in the forebrain, including the cortex, hippocampus, and striatum. Pharmacologic evidence has suggested their involvement in memory and synaptic plasticity, and recent evaluation of mice lacking the M1 receptor gene revealed deficits in memory tasks believed to require interactions between the cortex and the hippocampus.

Nicotinic receptors have been implicated in cognitive function, especially working memory, attention, and processing speed. Cortical and hippocampal nicotinic acetylcholine receptors appear to be significantly decreased in Alzheimer disease, and nicotine administration improves attention deficits in some patients. The acetylcholinesterase inhibitor galantamine used in the treatment of Alzheimer disease also acts to modulate nicotinic receptor function positively. The α_7 nicotinic acetylcholine receptor subtype has been implicated as one of many possible susceptibility genes for schizophrenia, with lower levels of this receptor being associated with impaired sensory gating. Some rare forms of the familial epilepsy syndrome autosomal

dominant nocturnal frontal lobe epilepsy (ADNFLE) are associated with mutations in the α_4 or β_2 subunits of the nicotinic acetylcholine receptor. Finally, the reinforcing properties of tobacco use are proposed to involve the stimulation of nicotinic acetylcholine receptors located in mesolimbic dopaminergic reward pathways.

Amino Acid Neurotransmitters

For more than 50 years, biogenic amines have dominated thinking about the role of neurotransmitters in the pathophysiology of psychiatric disorders. However, over the last decade, evidence has accumulated from postmortem, brain imaging, and genetic studies that the amino acid neurotransmitters, in particular glutamic acid and GABA, play an important, if not central, role in the pathophysiology of a broad range of psychiatric disorders including schizophrenia, bipolar disorder, major depression, Alzheimer disease, and anxiety disorders.

Glutamic Acid. Glutamate mediates fast excitatory neurotransmission in the brain and is the transmitter for approximately 80 percent of brain synapses, particularly those associated with dendritic spines. The repolarization of neuronal membranes that are depolarized by glutamatergic neurotransmission may explain perhaps 80 percent of the brain's energy expenditure. The concentration of glutamate in the brain is 10 mM, the highest of all amino acids, of which approximately 20 percent represents the neurotransmitter pool of glutamate.

Two families of receptors mediate the postsynaptic effects of glutamate. The first are the glutamate-gated cation channels that are responsible for fast neurotransmission. The second type of glutamate receptor are the metabotropic glutamate receptors (mGluR), which are G-protein–coupled receptors like α-adrenergic receptors and dopamine receptors. The mGluRs primarily modulate glutamatergic neurotransmission.

MAJOR GLUTAMATERGIC PATHWAYS IN THE BRAIN. All primary sensory afferent systems appear to use glutamate as their neurotransmitter, including retinal ganglion cells, cochlear cells, trigeminal nerve, and spinal afferents. The thalamocortical projections that distribute afferent information broadly to

the cortex are glutamatergic. The pyramidal neurons of the corticolimbic regions, the primary source of intrinsic, associational, and efferent excitatory projections from the cortex, are glutamatergic. A temporal lobe circuit that figures significantly in the development of new memories is a series of four glutamatergic synapses: The perforant path innervates the hippocampal granule cells that innervate CA3 pyramidal cells that innervate CA1 pyramidal cells. The climbing fibers innervating the cerebellar cortex are glutamatergic, as well as the corticospinal tracks.

IONOTROPIC GLUTAMATE RECEPTORS. Three families of ionotropic glutamate receptors have been identified based on selective activation by conformationally restricted or synthetic analogs of glutamate. These include α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA), kainic acid (KA), and *N*-methyl-D-aspartic acid (NMDA) receptors. Subsequent cloning revealed 16 mammalian genes that encode structurally related proteins, which represent subunits that assemble into functional receptors. Glutamate-gated ion channel receptors appear to be tetramers, and subunit composition affects both the pharmacologic and the biophysical features of the receptor.

METABOTROPIC GLUTAMATE RECEPTORS. These receptors are so designated because G proteins mediate their effects. All mGluRs are activated by glutamate, although their sensitivities vary remarkably. To date, eight mGluRs have been cloned. These genes encode for seven membrane-spanning proteins that are members of the superfamily of G-protein–coupled receptors.

THE ROLE OF ASTROCYTES. Specialized end-feet of the astrocyte surround glutamatergic synapses. The astrocyte expresses the two Na^+-dependent glutamate transporters that play the primary role in removing glutamate from the synapse, thereby terminating its action: EAAT1 and EAAT2 (*excitatory amino acid transporter*). The neuronal glutamate transporter, EAAT3, is expressed in upper motor neurons, whereas EAAT4 is expressed primarily in cerebellar Purkinje cells and EAAT5 in the retina. Mice homozygous for null mutations of either EAAT1 or EAAT2 exhibit elevated extracellular glutamate and excitotoxic neurodegeneration. Notably, several studies have

described the loss of EAAT2 protein and transport activity in the ventral horn in amyotrophic lateral sclerosis.

The astrocytes express AMPA receptors so that they can monitor synaptic glutamate release. GlyT1, which maintains subsaturating concentrations of glycine in the synapse, is expressed on the astrocyte plasma membrane. GlyT1 transports three Na^+ out for each molecule of glycine transported into the astrocyte. This stoichiometry results in a robust reversal of the direction of transport when glutamate released in the synapse activates the AMPA receptors on the astrocyte, thus depolarizing the astrocyte. Thus glycine release in the synapse by GlyT1 is coordinated with glutamatergic neurotransmission.

Similarly, activation of the astrocyte AMPA receptors causes GRIP to dissociate from the AMPA receptor and bind to serine racemase, activating it to synthesize D-serine. D-Serine levels are also determined by D-amino acid oxidase (DAAO) with low D-serine levels in the cerebellum and brainstem where DAAO expression is high, and high D-serine levels are found in corticolimbic brain regions where DAAO expression is relatively low. In contrast, the expression of GlyT1 is highest in the cerebellum and brainstem. This distribution suggests that D-serine is the primary modulator of the NMDA receptor in the forebrain, whereas glycine is more prominent in the brainstem and cerebellum.

PLASTICITY IN GLUTAMATERGIC NEUROTRANSMISSION. The extinction of conditioned fear is an active process mediated by the activation of NMDA receptors in the amygdala. Treatment of rats with NMDA receptor antagonists prevents the extinction of conditioned fear, whereas treatment with the glycine modulatory site partial agonist D-cycloserine facilitates the extinction of conditioned fear. (D-Cycloserine is an antibiotic used to treat tuberculosis that has 50 percent of the efficacy of glycine at the NMDA receptor.) Patients with acrophobia were administered either placebo or a single dose of D-cycloserine along with cognitive-behavioral therapy (CBT) to determine whether the phenomenon generalizes to humans. D-Cycloserine plus CBT resulted in a highly significant reduction in acrophobic symptoms that persisted for at least 3 months as compared to placebo plus CBT. Other placebo-controlled clinical trials support the notion that D-cycloserine is a

robust enhancer of CBT, suggesting that pharmacologically augmenting neural plasticity may be used to bolster psychological interventions.

Fragile X mental retardation protein (FMRP), which is deficient in individuals with fragile X syndrome, appears to be synthesized locally within the spine during times of NMDA receptor activation and also plays a role in transporting specific mRNAs to the spine for translation. Notably, mice in which the FMRP gene has been inactivated through a null mutation, as well as patients with fragile X syndrome have fewer dendritic spines, the preponderance of which have an immature morphology. Loss of FMRP exaggerates responses of mGluR5, which stimulates dendritic protein synthesis, and treatment with an mGluR5 antagonist reverses the fragile-X–like phenotype in mice with the FMRP gene inactivated.

EXCITOTOXICITY. In the early 1970s, it was shown that the systemic administration of large amounts of monosodium glutamate to immature animals resulted in the degeneration of neurons in brain regions where the BBB was deficient.

Excitotoxicity is also implicated as a proximate cause of neuronal degeneration in Alzheimer disease. Most evidence points to the toxic consequences of aggregates of β-amyloid, especially β-amyloid$_{1\text{-}42}$. The β-amyloid fibrils depolarize neurons, resulting in loss of the Mg^{2+} block and enhanced NMDA receptor sensitivity to glutamate. The fibrils also impair glutamate transport into astrocytes, thereby increasing the extracellular concentration of glutamate. β-Amyloid directly promotes oxidative stress through inflammation that further contributes to neuronal vulnerability to glutamate. Thus, several mechanisms contribute to neuronal vulnerability to NMDA-receptor–mediated excitotoxicity in Alzheimer disease. Memantine, a recently approved treatment for mild to moderate Alzheimer disease, is a weak noncompetitive inhibitor of NMDA receptors. It reduces the tonic sensitivity of NMDA receptors to excitotoxicity but does not interfere with "phasic" neurotransmission, thereby attenuating neuronal degeneration in Alzheimer disease.

Inhibitory Amino Acids: GABA. GABA is the major inhibitory neurotransmitter in the brain, where it is broadly distributed and occurs in millimolar concentrations. Given its physiologic effects and distributions, it is

not surprising that the dysfunction of GABAergic neurotransmission has been implicated in a broad range of neuropsychiatric disorders, including anxiety disorders, schizophrenia, alcohol dependence, and seizure disorders. Chemically, GABA differs from glutamic acid, the major excitatory neurotransmitter, only by the removal of a single carboxyl group from the latter.

GABA is synthesized from glutamic acid by glutamic acid decarboxylase (GAD), which catalyzes the removal of the α-carboxyl group. In the CNS, the expression of GAD appears to be restricted to GABAergic neurons, although in the periphery, it is expressed in pancreatic islet cells. Two distinct but related genes encode GAD. GAD65 is localized to nerve terminals, where it is responsible for synthesizing GABA that is concentrated in the synaptic vesicles. Consistent with its role in fast inhibitory neurotransmission, mice homozygous for a null mutation of GAD65 have an elevated risk for seizures. GAD67 appears to be the primary source for neuronal GABA because mice homozygous for a null mutation of GAD67 die at birth, have a cleft pallet, and exhibit significant reductions in brain GABA.

GABA is catabolized by GABA transaminase (GABA-T) to yield succinic semialdehyde. Transamination generally occurs when the parent compound, α-ketoglutarate, is present to receive the amino group, thereby regenerating glutamic acid. Succinic semialdehyde is oxidized by succinic semialdehyde dehydrogenase (SSADH) into succinic acid, which reenters the Krebs cycle. GABA-T is a cell surface, a membrane-bound enzyme expressed by neurons and glia, which is oriented toward the extracellular compartment. As would be anticipated, drugs that inhibit the catabolism of GABA have anticonvulsant properties. One of the mechanisms of action of valproic acid is the competitive inhibition of GABA-T. γ-Vinyl-GABA is a suicide substrate inhibitor of GABA-T that is used as an anticonvulsant in Europe (vigabatrin [Sabril]).

The synaptic action of GABA is also terminated by high-affinity transport back into the presynaptic terminal as well as into astrocytes. Four genetically distinct GABA high-affinity transporters have been identified with differing kinetic and pharmacologic characteristics. They all share homology with other neurotransmitter transporters with the characteristic of 12 membrane-spanning domains. The active transport is driven by the sodium gradient so that upon depolarization, transportation of GABA out of the neuron is

favored. GABA transported into astrocytes is catabolized by GABA-T and ultimately converted to glutamic acid and then to glutamine, which is transported back into the presynaptic terminal for GABA synthesis. Tiagabine (Gabitril) is a potent GABA transport inhibitor that is used to treat epilepsy. Preliminary results suggest that it also may be useful in panic disorder.

$GABA_A$ RECEPTORS. $GABA_A$ receptors are distributed throughout the brain. The $GABA_A$ complex, when activated, mediates an increase in membrane conductance with an equilibrium potential near the resting membrane potential of –70 mV (Fig. 33-20). In the mature neuron, this typically results with an influx of Cl^-, causing membrane hyperpolarization. Hyperpolarization is inhibitory because it increases the threshold for generating an action potential. In immature neurons, which have unusually high levels of intracellular Cl^-, activating the $GABA_A$ receptor can counterintuitively cause depolarization. For this reason, anticonvulsants that act by enhancing $GABA_A$ receptor activity may exacerbate seizures in the neonatal period.

Barbiturates such as phenobarbital and pentobarbital are noted for their sedative and anticonvulsant activities. Barbiturates allosterically increase the affinities of the binding sites for GABA and benzodiazepines at pharmacologically relevant concentrations. Barbiturates also affect channel dynamics by markedly increasing the extended open state and reducing the short open state, thereby increasing Cl^- inhibition. Chemically modified analogs of progesterone and corticosterone have been shown in behavioral studies to have sedative and anxiolytic effects through their interaction with the $GABA_A$ receptor complex. They share features with barbiturates, although they act at a distinctly different site. Thus, they allosterically enhance agonist ligand binding to the receptor and increase the duration of chloride channel opening. A variety of behavioral effects associated with steroid administration or fluctuation of endogenous steroids and sex-specific effects of GABAergic drugs have been linked to the action of endogenous neurosteroids.

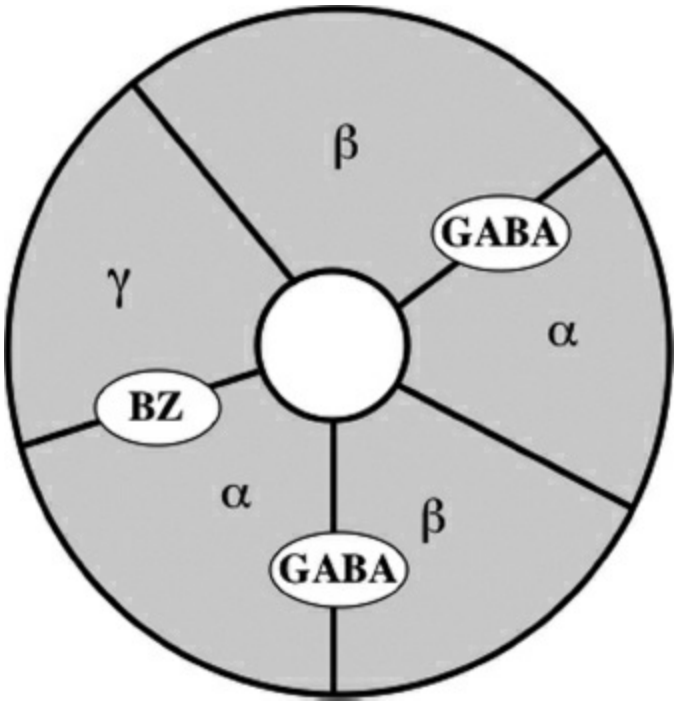

FIGURE 33-20
Schematic representation of the $GABA_A$ receptor. The receptor-channel complex is a heteropentamer. The GABA binding site is at the interface of the α and β subunits. The benzodiazepine binding site is at the interface between the γ and α subunits. (From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2009:81.)

Concerning $GABA_A$ receptor antagonists, picrotoxin, like the barbiturates, alters channel dynamics but in the opposite direction by reducing long open states and favoring the briefest open state. The proconvulsant pentylenetetrazol also acts by reducing chloride channel permeability. Penicillin, which at high concentrations is proconvulsant, binds to the positively charged residues in the channel, thereby occluding it. As a general class, anesthetics, including barbiturates, steroids, and volatile anesthetics, increase chloride conductance, thereby inhibiting neurotransmissions. Amino acids in the membrane-spanning domain of the GABA receptor subunits confer sensitivity to anesthetics. The precise mechanism whereby ethanol enhances $GABA_A$ receptor function remains unclear due to inconsistent results, suggesting that subunit composition may be necessary. However, recent studies suggest that ethanol increases the response of the tonic GABA-activated currents, which contain the δ subunit and exhibit remarkably high

affinity to GABA.

Recently, recombinant DNA strategies exploiting site-directed mutagenesis have permitted the identification of sites on the specific subunits that mediate the pharmacologic action of drugs such as the benzodiazepines. Removal of the binding ability for benzodiazepines has established that the α_1 subunit plays a significant role in the sedative and amnestic effects of benzodiazepines, whereas inactivating the benzodiazepine site on the α_2 subunit eliminates the anxiolytic effect of benzodiazepines

$GABA_B$ RECEPTORS. The $GABA_B$ receptors are distinguished pharmacologically from $GABA_A$ receptors by the fact that they are insensitive to the canonical $GABA_A$ receptor antagonist bicuculline and that they are potently activated by baclofen [β-(4-chlorophenyl)-GABA], which is inactive at $GABA_A$ receptors. They are members of the G-protein–coupled superfamily of receptors but are highly unusual, as they are made of a dimer of two seven-transmembrane–spanning subunits. $GABA_B$ receptors are widely distributed throughout the nervous system and are localized both presynaptically and postsynaptically. The postsynaptic $GABA_B$ receptors cause a long-lasting hyperpolarization by activating potassium channels. Presynaptically, they act as autoreceptors and heteroreceptors to inhibit neurotransmitter release.

GLYCINE AS A NEUROTRANSMITTER. Glycine is an inhibitory neurotransmitter primarily in the brainstem and spinal cord, although the expression of glycine receptor subunits in the thalamus, cortex, and hippocampus suggests a broader role. Glycine is a nonessential amino acid that is synthesized in the brain from L-serine by serine hydroxymethyltransferase. Glycine is concentrated within synaptic vesicles by H^+-dependent vesicular inhibitory amino acid transporter (VIAAT or VGAT), which also transports GABA. Termination of the synaptic action of glycine is through reuptake into the presynaptic terminal by the glycine transporter II (GlyT2), which is quite distinct from GlyT1 that is expressed in astrocytes and modulates NMDA receptor function.

The inhibitory effects of glycine are mediated by a ligand-gated chloride

channel, which can also respond to β-alanine, taurine, L-alanine, L-serine, and proline, but not to GABA. The canonical antagonist for the glycine receptor is the plant alkaloid strychnine. The receptor was first identified through the specific binding of [^{3}H]strychnine. [^{3}H]Glycine binds to two sites: One that is displaceable by strychnine and represents the glycine A receptor and a second that is insensitive to strychnine and is designated the glycine B receptor, representing the glycine modulatory site on the NMDA receptor.

Neuropsychiatric Implications of Amino Acid Transmitters

SCHIZOPHRENIA. Evidence accumulating from postmortem, pharmacologic, and genetic studies is shifting the focus of the pathophysiology of schizophrenia from dopamine to glutamate and GABA. Indeed, after the use of D_2 receptor antagonists as the sole treatment of schizophrenia for the last 50 years, more than two-thirds of the treated patients remain substantially disabled. Early postmortem studies indicated a reduction in the activity of GAD in the cortex in patients with schizophrenia as compared to suitable controls. With the advent of immunocytochemistry and gene expression techniques, it has been possible to define the GABAergic deficit in schizophrenia more precisely. It appears that the parvalbumin-positive GABAergic interneurons in the intermediate layers of the cortex bear the brunt of the pathology, which includes reduced expression of GAD67, parvalbumin, and the GABA transporter (GAT). The finding that $GABA_A$ receptors are upregulated, as measured by autoradiography or with antibodies, supports the theory that these changes reflect the hypofunction of the presynaptic GABAergic neurons. These particular GABAergic interneurons, which include the chandelier cells, play an essential role in negative feedback inhibition to the pyramidal cells in the cortex. Despite this highly reproducible neuropathology, genes related to GABAergic function have not figured prominently in genome-wide searches, suggesting that GABAergic deficits may be a downstream consequence of some more proximal genetic defects.

The theory that hypofunction of NMDA receptors is an etiologic factor in schizophrenia initially arose from the observation that phencyclidine (PCP) and related dissociative anesthetics that block NMDA receptors produce a syndrome that can be indistinguishable from schizophrenia (Fig. 33-21).

Dissociative anesthetics are so named because they prevent the acquisition of new memories while the patient is conscious. In fact, under laboratory conditions, low-dose infusion of ketamine can produce positive symptoms, negative symptoms, and specific cognitive deficits associated with schizophrenia in clear consciousness. Subsequent studies indicated that low-dose ketamine could also cause enhanced amphetamine-induced subcortical dopamine release as is observed in schizophrenia, as well as abnormal cortical event-related potentials (ERPs) and disruption of prepulse inhibition in experimental animals.

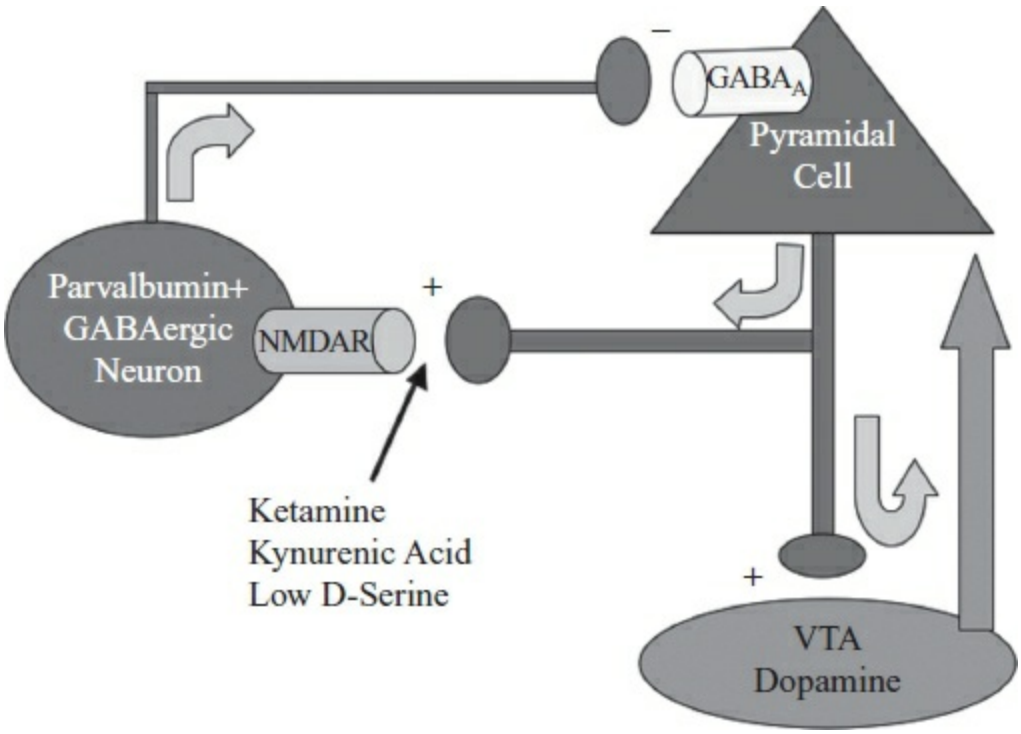

FIGURE 33-21
Pathologic circuit in schizophrenia. The NMDA receptors on the rapidly firing parvalbumin (PV) expressing GABAergic interneurons in the intermediate levels of the cortex are disproportionately sensitive to antagonists or loss of the coagonist, d-serine. NMDA receptor hypofunction causes reduced expression of PV, GAD67, and the GABA transporter and upregulation of $GABA_A$ receptors on pyramidal neurons. Disinhibition of the pyramidal neurons causes cognitive dysfunction and negative symptoms and drives excessive subcortical dopamine release resulting in psychosis. (From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2009:83.)

Several putative risk genes for schizophrenia are closely associated with

the NMDA receptor function. DAAO, which encodes a protein that activates D-amino acid oxidase, has been repeatedly linked to the risk of schizophrenia. D-Amino acid oxidase itself has been associated with increased risk. Recently an allelic variant of serine racemase in the promoter region has also been associated with the risk for schizophrenia. Each of these gene variants could reduce the availability of D-serine in the cortex, thereby impairing the NMDA receptor function. Notably, CSF and blood levels of D-serine are significantly reduced in patients with schizophrenia. Neuregulin 1 appears to be a convincing risk gene and interacts directly with NMDA receptors. Dysbindin, another risk gene, is expressed in glutamatergic terminals. mGluR3, which downregulates glutamate release, has also been associated with schizophrenia.

Recent findings have provided a link between the GABAergic neuropathology and NMDA receptor hypofunction. Chronic treatment of rats with NMDA receptor antagonists causes downregulation of GAD67, parvalbumin, and GAT. The sensitive subpopulation of GABAergic neurons are interneurons that fire rapidly and provide the perisomatic innervation of the pyramidal cells. Their NMDA receptors appear to be much more sensitive to antagonists than those less active GABAergic neurons and pyramidal cells. The subtly reduced GABAergic inhibition results in a disinhibition of the glutamatergic pyramidal output. This degradation of the inhibitory feedback could account for the cognitive deficits and negative symptoms in schizophrenia, and the disinhibited output also results in elevated subcortical dopamine release and psychosis. Thus psychosis would be considered a downstream event resulting from a disruption in critical glutamatergic-GABAergic synaptic function in the cerebral cortex.

ANXIETY AND DEPRESSION. GABAergic dysfunction has been associated with anxiety disorders, especially panic disorder, as well as with major depressive disorder. Clinically, there is considerable comorbidity between anxiety and affective disorders. Decreased levels of the $GABA_A$ receptor modulators, the three α-reduced neuroactive steroids, have been found both in plasma and in CSF in major depressive disorder. Effective treatment with SSRIs increases the neurosteroid levels. In contrast, in patients with panic disorder, the plasma neurosteroid levels were significantly elevated, perhaps as a compensatory mechanism. Magnetic resonance spectroscopy (MRS) has disclosed significant reductions in GABA levels in the anterior cingulate and the basal ganglia of medicated patients with panic disorder. PET scanning reveals a highly selective reduction in benzodiazepine receptor sites bilaterally in the insular cortex in panic disorder. A genome-wide screen has shown significant linkage at 15q in a region containing $GABA_A$ receptor subunit genes and panic disorder. MRS reveals significant reductions in both GABA and glutamate/glutamine (Glx) in the prefrontal cortex in major depressive disorder. Postmortem studies indicate upregulation of the $GABA_A$ receptor α_1 and β_3 subunits in the cerebral cortices of depressed patients who committed suicide, consistent with a reduction in GABAergic neurotransmission. The reduced levels of GABA in the occipital cortex in episodes of major depressive disorder normalized with effective treatment with SSRI or with ECT.

Glutamatergic dysfunction has also been implicated in depression. NMDA receptor antagonists have antidepressant effects in several animal models of depression, including forced swim, tail suspension, and learned helplessness. A single injection of ketamine protects the induction of behavioral despair in rats for up to 10 days. Chronic treatment with antidepressants alters the expression of NMDA receptor subunits and decreases glycine receptor B binding. Two placebo-controlled clinical trials have shown that a single dose of ketamine can produce a rapid, substantial, and persistent reduction in symptoms in patients with major depressive disorder.

ALCOHOLISM. Ethanol at concentrations associated with intoxication has a dual action of enhancing GABAergic receptor function and attenuating the

NMDA receptor function. The GABA receptor effects may be associated with the anxiolytic effects of ethanol. Persistent abuse and dependency on ethanol result in a downregulation of $GABA_A$ receptors and an upregulation of NMDA receptors such that acute discontinuation of ethanol results in a hyperexcitable state characterized by delirium tremens. Furthermore, supersensitive NMDA receptors in the context of thiamine deficiency may contribute to the excitotoxic neuron degeneration of Wernicke–Korsakoff syndrome.

Acamprosate is a derivative of homotaurine that was developed as an agent to reduce alcohol consumption, craving, and relapse in alcoholic patients, for which it exhibits moderate efficacy in clinical trials. Because taurine resembles GABA, it was thought that acamprosate acted via $GABA_A$ receptors, but electrophysiologic studies found little evidence to support this hypothesis. Subsequent studies demonstrated that it inhibited NMDA receptor responses in cortical slices and recombinant NMDA receptors. The precise mechanism whereby acamprosate alters NMDA receptor function, however, remains unclear.

Fetal alcohol syndrome is the most common preventable cause of mental retardation. Convincing evidence has been developed that the microencephaly associated with fetal alcohol exposure results from inhibition of NMDA receptor function, resulting in widespread neuronal apoptosis in the immature cortex. NMDA receptor activation is essential for immature neuronal survival and differentiation.

Neuropeptides

Neuropeptides represent the most diverse class of signaling molecules in the CNS. Initially discovered for their role in the hypothalamic regulation of pituitary hormone secretion, the complex role of peptides in brain function has emerged over the last 30 years. Many neuropeptides and their receptors are widely distributed within the CNS, where they have an extraordinary array of direct or neuromodulatory effects, ranging from modulating neurotransmitter release and neuronal firing patterns to the regulation of emotionality and complex behaviors. More than 100 unique biologically active neuropeptides have been identified in the brain, a subset of which is presented in Table 33-3. Adding to the complexity of neuropeptide systems

in the CNS, the actions of many peptides are mediated via multiple receptor subtypes localized in different brain regions. The discovery of new peptides and receptor subtypes has outpaced our understanding of the roles of these peptides in normal or aberrant CNS function. Pharmacologic, molecular, and genetic approaches are now leading the way in our understanding of the contribution of neuropeptide systems in psychiatric disorders.

Neuropeptides have been implicated in the regulation of a variety of behavioral and physiologic processes, including thermoregulation, food and water consumption, sex, sleep, locomotion, learning and memory, responses to stress and pain, emotion, and social cognition. Involvement in such behavioral processes suggests that neuropeptidergic systems may contribute to the symptoms and behaviors exhibited in major psychiatric illnesses such as psychoses, mood disorders, dementia, and ASDs.

Table 33-3
Selected Neuropeptide Transmitters

Adrenocorticotropic hormone (ACTH)
Angiotensin
Atrial natriuretic peptide
Bombesin
Calcitonin
Calcitonin gene-related peptide (CGRP)
Cocaine and amphetamine regulated transcript (CART)
Cholecystokinin (CCK)
Corticotropin-releasing factor (CRF)
Dynorphin
β-Endorphin
Leu-enkephalin
Met-enkephalin
Galanin
Gastrin
Gonadotropin-releasing hormone (GnRH)
Growth hormone

Growth hormone-releasing hormone (GHRH; GRF)
Insulin
Motilin
Neuropeptide S
Neuropeptide Y (NPY)
Neurotensin
Neuromedin N
Orphanin FQ/Nociceptin
Orexin
Oxytocin
Pancreatic polypeptide
Prolactin
Secretin
Somatostatin (SS; SRIF)
Substance K
Substance P
Thyrotropin-releasing hormone (TRH)
Urocortin (1, 2, and 3)
Vasoactive intestinal polypeptide (VIP)
Vasopressin (AVP; ADH)

Investigating Neuropeptide Function. The roles of neuropeptides in CNS function and behavior have been examined using a multitude of experimental techniques. The levels of analysis include the following: Molecular structure and biosynthesis of the peptide and its receptor(s), the neuroanatomical localization of the peptide and its receptor(s), the regulation of the expression and release of the peptide, and the behavioral effects of the peptide. Most information on neuropeptide biology is derived from laboratory animal studies; however, there is a growing database on the localization, activity, and potential psychiatric relevance of several neuropeptide systems in humans.

Most neuropeptide structures have been identified based on the chemical

analysis of purified biologically active peptides, leading ultimately to the cloning and characterization of the genes encoding them. Characterization of the gene structure of peptides and their receptors has provided insight into the molecular regulation of these systems, and their chromosomal localization is useful in genetic studies examining the potential roles of these genes in psychiatric disorders. Structural characterization permits the production of immunologic and molecular probes that are useful in determining peptide distribution and regulation in the brain. Quantitative radioimmunoassays on microdissected brain regions or immunocytochemistry on brain sections are typically used to localize the distribution of peptide within the brain. Both techniques use specific antibodies generated against the neuropeptide to detect the presence of the peptide. Immunocytochemistry allows researchers to visualize the precise cellular localization of peptide-synthesizing cells as well as their projections throughout the brain, although the technique is generally not quantitative. With molecular probes homologous to the mRNA encoding the peptides or receptor, in situ hybridization can be used to localize and quantify gene expression in brain sections. This technique is a powerful way to examine the molecular regulation of neuropeptide synthesis with a precise neuroanatomical resolution, which is impossible for other classes of nonpeptide neurotransmitters that are not derived directly from the translation of mRNAs, such as dopamine, serotonin, and norepinephrine.

Generally, the behavioral effects of neuropeptides are initially investigated by infusions of the peptide directly into the brain. Unlike many nonpeptide neurotransmitters, most neuropeptides do not penetrate the BBB in amounts sufficient enough to produce CNS effects. Furthermore, serum and tissue enzymes tend to degrade the peptides before they reach their target sites. The degradation is usually the result of the cleavage of specific amino acid sequences targeted by a specific peptidase designed for that purpose. Thus, intracerebroventricular (ICV) or site-specific infusions of the peptide in animal models are generally required to probe for the behavioral effects of peptides. However, there are examples of the delivery of neuropeptides via intranasal infusions in human subjects, which may help the peptide access the brain.

One of the most significant impediments for exploring the roles and potential therapeutic values of neuropeptides is the inability of the peptides or their agonists/antagonists to penetrate the BBB. Thus the behavioral effects

of most peptides in humans are mostly uninvestigated, except for a few studies utilizing intranasal delivery. However, in some instances, small-molecule, nonpeptide agonists/antagonists have been developed that can be administered peripherally and permeate the BBB in sufficient quantities to affect receptor activation.

The use of pretreatment and posttreatment CSF samples or of samples obtained during the active disease state versus when the patient is in remission addresses some of the limitations in study design. For such progressive diseases as schizophrenia or Alzheimer disease, serial CSF samples may be a valuable indicator of disease progression or response to treatment. Even with these constraints, significant progress has been made in describing the effects of various psychiatric disease states on neuropeptide systems in the CNS.

Biosynthesis. Unlike other neurotransmitters, neuropeptide biosynthesis involves mRNA transcription from a specific gene, translation of an mRNA-encoded polypeptide preprohormone, and posttranslational processing involving proteolytic cleavage of the preprohormone. Over the last 25 years, the gene structures and biosynthetic pathways of many neuropeptides have been elucidated. The gene structure of selected neuropeptides is illustrated in Figure 33-22. Neuropeptide genes are generally composed of multiple exons that encode a protein preprohormone. The N-terminus of the preprohormone contains a signal peptide sequence, which guides the growing polypeptide to the rough endoplasmic reticulum (RER) membrane. The single preprohormone molecule often contains the sequences of multiple peptides that are subsequently separated by proteolytic cleavage by specific enzymes. For example, translation of the gene encoding NT yields a preprohormone, which upon enzymatic cleavage produces both NT and neuromedin N.

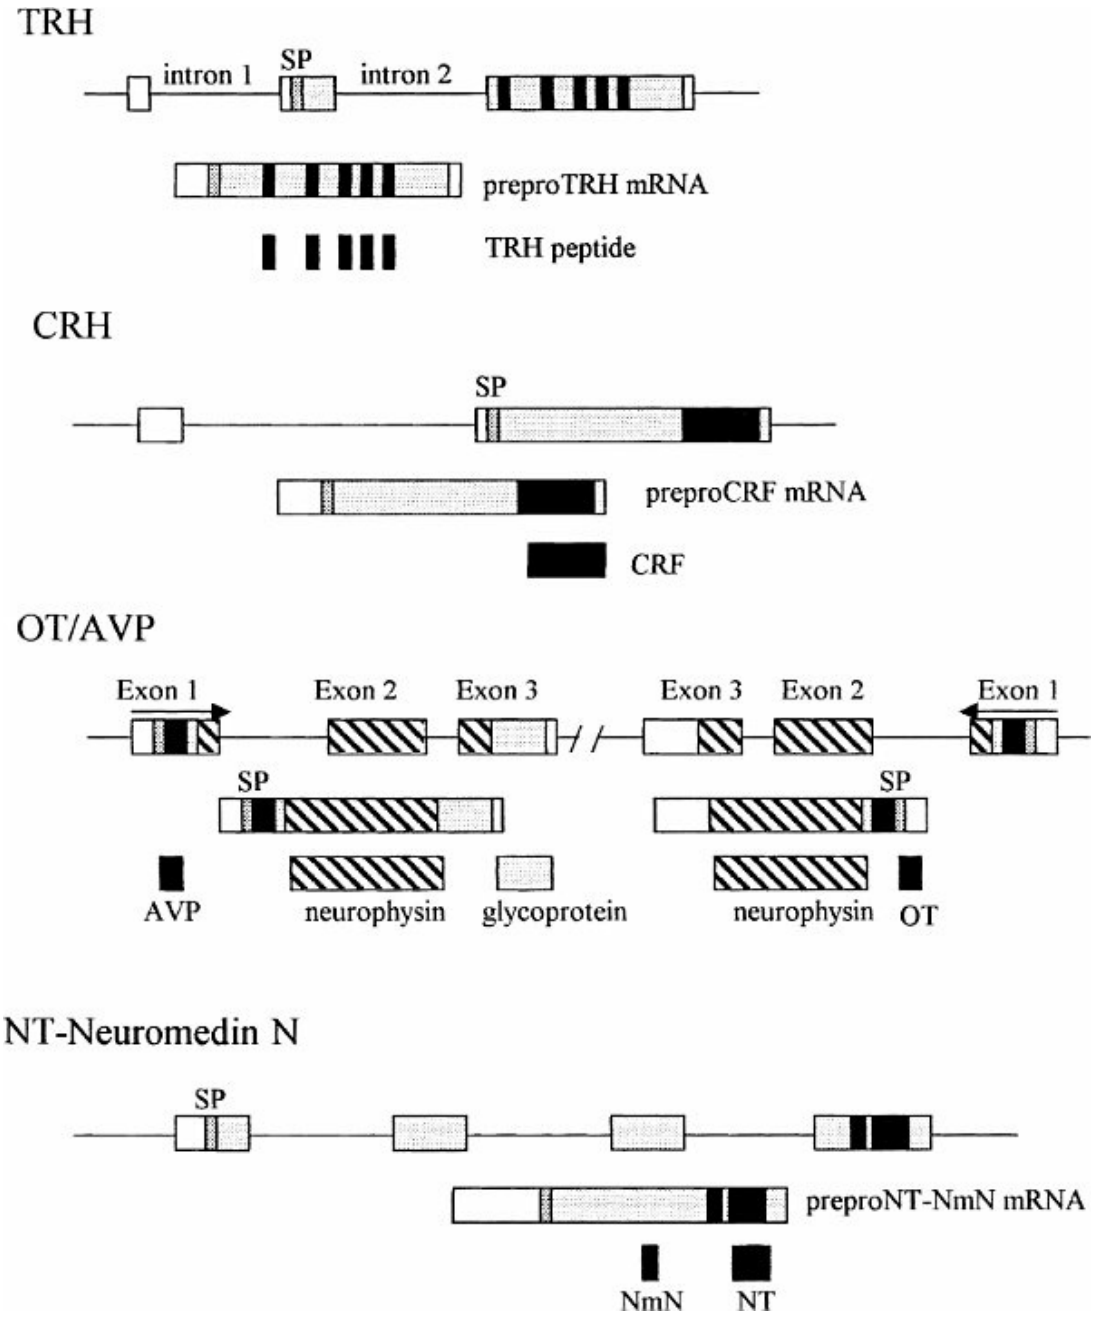

FIGURE 33-22

Schematics illustrating the gene structure, preprohormone messenger RNA (mRNA), and processed neuropeptides of thyrotropin-releasing hormone (TRH), corticotropin-releasing factor (CRF), oxytocin (OT), arginine vasopressin (AVP), and neurotensin (NT). *Boxed regions* indicate the locations of the exons in the respective genes. *Shaded or hatched regions* indicate coding regions. Each preprohormone begins with a signal peptide (SP) sequence. *Black boxes* indicate the locations of the sequences encoding the neuropeptide. (From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2009:87.)

Distribution and Regulation. Although many neuropeptides were initially isolated from the pituitary and peripheral tissues, the majority of neuropeptides were subsequently found to be widely distributed throughout the brain. Those peptides involved in regulating pituitary secretion are concentrated in the hypothalamus. Hypothalamic releasing and inhibiting factors are produced in neurosecretory neurons adjacent to the third ventricle that send projections to the median eminence where they contact and release peptide into the hypothalamohypophysial portal circulatory system. Peptides produced in these neurons are often subject to regulation by the peripheral hormones that they regulate. For example, thyrotropin-releasing hormone (TRH) regulates the secretion of thyroid hormones, and thyroid hormones negatively feedback on TRH gene expression. However, neuropeptide-expressing neurons and their projections are found in many other brain regions, including limbic structures, midbrain, hindbrain, and spinal cord.

Neuropeptide Signaling. Neuropeptides may act as neurotransmitters, neuromodulators, or neurohormones. Neurotransmitters are typically released from axonal terminals into a synapse where they change the postsynaptic membrane potential, either depolarizing or hyperpolarizing the cell. For classical neurotransmitters, this often involves direct modulation of voltage-gated ion channels. In contrast, neuromodulators and neurohormones do not directly affect the firing of the target cell itself but may alter the response of the cell to other neurotransmitters through the modulation of second messenger pathways. Neuropeptide release is not restricted to synapses or axon terminals but may occur throughout the axon or even from dendrites.

Specific neuropeptide receptors mediate the cellular signaling of neuropeptides. Thus understanding neuropeptide receptor function is essential for understanding neuropeptide biology. Neuropeptide receptors have undergone the same process of discovery and characterization that receptors for other neurotransmitters have enjoyed. Most neuropeptide receptors are G-protein–coupled, seven-transmembrane domain receptors belonging to the same family of proteins as the monoamine receptors.

Molecular technology has made it possible to clone and characterize neuropeptide receptor genes and complementary DNAs (cDNAs). This process is most often accomplished in one of three ways. First, the neuropeptide receptor protein is biochemically purified and partially

sequenced, which allows the development of oligonucleotide probes that can be used to isolate the cDNA encoding the protein from a cDNA library. A second approach involves producing expression libraries in which cells containing the receptor cDNA can be isolated based on their ability to bind to a radiolabeled peptide ligand. Finally, many neuropeptide receptors are now isolated based on their sequence homology with other known peptide receptors. Once the cDNA of the receptor has been isolated, it can be used to produce purified receptor protein for structural and functional studies. By mutation of specific amino acids in the receptor structure and determination of relative binding affinities of peptides with various amino acid substitutions, it is possible to elucidate the nature of the ligand–receptor interaction. This information facilitates the development of drugs that specifically modulate receptor function, including nonpeptide drugs, leading to the ability to manipulate peptide systems in ways that are currently enjoyed by the more classic neurotransmitters. The availability of cDNAs encoding the receptor also permits the neuroanatomical mapping of the receptor-producing cells in the brain, which is critical for understanding the neural circuits modulated by the peptide. Finally, with the cloned receptor in hand, it is possible to use transgenic techniques, such as targeted gene overexpression or gene knockouts, to elucidate the functions of these receptors further. siRNA techniques now allow the targeted synthesis disruption of specific receptor populations, allowing researchers to examine the roles of these receptor populations on physiology and behavior.

The following three factors determine the biologic roles of a neuropeptide hormone: (1) the temporal-anatomical release of the peptide, (2) functional coupling of the neuropeptide receptor to intracellular signaling pathways, and (3) the cell type and circuits in which the receptor is expressed. Genetic studies have demonstrated that regulatory sequences flanking the receptor coding region determine the expression pattern of the receptor and thus the physiologic and behavioral response to the neuropeptide.

Peptidases. Unlike monoamine neurotransmitters, peptides are not actively taken up by presynaptic nerve terminals. Instead, released peptides are degraded into smaller fragments, and eventually into single amino acids by specific enzymes termed peptidases. The enzymes may be found bound to presynaptic or postsynaptic neural membranes or in solution in the cytoplasm

and extracellular fluid, and they are distributed widely in peripheral organs and serum as well as in the CNS. As a result, neuropeptides generally have half-lives on the order of minutes once released.

Specific Neuropeptides as Prototypes of Neuropeptide Biology

THYROTROPIN-RELEASING HORMONE. In 1969, TRH, a pyroglutamylhistidylprolinamide tripeptide (Table 33-4), became the first of the hypothalamic releasing hormones to be isolated and characterized. The discovery of the structure of this hormone led to the conclusive demonstration that peptide hormones secreted from the hypothalamus regulate the secretion of hormones from the anterior pituitary. The gene for TRH in humans resides on chromosome 3q13.3–q21. In the rat, it consists of three exons (coding regions) separated by two introns (noncoding sequences) (see Fig. 33-22). The first exon contains the 5′ untranslated region of the mRNA encoding the TRH preprohormone, the second exon contains the signal peptide (SP) sequence and much of the remaining N-terminal end of the precursor peptide, and the third contains the remainder of the sequence, including five copies of the TRH precursor sequence, the C-terminal region, and the 3′ untranslated region. The 5′ flanking of the gene, or promoter, contains sequences homologous to the glucocorticoid receptor and the DNA-binding sites for thyroid hormone, providing a mechanism for the regulation of this gene by cortisol and negative feedback by thyroid hormone. Enzymatic processing of TRH begins with excision of the progenitor peptides by carboxypeptidases, amidation of the C-terminal proline, and cyclization of the N-terminal glutamine to yield five TRH molecules per prohormone molecule. TRH is widely distributed in the CNS with TRH immunoreactive neurons being located in the olfactory bulbs, entorhinal cortices, hippocampus, extended amygdala, hypothalamus, and midbrain structures. As is the case for most neuropeptides, the TRH receptor is also a member of the seven-transmembrane domain, G-protein–coupled receptor family.

Hypothalamic TRH neurons project nerve terminals to the median eminence; there, they release TRH into the hypothalamohypophyseal portal system where it is transported to the adenohypophysis, causing the release of thyroid-stimulating hormone (TSH) into the systemic circulation. TSH subsequently stimulates the release of the thyroid hormones triiodothyronine

(T_3) and thyroxine (T_4) from the thyroid gland. TRH neurons in the paraventricular nucleus (PVN) contain thyroid hormone receptors and respond to increases in thyroid hormone secretion with a decrease in TRH gene expression and synthesis. This negative feedback of thyroid hormones on the TRH-synthesizing neurons was first demonstrated by a decrease in TRH content in the median eminence, but not in the PVN of the hypothalamus after thyroidectomy. This effect can be reversed with exogenous thyroid hormone treatment. The treatment of normal rats with exogenous thyroid hormone decreases TRH concentration in the PVN and the posterior nucleus of the hypothalamus. With a probe against the TRH preprohormone mRNA, in situ hybridization studies have demonstrated that TRH mRNA is increased in the PVN 14 days after thyroidectomy. The ability of thyroid hormones to regulate TRH mRNA can be superseded by other stimuli that activate the hypothalamic–pituitary–thyroid (HPT) axis. In that regard, repeated exposure to cold (which releases TRH from the median eminence) induces increases in the levels of TRH mRNA in the PVN despite concomitantly elevated concentrations of thyroid hormones.

Table 33-4
Selected Neuropeptide Structures

Name	Amino Acid Sequence
Thyrotropin-releasing hormone (TRH)	pE-H-P-NH_2
Corticotropin-releasing factor (CRF)	S-E-E-P-P-I-S-L-D-L-T-F-H-L-L-R-E-V-L-E-M-A-R-A-E-Q-L-A-Q-Q-A-H-S-N-R-K-L-M-E-I-I-NH_2
Arginine vasopressin (AVP)	C-Y-I-Q-N-C-P-L-G-NH_2
Oxytocin (OT)	C-Y-F-Q-N-C-P-R-G-NH_2
Neurotensin (NT)	pE-L-Y-E-N-K-P-R-R-P-Y-I-L-OH

Note the cyclized glutamines at the N-termini of TRH and NT indicated by pE-, the cysteine–cysteine disulfide bonds of AVP and OT, and the amidated C-termini of TRH, CRF, AVP, and OT.

From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2009:85.

Further evidence of the different levels of communication of the HPT axis is seen in the ability of TRH to regulate the production of mRNA for the pituitary TRH receptor. It is also seen for TRH concentrations to regulate the mRNA coding for both the α and β subunits of the thyrotropin (TSH) molecule. Also, TRH-containing synaptic boutons have been observed in contact with TRH-containing cell bodies in the medial and periventricular subdivisions of the paraventricular nucleus, thus providing anatomical evidence for ultrashort feedback regulation of TRH release. Negative feedback by thyroid hormones may be limited to the hypothalamic TRH neurons because negative feedback on TRH synthesis by thyroid hormones has not been found in extrahypothalamic TRH neurons.

The early availability of adequate tools to assess HPT axis function (i.e., radioimmunoassays and synthetic peptides), coupled with observations that primary hypothyroidism is associated with depressive symptomatology, ensured extensive investigation of the involvement of this axis in affective disorders. Early studies established the hypothalamic and extrahypothalamic distribution of TRH. This extrahypothalamic presence of TRH quickly led to speculation that TRH might function as a neurotransmitter or neuromodulator. Indeed, a large body of evidence supports such a role for TRH. Within the CNS, TRH is known to modulate several different neurotransmitters, including dopamine, serotonin, acetylcholine, and opioids. TRH has been shown to arouse hibernating animals and counteracts the behavioral response and hypothermia produced by a variety of CNS depressants, including barbiturates and ethanol.

The use of TRH as a provocative agent for the assessment of the HPT axis function evolved rapidly after its isolation and synthesis. Clinical use of a standardized TRH stimulation test, which measures negative feedback responses, revealed blunting of the TSH response in approximately 25 percent of euthyroid patients with major depression. These data have been widely confirmed. The observed TSH blunting in depressed patients does not

appear to be the result of excessive negative feedback due to hyperthyroidism because thyroid measures such as basal plasma concentrations of TSH and thyroid hormones are generally in the normal range in these patients. TSH blunting may be a reflection of pituitary TRH receptor downregulation due to median eminence hypersecretion of endogenous TRH. Indeed, the observation that CSF TRH concentrations are elevated in depressed patients as compared to those of controls supports the hypothesis of TRH hypersecretion but does not elucidate the regional CNS origin of this tripeptide. TRH mRNA expression in the PVN of the hypothalamus is decreased in patients with major depression. However, it is not clear whether the altered HPT axis represents a causal mechanism underlying the symptoms of depression or only a secondary effect of depression-associated alterations in other neural systems.

CORTICOTROPIN-RELEASING FACTOR (CRF) AND UROCORTINS. There is convincing evidence to support the hypothesis that CRF and the urocortins play an intricate role in integrating the endocrine, autonomic, immunologic, and behavioral responses of an organism to stress.

Although it was initially isolated because of its functions in regulating the HPA axis, CRF is widely distributed throughout the brain. The PVN of the hypothalamus is the primary site of CRF-containing cell bodies that influence anterior pituitary hormone secretion. These neurons originate in the parvocellular region of the PVN and send axon terminals to the median eminence, where CRF is released into the portal system in response to stressful stimuli. A small group of PVN neurons also projects to the brainstem and spinal cord, where they regulate autonomic aspects of the stress response. CRF-containing neurons are also found in other hypothalamic nuclei, the neocortex, the extended amygdala, brainstem, and spinal cord. Central CRF infusion into laboratory animals produces physiologic changes and behavioral effects similar to those observed following stress, including increased locomotor activity, increased responsiveness to an acoustic startle, and decreased exploratory behavior in an open field.

The physiologic and behavioral roles of the urocortins are less understood, but several studies suggest that urocortins 2 and 3 are anxiolytic and may dampen the stress response. This research has led to the hypothesis that CRF

and the urocortins act in opposition, but this is likely an oversimplification. Urocortin 1 is primarily synthesized in the Edinger–Westphal nucleus, lateral olivary nucleus, and supraoptic hypothalamic nucleus. Urocortin 2 is synthesized primarily in the hypothalamus, while urocortin three-cell bodies are found more broadly in the extended amygdala, perifornical area, and preoptic area.

Hyperactivity of the HPA axis in major depression remains one of the most consistent findings in biologic psychiatry. The reported HPA axis alterations in major depression include hypercortisolemia, resistance to dexamethasone suppression of cortisol secretion (a measure of negative feedback), blunted adrenocorticotropic hormone (ACTH) responses to intravenous CRF challenge, increased cortisol responses in the combined dexamethasone/CRF test, and elevated CSF CRF concentrations. The exact pathologic mechanism(s) underlying HPA axis dysregulation in major depression and other affective disorders remains to be elucidated.

Mechanistically, two hypotheses have been advanced to account for the ACTH blunting following exogenous CRF administration. The first hypothesis suggests that pituitary CRF receptor downregulation occurs as a result of hypothalamic CRF hypersecretion. The second hypothesis postulates the altered sensitivity of the pituitary to glucocorticoid negative feedback. Substantial support has accumulated favoring the first hypothesis. However, neuroendocrine studies represent a secondary measure of CNS activity; the pituitary ACTH responses principally reflect the activity of hypothalamic CRF rather than that of the corticolimbic CRF circuits. The latter of the two is more likely to be involved in the pathophysiology of depression.

Of particular interest is the demonstration that the elevated CSF CRF concentrations in drug-free depressed patients are significantly decreased after successful treatment with ECT, indicating that CSF CRF concentrations, like hypercortisolemia, represent a state rather than a trait marker. Other recent studies have confirmed this normalization of CSF CRF concentrations following successful treatment with fluoxetine. One group demonstrated a significant reduction of elevated CSF CRF concentrations in 15 female patients with major depression who remained depression-free for at least 6 months following antidepressant treatment, as compared to little significant treatment effect on CSF CRF concentrations in 9 patients who relapsed in these 6 months. This finding suggests that elevated or increasing CSF CRF

concentrations during antidepressant treatment may be the harbinger of an inadequate response in major depression despite early symptomatic improvement. Of interest, treatment of normal subjects with desipramine or, as noted above, of individuals with depression with fluoxetine is associated with a reduction in CSF CRF concentrations.

If CRF hypersecretion is a factor in the pathophysiology of depression, then reducing or interfering with CRF neurotransmission might be an effective strategy to alleviate depressive symptoms. Over the last several years, several pharmaceutical companies have committed considerable effort to the development of small-molecule CRF_1 receptor antagonists that can effectively penetrate the BBB. Several compounds have been produced with reportedly promising characteristics.

OXYTOCIN (OT) AND VASOPRESSIN (AVP). The vasopressor effects of posterior pituitary extracts were first described in 1895, and the potent extracts were named AVP. OT and AVP mRNAs are among the most abundant messages in the hypothalamus, being heavily concentrated in the magnocellular neurons of the PVN and the supraoptic nucleus of the hypothalamus, which send axonal projections to the neurohypophysis. These neurons produce OT and AVP, which is released into the bloodstream, where these peptides act like hormones on peripheral targets. OT and AVP are generally synthesized in separate neurons within the hypothalamus. OT released from the pituitary is most often associated with functions associated with female reproduction, such as regulating uterine contractions during parturition and the milk ejection reflex during lactation. AVP, also known as antidiuretic hormone, regulates water retention in the kidney and vasoconstriction through interactions with vasopressin V2 and V1a receptor subtypes, respectively. AVP is released into the bloodstream from the neurohypophysis following a variety of stimuli, including plasma osmolality, hypovolemia, hypertension, and hypoglycemia. The actions of OT are mediated via a single receptor subtype (oxytocin receptor, OTR), which is distributed in the periphery and within the limbic CNS.

In contrast to the OTR, there are three vasopressin receptor subtypes, V1a, V1b, and V2 receptors, each of which is a G-protein–coupled seven-transmembrane domain receptor. The V2 receptor is localized in the kidney

and is not found in the brain. The V1a receptor is distributed widely in the CNS and is thought to mediate most of the behavioral effects of AVP. The V1b receptor is concentrated in the anterior pituitary, and some reports describe V1b receptor mRNA in the brain, although its function is unknown.

Neurotensin (NT). Although NT is found in several brain regions, it has been most thoroughly investigated in terms of its association with other neurotransmitter systems, particularly the mesolimbic dopamine system, and has gained interest in research on the pathophysiology of schizophrenia. There are several lines of evidence suggesting that NT and its receptors should be considered as potential targets for pharmacologic intervention in this disorder. First, the NT system is positioned anatomically to modulate the neural circuits implicated in schizophrenia. Second, peripheral administration of antipsychotic drugs has been shown to modulate NT systems consistently. Third, there is evidence that central NT systems are altered in patients with schizophrenia.

NT was first shown to interact with dopamine systems while undergoing characterization of its potent hypothermic-potentiating and sedative-potentiating activities. Subsequent work indicated that NT possessed many properties that were also shared by antipsychotic drugs, including the ability to inhibit avoidance, but not escape responding in a conditioned active avoidance task; the ability to block the effects of indirect dopamine agonists or endogenous dopamine in the production of locomotor behavior; and the ability to elicit increases in dopamine release and turnover. Perhaps most importantly, both antipsychotic drugs and NT neurotransmission enhance sensorimotor gating. Sensorimotor gating is the ability to screen or filter relevant sensory input, deficits in which may lead to involuntary flooding of indifferent sensory data. Increasing evidence suggests that deficits in sensorimotor gating are a cardinal feature of schizophrenia. Both dopamine agonists and NT antagonists disrupt performance on tasks designed to gauge sensorimotor gating. Unlike antipsychotic drugs, NT is not able to displace dopamine from its receptor. As noted earlier, NT is colocalized in specific subsets of dopamine neurons and is coreleased with dopamine in the mesolimbic and medial prefrontal cortex dopamine terminal regions that are implicated as the sites of dopamine dysregulation in schizophrenia. Antipsychotic drugs that act at D_2 and D_4 receptors increase the synthesis,

concentration, and release of NT in those dopamine terminal regions but not in others. That effect of antipsychotic drugs in increasing NT concentrations persists after months of treatment and is accompanied by the expected increase in NT mRNA concentrations as well as expression of the "immediate early gene" c-fos within hours of initial drug treatment. The altered regulation of NT expression by antipsychotic drugs extends to the peptidases that degrade the peptide because recent reports have revealed decreased NT metabolism in rat brain slices 24 hours after the acute administration of haloperidol. When administered directly into the brain, NT preferentially opposes dopamine transmission in the nucleus accumbens but not the caudate-putamen. In the nucleus accumbens, NT receptors are located predominantly on GABAergic neurons, which release GABA on dopamine terminals, thereby inhibiting release.

Decreased CSF NT concentrations have been reported in several populations of patients with schizophrenia when compared to those of controls or other psychiatric disorders. Although treatment with antipsychotic drugs has been observed to increase NT concentrations in the CSF, it is not known whether this increase is causal or merely accompanies the decrease in psychotic symptoms seen with successful treatment. Postmortem studies have shown an increase in NT concentrations in the dopamine-rich Brodmann area 32 of the frontal cortex, but that result may have been confounded by premortem antipsychotic treatment. Other researchers have found no postmortem alterations in NT concentrations of a broad sampling of subcortical regions. Decreases in NT receptor densities in the entorhinal cortex have been reported in entorhinal cortices of schizophrenic postmortem samples. A critical test of the hypothesis that NT may act as an endogenous antipsychotic-like substance awaits the development of an NT receptor agonist that can penetrate the BBB.

Other Neuropeptides. Several other neuropeptides have been implicated in the pathophysiology of psychiatric disorders. These include, but are not limited to, cholecystokinin (CCK), substance P, and neuropeptide Y.

CCK initially discovered in the gastrointestinal tract, and its receptors are found in areas of the brain associated with emotion, motivation, and sensory processing (e.g., cortex, striatum, hypothalamus, hippocampus, and amygdala). CCK is often colocalized with dopamine in the VTA neurons that

comprise the mesolimbic and mesocortical dopamine circuits. Like NT, CCK decreases dopamine release. Infusions of a CCK fragment have been reported to induce panic in healthy individuals, and patients with panic disorder exhibit increased sensitivity to the CCK fragment compared to that of normal controls. Pentagastrin, a synthetic CCK agonist, dose-dependently produced increased blood pressure, pulse, HPA activation, and physical symptoms of panic. Recently, a CCK receptor gene polymorphism has been associated with panic disorder.

The undecapeptide substance P is localized in the amygdala, hypothalamus, periaqueductal gray, LC, and parabrachial nucleus and is colocalized with norepinephrine and serotonin. Substance P serves as a pain neurotransmitter, and administration to animals elicits behavioral and cardiovascular effects resembling the stress response. More recent data suggest a role for substance P in major depression and PTSD. Both depressed and PTSD patients had elevated CSF substance P concentrations. Furthermore, in PTSD patients, marked increases in CSF substance P concentrations were detected following precipitation of PTSD symptoms. One study has indicated that a substance P receptor (termed the neurokinin 1 [NK1] receptor) antagonist capable of passing the BBB is more effective than a placebo and as useful as paroxetine in patients with major depression with moderate to severe symptom severity. However, subsequent studies have been unable to confirm these findings.

Neuropeptide Y (NPY) is a 36 amino acid peptide found in the hypothalamus, brainstem, spinal cord, and several limbic structures and is involved in the regulation of appetite, reward, anxiety, and energy balance. NPY is colocalized with serotonergic and noradrenergic neurons and is thought to facilitate the containment of adverse effects following exposure to stress. Suicide victims with a diagnosis of major depression are reported to have a pronounced reduction in NPY levels in the frontal cortex and caudate nucleus. Furthermore, CSF NPY levels are decreased in depressed patients. Chronic administration of antidepressant drugs increases neuropeptide Y concentrations in the neocortex and hippocampus in rats. Plasma NPY levels were found to be elevated in soldiers subjected to the “uncontrollable stress” of interrogation, and NPY levels were correlated with the feelings of dominance and confidence during the stress. Also, low NPY response to stress has been associated with increased vulnerability to depression and

PTSD.

Novel Neurotransmitters

Nitric Oxide. The discovery that gases could function as neurotransmitters revealed that highly atypical modes of signaling existed between neurons. In the early 1990s, nitric oxide was the first gas to be ascribed a neurotransmitter function and proved to be an atypical neurotransmitter for several reasons. First, it was not stored in or released from synaptic vesicles, as it was a small gas it could freely diffuse into the target neuron. Second, its target was not a specific receptor on the surface of a target neuron, but intracellular proteins whose activity could directly be modulated by nitric oxide, leading to neurotransmission. Nitric oxide also lacks a reuptake mechanism to remove it from the synapse. Although enzymatic inactivation of it is postulated to exist, nitric oxide appears to have a very short half-life of a few seconds.

Nitric oxide was initially discovered as a bactericidal compound released from macrophages, and as an endothelial cell, it derived relaxation factor allowing for the dilation of blood vessels. A role for nitric oxide in the brain followed, revealing a role for the gas in neurotransmission, learning and memory processes, neurogenesis, and neurodegenerative disease.

NITRIC OXIDE AND BEHAVIOR. Nitric oxide neurotransmission can play a role in behavior, as neuronal nitric oxide synthase (nNOS)-deficient male mice display exaggerated aggressive tendencies and increased sexual activity. In female mice, the contrary is true, as they have reduced aggression. As manic bipolar patients may show both hypersexuality and aggression, the nitric oxide pathway may participate in the psychopathology of affective states.

In the periphery, nNOS localizes to neurons that innervate blood vessels of the penis, including the corpus cavernosa. Stimulation of these nerves releases nitric oxide, leading to cyclic guanosine monophosphate (cGMP) formation, blood vessel wall relaxation and vasodilation, penile engorgement, and initial erection. The sustained phase of erection also depends on nitric oxide; turbulent blood flow leads to phosphorylation of eNOS and sustained nitric oxide production. Drugs used in the treatment of erectile dysfunction—sildenafil (Viagra), tadalafil (Cialis), and vardenafil (Levitra)—act to inhibit

phosphodiesterase type 5 (PDE5), an enzyme that degrades cGMP in the penis (Fig. 33-23), thereby potentiating nitric oxide neurotransmission and penile erection.

Numerous lines of evidence have suggested a role for nitric oxide in the regulation of sleep–wake cycles. nNOS expressing neurons occur in several areas that initiate REM sleep, including the pons, dorsal raphe nucleus, laterodorsal tegmentum, and pedunculopontine tegmentum. In animal models, microinjection of compounds that release nitric oxide decreases wakefulness and increases slow-wave sleep compared with controls. Consistent with this, NOS inhibitors show a trend toward decreasing slow-wave and REM sleep. Studies of NOS-deficient mice suggest that nitric oxide may serve a more involved role than merely promoting sleep. nNOS-deficient animals also show reduced REM sleep; however, inducible nitric oxide synthase (iNOS)-deficient mice demonstrate the reverse, suggesting a complex interplay between NOS enzymatic isoforms.

NITRIC OXIDE AND MOOD DISORDERS. NOS-expressing neurons are well represented in areas implicated in depression, including the dorsal raphe nucleus and prefrontal cortex. A role for nitric oxide has been suggested in antidepressant response, as SSRI antidepressants can directly inhibit NOS activity. Moreover, in animal studies such as the forced swim test, NOS and soluble guanylyl cyclase inhibitors can achieve antidepressant-like effects. Plasma nitric oxide levels were elevated in patients with bipolar disorder compared to healthy controls. However, in depressed subjects, studies have found decreased nitric oxide levels and increased plasma nitrite, a byproduct of nitric oxide. Reduced NOS has also been described in the paraventricular nucleus of patients with schizophrenia and depression compared to controls.

Nitric oxide has been questioned as to its ability to regulate neurotransmission at serotonin, norepinephrine, and dopamine nerve termini. However, there has been no clear consensus, and nitric oxide appears to be able to increase or decrease activity at these neurons depending on the timing of its activation and the region of the brain studied.

NITRIC OXIDE AND SCHIZOPHRENIA. Nitric oxide has been investigated as a candidate molecule contributing to symptoms of schizophrenia. Two genetic studies have identified schizophrenia-associated single nucleotide

polymorphisms (SNPs) in CAPON, a protein that associates with nNOS. SNPs in nNOS itself have been associated with schizophrenia, although others have not been able to reproduce such findings. Changes in NOS levels have been reported in postmortem brain samples of individuals with schizophrenia. Abnormalities have been noted in the cortex, cerebellum, hypothalamus, and brainstem, although no specific trend can be discerned. Elevated NOS activity has been noted in platelets from drug-naive and drug-treated individuals with schizophrenia. Some investigators find increased nitric oxide activity and others the reverse. In autopsy samples, schizophrenic patients were found to have abnormally localized NOS expressing neurons in the prefrontal cortex, hippocampus, and lateral temporal lobe, consistent with abnormal migration of these neuronal types during development. In a rat model, prenatal stress led to reduced NOS expressing neurons in the fascia dentate and hippocampus.

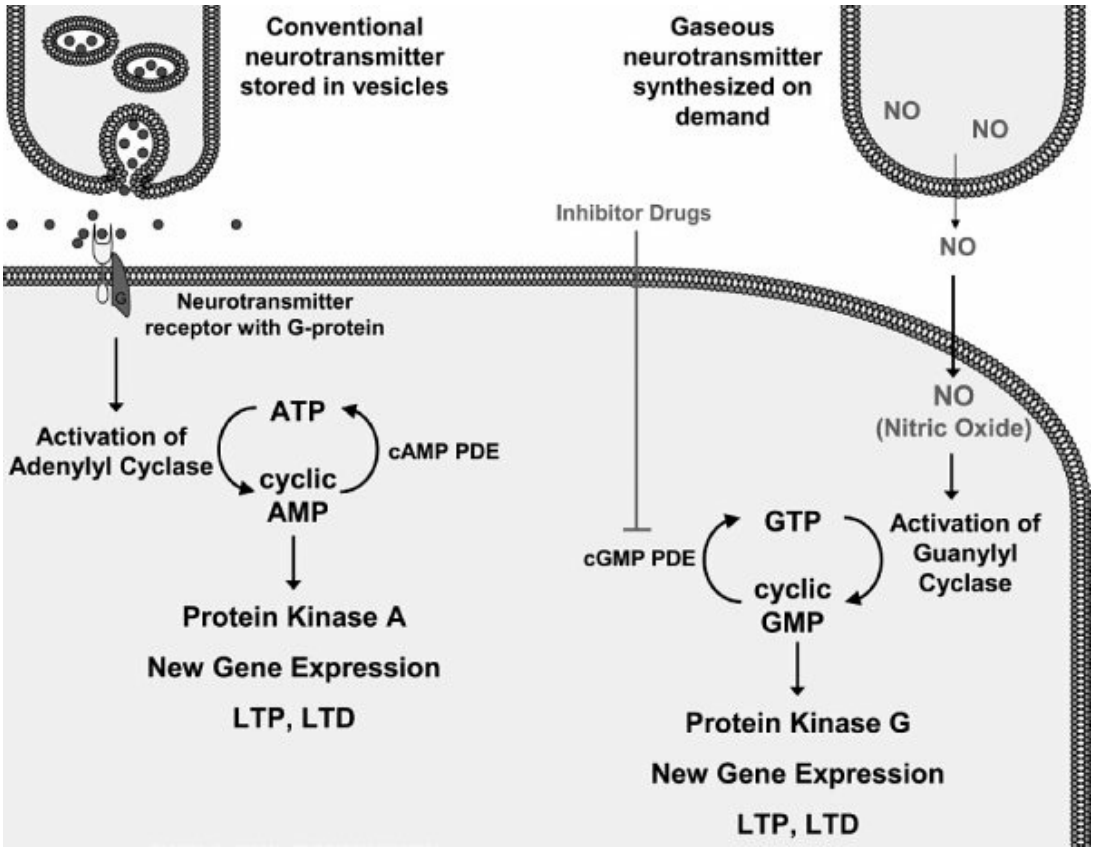

FIGURE 33-23
Neurotransmitter and signaling functions of nitric oxide (NO) via production of cyclic guanosine monophosphate (cGMP). Gaseous nitric oxide is enzymatically generated and freely diffuses into an adjacent neuron (*upper right*). In comparison

to traditional neurotransmitters (*upper left*), nitric oxide (NO) does not act via a specific neurotransmitter receptor on the surface membrane of a neuron. In contrast, NO freely diffuses across the neuronal membrane and activates the enzyme, guanylyl cyclase, which converts guanosine 5'-triphosphate (GTP) into the second messenger, cGMP. Nitric oxide effects are mediated, in part, by cGMP activation of neuronal protein kinases, new gene expression, and effects on neuronal long-term potentiation (LTP) and long-term depression (LTD). ATP, adenosine triphosphate. (From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2009:104.)

NEUROPATHOLOGIC ROLES OF NITRIC OXIDE. Abundant evidence exists that nitric oxide is a direct participant in a variety of neuropathic events. Superoxide, a byproduct of cellular metabolism, can react with nitric oxide to form peroxynitrite (chemical formula $ONOO^-$). This labile and toxic compound forms chemical adducts with protein tyrosine residues, a process termed *protein nitration,* and DNA, leading to cellular dysfunction.

Cell loss resulting from ischemic stroke is mediated in part by overstimulation of the glutamate NMDA receptor, a process termed *excitotoxicity.* Nitric oxide produced by NMDA activation appears to mediate a significant portion of this excitotoxic neuronal death, and stroke damage is reduced in mice with a genetic deletion of nNOS.

S-Nitrosylation has also been implicated in pathologic processes in the brain. Mutations in the Parkin protein are associated with early-onset Parkinson disease. Parkin is an E3 ubiquitin ligase, adding ubiquitin molecules to proteins and targeting them for destruction in the cell proteasome. In sporadic Parkinson disease (i.e., without the early-onset mutation), nitric oxide can nitrosylate the Parkin protein and inhibit its protective E3 ubiquitin ligase function. An overabundance of nitric oxide signaling may thus predispose to the dysfunction and cell death of dopaminergic neurons in Parkinson disease by interfering with proteins essential for cell functioning. In Alzheimer disease, excess oxidation of brain protein, lipids, and carbohydrates has long been appreciated, but nitrosative stress from excess nitric oxide also appears to participate in the disease. Protein disulfide isomerase (PDI) is a cellular protective protein that may help combat the accumulation of misfolded proteins, such as the amyloid fibrils occurring in the disease. In both Alzheimer and Parkinson disease brains, PDI appears to be S-nitrosylated in a harmful way that impedes its

cellular protective function.

The discovery that nitric oxide participates in neurodegenerative processes raises the possibility for improved diagnostic processes, such as detecting damage to cellular components produced by nitric oxide before the onset of full-blown symptoms. Also, drugs may be designed to attenuate the damage to crucial neuronal proteins that protect against disease onset. However, entirely and nonspecifically inhibiting or stimulating NOS is likely to produce significant side effects because of its wide-ranging activities throughout the body.

Carbon Monoxide. Although carbon monoxide (CO) is most well known as an air pollutant derived from combustion reactions, it is produced physiologically in a great variety of organisms ranging from human to bacterium. Once thought to be a toxic byproduct of metabolic reactions, carbon monoxide is increasingly recognized to play an essential role in regulating a variety of physiologic processes in the brain and other organs. These varied effects include regulation of olfactory neurotransmission, blood vessel relaxation, smooth muscle cell proliferation, and platelet aggregation.

Carbon monoxide is far better known for its toxic effects than its activities at physiologic concentrations. It binds tightly to heme molecules within hemoglobin, forming carboxyhemoglobin, which can no longer transport oxygen to tissues. One- to two-pack per day smokers typically have 3 to 8 percent of their hemoglobin as carboxyhemoglobin, with nonsmokers having less than 2 percent. Following acute carbon monoxide poisoning, 5 to 10 percent of carboxyhemoglobin is associated with impaired alertness and cognition, and 30 to 50 percent of carboxyhemoglobin leads to significant drops in oxygen transport to tissues.

CARBON MONOXIDE AND NEUROTRANSMISSION. Carbon monoxide appears to participate in the neurotransmission of odorant perception. Odorants lead to carbon monoxide production and subsequent cGMP synthesis that promotes long-term adaptation to odor stimuli. Carbon monoxide has the potential to regulate a variety of perceptual and cognitive processes that are yet untested. Similarly, in the rat retina, long periods of light exposure led to increased HO1 expression, carbon monoxide production, and cGMP signaling. Carbon monoxide may also participate in adaptation to chronic pain. HO2-deficient

animals manifest reduced hyperalgesia and allodynia after exposure to chronic pain stimuli. Carbon monoxide may thus set the threshold for pain perception, although it is unclear whether the effect occurs in the central or peripheral nervous system. Aside from its role in promoting cGMP production, carbon monoxide may also directly bind to and open the calcium-activated big potassium (BK_{Ca}) channel, leading to as yet uncharacterized effects on neurotransmission.

In the gastrointestinal (GI) nervous system, carbon monoxide serves as a neurotransmitter to relax the internal anal sphincter in response to nonadrenergic noncholinergic (NANC) nerve stimulation and vasoactive intestinal peptide (VIP).

Carbon monoxide has been implicated in the development of hippocampal LTP, although lines of evidence are contradictory. Carbon monoxide and tetanic stimulation of nerves lead to increased excitatory postsynaptic potentials (EPSPs). HO inhibitors that block carbon monoxide production lead to impaired induction of LTP and reduced calcium-dependent release of glutamate neurotransmitter. However, HO_2-deficient animals fail to manifest any differences in LTP. These disparate findings may be explained by a role for HO_1 in LTP, or an ability of HO inhibitors to block some other processes necessary to LTP induction nonspecifically.

At toxic levels, carbon monoxide is well known to impair oxygen transport by binding to hemoglobin with a higher affinity than oxygen. Amazingly, carbon monoxide itself plays a physiologic role in the mechanism by which the carotid body senses oxygen. HO, expressed in glomus cells of the carotid body, uses oxygen as a substrate in the production of carbon monoxide (Fig. 33-24). When oxygen levels drop, so does carbon monoxide production, leading to a resetting of the threshold in which the carotid body senses oxygen. The molecular mechanism may occur via carbon monoxide regulation of the carotid body BK ion channel.

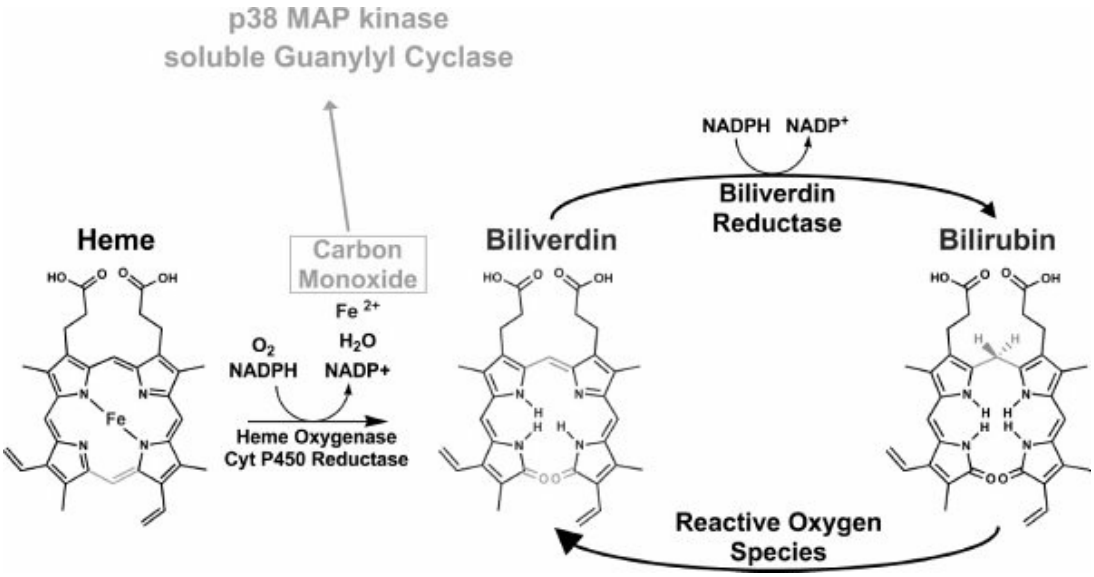

FIGURE 33-24
Synthesis of carbon monoxide (CO), an unexpected neurotransmitter. Gaseous carbon monoxide is enzymatically synthesized in neurons by way of the enzyme heme oxygenase, also converting heme into the molecule biliverdin and liberating free iron (Fe). Similar to nitric oxide, CO is not stored in neuronal vesicles and can freely diffuse across neuronal membranes. CO also similarly activates soluble guanylyl cyclase, and leads to activation of multiple intracellular signaling molecules such as p38 MAP kinase. CO exerts its neurotransmitter and signaling functions at concentrations far below that at which classical CO toxicity occurs. The significance of this pathway in neurons is underlined by the existence of two distinct heme oxygenase enzymes, one of which is predominantly expressed in the brain. Biliverdin is converted to bilirubin via the enzyme biliverdin reductase. Similar to CO, bilirubin is no longer relegated to the status of toxic byproduct and may be an important antioxidant. (From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2009:107.)

Endocannabinoids: From Marijuana to Neurotransmission. Whether known as cannabis, hemp, hashish, ma-fen, or a variety of slang terms, marijuana has been cultivated and utilized by human populations for thousands of years. Despite a long debate about risks and benefits, it has only been in recent decades that we have started to learn how marijuana exerts its effects on the brain. The "high" users experience, euphoria and tranquility, relates to cannabis acting on a neural pathway involving cannabinoids endogenous to the human brain, or endocannabinoids.

The first described medicinal use of cannabis dates to approximately 2700 BC in the pharmacopeia of Chinese Emperor Shen Nung, who recommended its use for a variety of ailments. At this time, adverse properties were also

apparent, and large amounts of the fruits of hemp could lead to “seeing devils,” or a user might “communicate with spirits and lightens one’s body.” For centuries, cannabis was employed in India as an appetite stimulant; habitual marijuana users remain well acquainted with “the munchies.”

For many years the mechanisms by which the active components of marijuana, *cannabinoids,* exerted their psychoactive effects remained a mystery. Chemists sought to isolate the psychoactive components of cannabis from the many components of the plant oil (Table 33-5).

Table 33-5
Selected Discoveries in Cannabinoid Research

1899	Cannabinol isolated from cannabis resin
1940	Identification of cannabinol structure
1964	Discovery of the structure of δ-9-tetrahydrocannabinol (THC), the most psychoactive component of cannabis
1988	Specific THC-binding sites identified in brain
1990	Identification of a brain cannabinoid receptor, CB1
1992	Discovery of the first endogenous brain endocannabinoid, anandamide
1993	Identification of a second cannabinoid receptor, CB2
1994	Rimonabant (Acomplia), a CB1 receptor blocker is developed
1995	Report of a second endocannabinoid, 2-AG
1996	Fatty acid amide hydrolase (FAAH), an endocannabinoid degrading enzyme, is discovered
2003	FAAH inhibitors reduce anxiety-like behaviors in animal studies
2003	Identification of enzymes that synthesize endocannabinoids
2006	Monoacylglycerol lipase (MAGL), a second endocannabinoid-degrading enzyme, is found

2006	Rimonabant approved for use in Europe for weight loss
2007	Rimonabant meta-analysis finds increased anxiety and depressive symptoms in humans without a history of psychiatric illness

From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2009:109.

DISCOVERY OF THE BRAIN ENDOCANNABINOID SYSTEM. Estimates suggest that 20 to 80 µg of tetrahydrocannabinol (THC) reaches the brain after one smokes a marijuana cigarette (i.e., "joint"). This quantity is comparable to the 100 to 200 µg of norepinephrine neurotransmitter present in the entire human brain. Thus the effects of THC might be explained by the effects on neurotransmitter systems. In the 1960s, there were at least two schools of thought on how THC exerted its psychoactive effects. One held that THC worked like that of the inhaled volatile anesthetics (i.e., no specific receptor existed), and it might have a generalized effect on neuronal membranes or widespread actions on neurotransmitter receptors. A competing school of thought speculated that specific receptors for cannabinoids existed in the brain, but they were difficult to identify due to the lipophilic nature of these chemicals. Novel cannabinoids were synthesized that were more water-soluble, and in the late 1980s, this allowed for the discovery of a specific cannabinoid receptor, CB1.

Several additional endocannabinoids were soon discovered, 2-arachidonylglycerol (2-AG), *N*-arachidonyldopamine (NADA), 2-arachidonoylglycerol ether (noladin ether), and virodhamine (Fig. 33-25). The different endocannabinoids have differing affinities for the cannabinoid receptors, CB1 and CB2. Anandamide appears to have the highest selectivity for the CB1 receptor, followed by NADA and noladin ether. In contrast, virodhamine prefers CB2 receptors and has only partial agonist activity at CB1. 2-AG appears not to discriminate between CB1 and CB2.

BIOSYNTHESIS OF ENDOCANNABINOIDS. Arachidonic acid is utilized as a building block for the biosynthesis of endocannabinoids, prostaglandins, and leukotrienes and is found within cellular phospholipids of the plasma membrane and other intracellular membranes. The synthesis of anandamide

requires the sequential action of two enzymes (Fig. 33-26). In the first reaction, the enzyme *N*-acetyltransferase (NAT) transfers an arachidonic acid side chain from a phospholipid to phosphatidylethanolamine (PE), generating NAPE (*N*-arachidonyl-phosphatidylethanolamine). In the second reaction, the enzyme *N*-arachidonyl-phosphatidylethanolamine phospholipase (NAPD-PLD) converts NAPE to anandamide. Because NAPE is already a natural component of mammalian membranes, it is the second step that generates anandamide, which is most crucial to neurotransmission.

Endocannabinoids are not stored in synaptic vesicles for later use but are synthesized on-demand, as is done for the gaseous neurotransmitters. An essential criterion for a signaling molecule to be considered a neurotransmitter is that neuronal depolarization should lead to its release. Depolarization leads to increases in cellular calcium, which in turn promotes the synthesis of the endocannabinoids and their release. The mechanism is explained in part by calcium activation of NAPE-PLD and DAGL, leading to augmented biosynthesis of anandamide and 2-AG, respectively.

Endocannabinoids generated in a neuron must cross the synaptic cleft to act on cannabinoid receptors. Similar to THC, endocannabinoids are highly lipophilic and thus poorly soluble in CSF. It is hypothesized that a specific endocannabinoid transporter exists to allow endocannabinoids to cross the synaptic cleft and allow entry into the target neuron.

INACTIVATION OF ENDOCANNABINOIDS. Neurotransmitters are typically inactivated either by reuptake from the neurons that release them or by degradation by highly specific enzymes, such as the example of acetylcholine being hydrolyzed by acetylcholinesterase. At least two enzymes exist to target the destruction of endocannabinoids and attenuate their neurotransmission. Fatty acid amide hydrolase (FAAH) converts anandamide to arachidonic acid and ethanolamine (Fig. 33-26). FAAH is found in regions of the brain where CB1 receptors are predominant and localize to postsynaptic neurons where anandamide is made. Rapid degradation of anandamide in part explains its relatively low potency compared to THC. Confirming the role of FAAH in anandamide inactivation, knockout mice without FAAH exhibit a 15-fold increase of anandamide, but not 2-AG. These mice have more significant behavioral responses to exogenous anandamide, owing to its decreased degradation. The endocannabinoid 2-AG

is inactivated by FAAH, but also by a monoacylglycerol lipase (MAGL) located in presynaptic neurons.

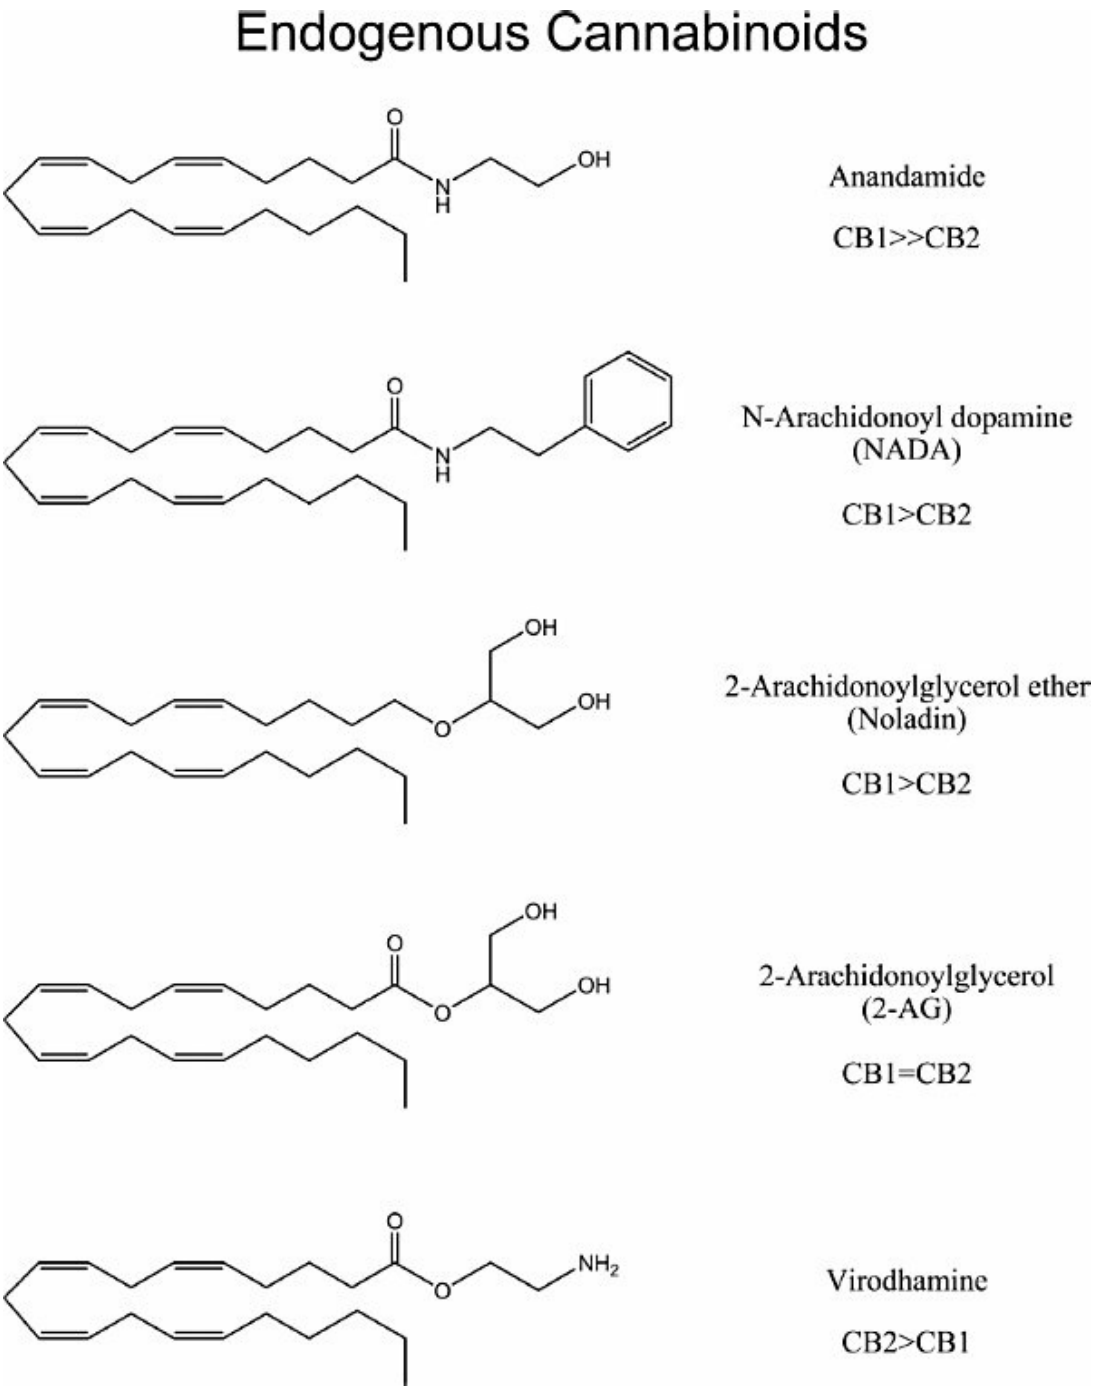

FIGURE 33-25
Endogenous cannabinoids. At least five endocannabinoids exist in the mammalian brain, each differing in affinity for CB1 and CB2 cannabinoid receptors. All are derived from the essential omega-6 fatty acid, arachidonic acid, which is also a substrate in the formation of prostaglandins and leukotrienes. (From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive*

Textbook of Psychiatry. 9th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2009:111.)

Pharmacologic inhibitors of FAAH have analgesic effects and reduce anxiety in animal models, but do not have the undesirable effects of THC such as immobility, lowered body temperature, or greater appetite. Such a pharmacologic strategy would be analogous to MAOIs and COMT inhibitors (COMTIs). MAOIs used to treat depression, slow the breakdown of serotonin and other monoamines, thereby increasing serotonin, whereas COMTIs serves an analogous role in blocking the destruction of dopamine and other catecholamines.

CANNABINOID RECEPTORS. CB1 receptors are possibly the most abundant G-protein–coupled receptors in the brain. They occur at the highest density in the basal ganglia, cerebellum, hippocampus, hypothalamus, anterior cingulate cortex, and cerebral cortex, particularly the frontal cortex. Humans or animals that receive large doses of THC develop catalepsy, a reduction of spontaneous movement, and freeze in bizarre and unnatural postures. The action of cannabinoids in the basal ganglia and cerebellum may be associated with these behaviors, which may prove relevant in understanding catatonic symptoms in schizophrenia.

CB1 receptors are predominantly found on axons and nerve termini, with little presence on neuronal dendrites and the cell body. CB1 receptors localize to the presynaptic rather than the postsynaptic side of the neuronal cleft, suggesting a role in the regulation of neurotransmission. A second cannabinoid receptor, CB2, is predominantly expressed on the surface of white blood cells of the immune system, but small amounts appear to be present in the brainstem.

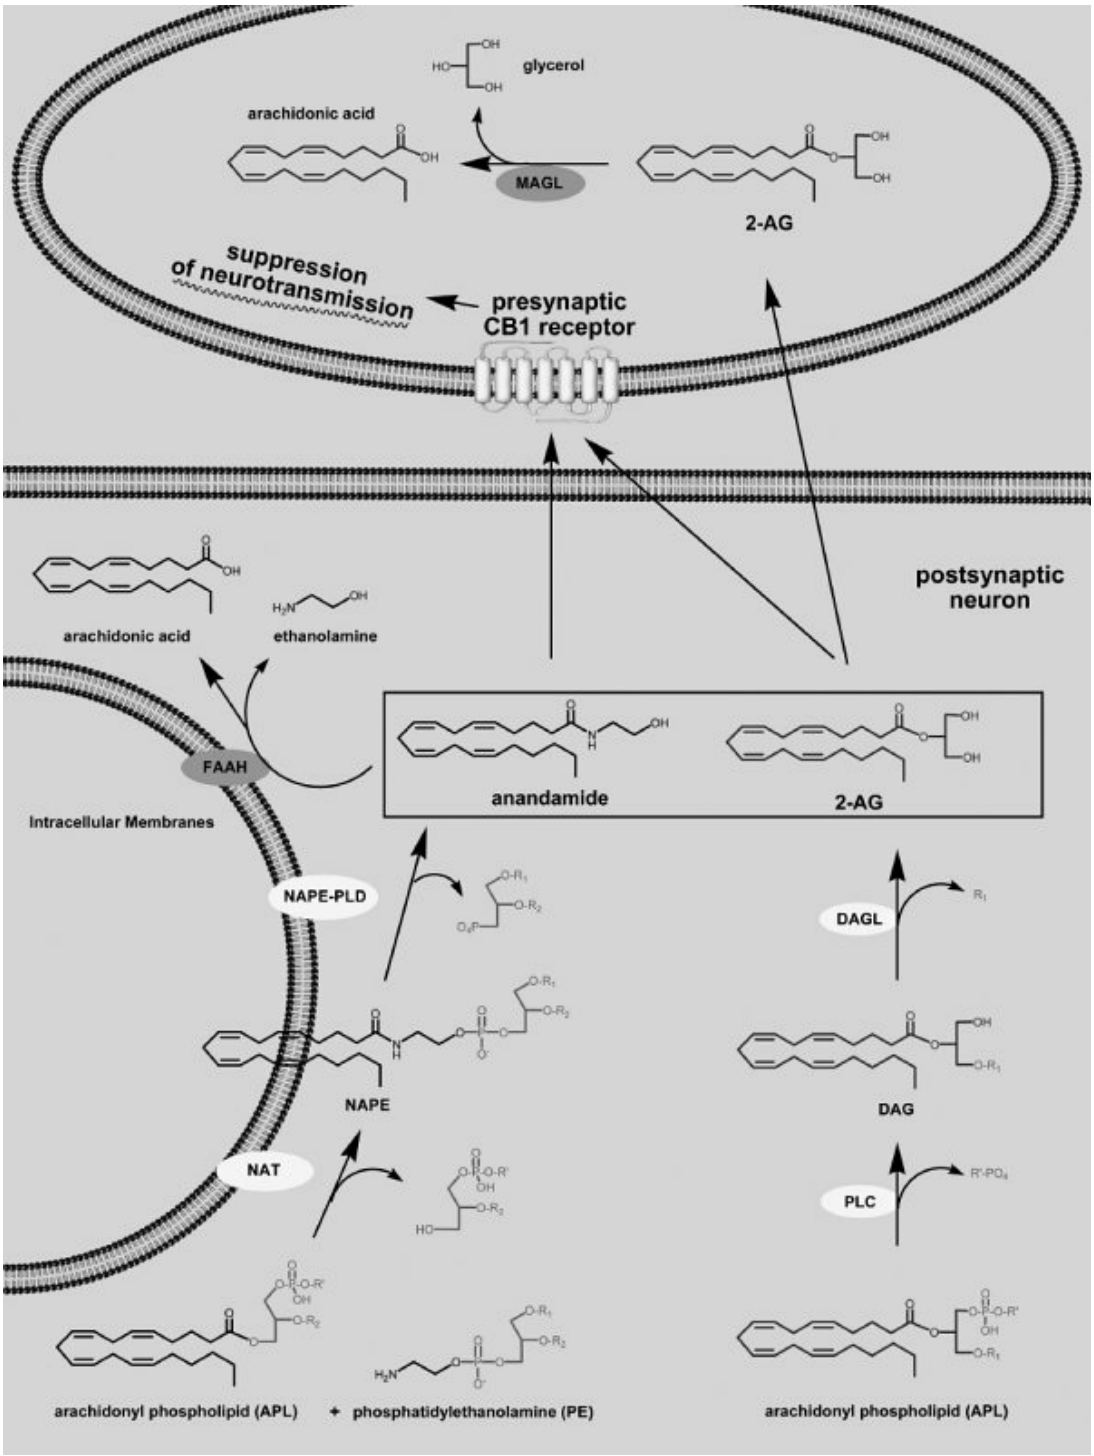

FIGURE 33-26

Retrograde neurotransmission of the endocannabinoids, anandamide, and 2-arachidonylglycerol (2-AG). Anandamide is synthesized on demand for neurotransmission via a two-step process. The enzyme NAT transfers the arachidonic acid chain from a phospholipid (APL) to phosphatidylethanolamine (PE), thereby producing NAPE. A second enzyme, NAPE-PLD, generates anandamide. 2-AG is similarly synthesized in two steps by the enzymes PLC and

DAGL. The endocannabinoids made in a postsynaptic neuron cross the synapse and activate presynaptic CB1 receptors, and suppress neurotransmission of the presynaptic neuron (although activation of the presynaptic neuron occurs in some cases). 2-AG is predominantly inactivated in the presynaptic neuron by MAGL, whereas anandamide is destroyed in the postsynaptic neuron by FAAH. PE, phosphatidylethanolamine; APL, arachidonyl phospholipids; NAT, *N*-acyltransferase; NAPE, *N*-arachidonyl-phosphatidylethanolamine; NAPE-PLD, *N*-arachidonyl-phosphatidylethanolamine phospholipase D; FAAH, fatty acid amide hydrolase; MAGL, monoacylglycerol lipase; PLC, phospholipase C; DAG, diacylglycerol; DAGL, diacylglycerol lipase; R_1-R_3, various acyl or akyl side chains of phospholipids; R', side chain of phospholipid head group. (From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2009:112.)

Effects on Neurotransmission. The cannabinoid CB1 receptor is associated with G proteins that mediate its intracellular signaling, in part, through inhibition of adenylyl cyclase. This action leads to a decrease in levels of the essential second messenger, cyclic adenosine monophosphate. Activation of the CB1 receptor also leads to the activation of potassium channels and inhibition of *N-type calcium channels. Because calcium is integral to neurotransmitter release, cannabinoids can block neurotransmission through this mechanism. Cannabinoid receptors also activate mitogen-activated protein kinases.*

With the use of cell culture models and slices of the brain, cannabinoids have been shown to block the release of a variety of neurotransmitters, including GABA, norepinephrine, and acetylcholine. Norepinephrine and acetylcholine tend to be excitatory neurotransmitters, and cannabinoid inhibition of their release would be expected to have an overall inhibitory effect. However, GABA is an inhibitory neurotransmitter, and cannabinoid inhibition of it would lead to overall excitatory effects, demonstrating that cannabinoids can have complex effects on neurotransmission depending on the specific context. Cannabinoids also appear to increase the release of brain endorphin neurotransmitters and increase dopamine release in the nucleus accumbens, a "reward center" relevant to addiction and learning. The endocannabinoids have been implicated in a variety of forms of synaptic plasticity, including LTP and long-term depression (LTD).

ENDOCANNABINOIDS IN ANXIETY AND MOOD. Endocannabinoid neurotransmission may be an essential regulator of anxiety, and cannabis

users regularly describe a tranquilizing effect of THC. The loss of signaling by the endocannabinoid system appears to promote anxiety-like states in animal studies. CB1 receptor-deficient animals exhibit more pronounced anxiety behavior when exposed to stress or new environs.

The endocannabinoid pathway may represent an attractive target in understanding posttraumatic stress responses and phobias. Although one cannot yet safely measure endocannabinoid levels in human subjects, this model is supported by clinical trials of the cannabinoid receptor blocker, rimonabant (Acomplia), which may offer promise as a strategy for weight loss (see below). A frequent adverse reaction to the drug is increased anxiety and depression.

Addiction. The endocannabinoid system may be an attractive target for understanding addiction. Mice deficient in CB1 receptors are unsurprisingly resistant to the behavioral effects of cannabinoids; they also appear to have reduced addiction to and withdrawal from opiates. Further interaction has also been found between the opioid and cannabinoid systems, as cannabinoids appear to increase the release of dopamine in the nucleus accumbens, a key reward area of the brain implicated in addiction. This dopamine release appears to require μ-opioid receptors, as pharmacologic inhibition of these receptors blocks the ability of cannabinoids to increase dopamine release. Rats with a preference for alcohol have decreased FAAH activity, suggestive of higher cannabinoid signaling. CB1 receptor antagonists dampen their alcohol consumption, whereas inhibiting FAAH increases their alcohol consumption. Furthermore, CB1-deficient animals also appear to have reduced alcohol intake. A single amino acid mutation in human FAAH is associated with drug abuse, and this abnormal enzyme appears to be less stable than its wild-type counterpart.

ENDOCANNABINOIDS IN PSYCHOSIS. Heavy use of cannabis can produce psychotic symptoms in individuals with no prior history of psychiatric disorder, although it is unclear whether this is solely due to the drug or an underlying vulnerability to psychosis in such persons. Cannabis use often worsens psychosis in schizophrenia, and heavy use has been associated with developing schizophrenia, although some suggest that this association is an accelerated development of symptoms in those who would eventually

manifest schizophrenia. Nonetheless, the endocannabinoid system has implications for the pathophysiology of schizophrenia, as cannabinoid signaling appears to increase the release of dopamine. Medications that act as antagonists of D_2 receptors will likely remain a component of schizophrenia treatment for some time.

Feeding. Following drug ingestion, THC users develop an increased appetite ("the munchies"), and cannabis has been utilized as an appetite stimulant for centuries. This effect may depend on CB1 receptors present in the hypothalamus. Endocannabinoid levels increase in the hypothalamus and limbic system when animals are deprived of food. Mice genetically deficient in CB1 receptors become resistant to developing obesity after being given a high-fat diet. Similarly, the CB1 receptor antagonist, rimonabant, appears to facilitate weight loss by blocking cannabinoid signaling. In a clinical trial of more than 3,000 obese patients, those treated with 20 mg/day of rimonabant lost 6.3 kg at 1 year, compared to 1.6 kg in the placebo group. Nausea was the most common side effect reported. A 2007 meta-analysis of clinical trials reported an overall 4.7 kg weight loss with rimonabant treatment, besting the weight-loss drugs orlistat (2.9 kg) and sibutramine (4.2 kg).

EFFECTS ON BRAIN INJURY AND PAIN. In mouse models of traumatic brain injury, 2-AG appears neuroprotective, reducing brain edema, infarct size, and cell death, while improving functional outcomes. Anandamide is also protected against brain injury in a model of multiple sclerosis (MS), and human patients with the disease have increased production of anandamide. A study of cannabinoid agonist, HU-211, led to more rapid clinical improvement following head trauma. FAAH inhibitors improved motor symptoms in a mouse model of Parkinson disease, likely via cannabinoids increasing dopamine neurotransmission.

There is increasing evidence that neurotransmission via the endocannabinoid pathway regulates pain perception. THC and cannabinoid agonists have proven effective in animal models of acute and chronic pain, ranging from burn injury to nerve damage and inflammation. The CB1 receptor plays an essential role in these effects, as the analgesic effects of cannabinoid drugs are lost when CB1 antagonist rimonabant is given. Similarly, the analgesic effect of THC is lost in mice that are genetically

deficient in the CB1 receptor.

Stress has long been associated with diminished pain perception, such as in cases of injured military personnel who demonstrate remarkable pain tolerance, a phenomenon known as *stress-induced analgesia.* The endocannabinoid system may mediate these effects. Animal models reveal anandamide and 2-AG production after stress, and stress-induced analgesia is blocked by the CB1 blocker, rimonabant, in these animals.

Endocannabinoid regulation of pain perception appears to be distinct from that of the endogenous opiate system, but the two pathways may share overlapping neural pathways. Evidence for this has been provided using CB1 blocker, rimonabant, and naloxone (Narcan), which blocks opiate receptors. Rimonabant attenuates analgesia provided by THC and cannabinoids, but only partially blocks the response to morphine. However, the opposite is true for opiates: Naloxone blocks morphine-induced analgesia but also partially blocks the analgesia of THC and cannabinoid drugs. Combinations of cannabinoid and opiate drugs evince synergistic analgesic effects in animal models.

Although it was initially assumed that cannabinoids exert their analgesic effects via the CNS, in animal models, it has been shown that localized administration of cannabinoids may also be useful, including drugs selective for the CB2 receptor, whose expression is minimal in the CNS.

Endocannabinoids may also influence pain sensitivity by mechanisms that do not involve the CB1 and CB2 receptors. Both anandamide and NADA can also activate a calcium channel known as the vanilloid receptor (also known as transient receptor potential vanilloid type 1 [TRPV-1]) that is found on sensory nerves. This same receptor is also famous for being activated by capsaicin, which causes the hot sensation after eating chili peppers. Thus endocannabinoids can exert opposing functions: Promoting analgesia through the CB1 and CB2 receptors but potentially increasing pain via TRP channels. Although CB2 receptors are primarily expressed in the periphery, postmortem analyses reveal an upregulation in the brain from those with Alzheimer disease.

The rapid development of novel cannabinoid drugs may allow for targeting of specific symptoms, rather than elicit all of the typical effects of THC. For instance, ajulemic acid demonstrates analgesic and anti-inflammatory properties but may offer a benefit of limited psychoactive side effects. In a

randomized clinical trial of this compound, Mathias Karst and colleagues found efficacy in reducing chronic neuropathic pain.

EFFECTS IN THE PERIPHERY. Cannabinoids lead to direct relaxation of vascular smooth muscle by local CB1 receptors. This vasodilation extends to the conjunctiva, leading to a "bloodshot" appearance in some cannabis users. Relaxation of ocular arteries by cannabinoids may offer utility as a treatment for glaucoma, a condition of high intraocular pressure, and activation of CB1 receptors in the kidney can improve renal blood flow. A role in generalized blood pressure regulation is unproven, and blood pressure is unaltered in persons treated with rimonabant or animals deficient in CB1 receptors. Cannabinoid signaling may also be relevant to ectopic pregnancy, as CB1-deficient mice retain many embryos in the oviduct.

Nonpsychoactive Cannabinoids. Although THC is the principal psychoactive component of cannabis, the many nonpsychoactive cannabinoids also have intriguing properties and may regulate neurotransmission.

Cannabidiol may offer potential therapeutic effects and appears to stimulate TRPV-1 receptors and influence endocannabinoid degradation. Also, cannabidiol demonstrated a protective effect in a mouse model of inflammatory arthritis. Although results have been mixed, purified cannabidiol may also exert antipsychotic activity, although the net effect of plant cannabis use typically exacerbates schizophrenia symptoms owing to THC. Tetrahydrocannabivarin is a plant cannabinoid that antagonizes CB1 receptors. It is a candidate marker to distinguish whether a patient has been using plant-derived cannabis or prescription THC, which contains no tetrahydrocannabivarin.

Eicosanoids

OVERVIEW. Clinical findings suggest that the dietary supplements omega-3 fatty acids, eicosapentaenoic acid (EPA), its ester ethyl-eicosapentaenoic (E-EPA), and docosahexaenoic acid (DHA) help relieve symptoms of depression, bipolar illness, schizophrenia, and cognitive impairment. DHA and EPA may help reduce behavioral outbursts and improve attention in

children.

CHEMISTRY. Essential fatty acids are a group of polyunsaturated fats that contain a carbon–carbon double bond in the third position from the methyl end group in the fatty acid chain. They are essential because unlike monosaturated and saturated fatty acids, polyunsaturated fatty acids cannot be synthesized de novo and can be acquired only through diet from natural fats and oils. Linoleic acid (LA) is the parent compound of omega-6 fatty acids, and α-linolenic acid (ALA) is the parent compound of omega-3 fatty acids. Both omega-3 and omega-6 groups use the same enzymes for desaturation and chain elongation. Algae and plankton synthesize Omega-3 fatty acids. Fish such as herring, salmon, mackerel, and anchovy feed on these aquatic species and become a rich dietary source of omega-3. EPA and DHA are highly unsaturated omega-3 fatty acids that contain 6 and 5 double bonds on their long structural chain, respectively. They are positioned in the cell membrane by phospholipids and play a crucial role in cell membrane signaling.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS. The most substantial scientific evidence for treatment with fatty acid supplements comes from the cardiovascular literature. Several human trials have demonstrated that omega-3 fatty acids lower blood pressure, reduce the rate of recurrent myocardial infarction, and lower triglyceride levels. In the nervous system, fatty acids are essential components of neurons, immune cells, and glial phospholipid membrane structures. They increase cerebral blood flow, decrease platelet aggregation, and delay the progression of atherosclerosis in the cardiovascular system. Omega-6 fatty acids appear to reduce inflammation and neuronal apoptosis and decrease phosphatidylinositol second messenger activity. Omega-3 fatty acids have been suggested to alter gene expression.

In the CNS, fatty acids are selectively concentrated in neuronal membranes and involved in cell membrane structure. Omega-6 arachidonic acid has been shown to enhance glutamate neurotransmission, stimulate stress hormone secretion, and trigger glial cell activation in the setting of oxidative toxicity and neurodegeneration. The omega-3 fatty acids DHA and EPA appear to protect neurons from inflammatory and oxidative toxicities. Increases in serotonin, enhancement of dopamine, and regulation of CRF have been

demonstrated in cell culture models.

In rodent models of depression, chronic EPA treatment normalized behavior in open field tests. Serotonin and norepinephrine were also increased in the limbic regions. Mice fed omega-3 poor diets had reduced memory, altered learning patterns, and more behavioral problems.

THERAPEUTIC INDICATIONS. Clinical research with the use of fish oil for mood disorders was based on epidemiology studies where there appears to be a negative correlation between fish consumption and depressive symptoms. Countries with lower per capita fish consumption had up to 60 times increased rates of major depression, bipolar disorder, and postpartum depression. Observational studies concluded that the lower incidence of seasonal affective disorder in Iceland and Japan, rather than latitude predicted, is related to the amount of fatty acid these populations consume in their diet. A study in Norway showed that the use of cod liver oil decreased depressive symptoms. Depression after a myocardial infarction shows higher arachidonic acid to EPA ratio. Postmortem studies in the brains of patients diagnosed with major depressive disorder show reduced DHA in the orbitofrontal cortex.

The first randomized, controlled pilot study of omega-3 fatty acids focused on adjunctive treatment in both bipolar and unipolar patients with depression in addition to their standard lithium (Eskalith) or valproic acid (Depakene) treatment. The omega-3 fatty acid group had significant improvement on the Hamilton Depression Scale and a more extended period of remission than the placebo group. A subsequent more extensive study supported a benefit from treatment with E-EPA for bipolar illness. However, a study of a group of patients with either bipolar disorder or rapid cycling treated with E-EPA showed no significant difference in any outcome measure between the EPA and placebo groups. Bleeding time was also increased in the treatment group. There are no current data on monotherapy in bipolar illness or depression.

The most convincing evidence comes from early brain development and learning studies. Pregnant mothers who consumed foods rich in DHA gave birth to infants who had improved problem-solving skills but not necessarily improved memory. Visual acuity and eye development are also associated with DHA supplementation during pregnancy.

Reports of behavioral studies of prisoners in England who consumed

higher amounts of seafood containing omega-3 fatty acids showed a decrease in assault rates. A Finnish study of violent criminals identified lower levels of omega-3 fatty acids in their system compared to the nonviolent offenders.

The negative and psychotic symptoms of schizophrenia may be improved with supplementation with omega-3 fatty acids. Antipsychotic medications like haloperidol (Haldol) appear to have fewer extrapyramidal side effects when combined with antioxidants and omega-3 fatty acids.

EPA and DHA have been associated with decreased dementia incidence. After reviewing the Rotterdam study of a longitudinal cohort of more than 5,300 patients, fish consumption appeared to be inversely related to the development of new cases of dementia. Later analysis of the study after 6 years demonstrated that low intake of omega-3 fatty acids was not associated with an increased risk of dementia. In contrast, the Zutphen study, also in the Netherlands, concluded that high fish consumption was inversely related to cognitive decline at a 3-year follow-up and after 5 years. Well-designed clinical trials are needed before omega-3 fatty acids can be recommended for the prevention of cognitive impairment.

PRECAUTIONS AND ADVERSE REACTIONS. The most adverse complication of eicosanoid use is an increased risk of bleeding. Dietary sources can contain heavy metals, and there is no standard preparation for capsule formulations. Treatment studies have yielded a variety of different doses, but evidence for the therapeutic dose and clinical guidelines are almost nonexistent. The length of treatment still needs to be determined.

Neurosteroids

BACKGROUND. Although steroids are critical for the maintenance of body homeostasis, neurosteroids are synthesized from cholesterol in the brain and independent of peripheral formation in the adrenals and gonads. Neurosteroids are produced by a sequence of enzymatic processes governed by cytochrome P450 (CYP) and non-CYP enzymes, either within or outside the mitochondria of several types of CNS and peripheral nervous system (PNS) cells.

Recent work has shown that neurosteroids can operate through a nongenomic pathway to regulate neuronal excitability through their effects on

neurotransmitter-gated ion channels. Receptors are generally located in the nucleus, membrane, or microtubules of the CNS and PNS. Although steroids and neurosteroids can act on the same nuclear receptors, neurosteroids differ from steroids in their topologic distribution and regional synthesis. The most well-known effect of neurosteroids is on the GABA receptor, particularly the $GABA_A$ receptor. Neurosteroids acting primarily at this site include allopregnanolone (3α,5α-tetrahydroprogesterone), pregnanolone (PREG), and tetrahydrodeoxycorticosterone (THDOC). Dehydroepiandrosterone sulfate (DHEA-S), the most prevalent neurosteroid, acts as a noncompetitive modulator of GABA. Its precursor dehydroepiandrosterone (DHEA) has also been shown to exert inhibitory effects at the GABA receptor. Some neurosteroids may also act at the NMDA, α-amino-3-hydroxy-5-methyl-4-isoxazole-propanoic acid (AMPA), kainate, glycine, serotonin, sigma type-1, and nicotinic acetylcholine receptors. Progesterone is also considered a neurosteroid and can regulate gene expression at progesterone receptors.

NEUROSTEROIDS IN NEURODEVELOPMENT AND NEUROPROTECTION. In general, neurosteroids stimulate axonal growth and promote synaptic transmission. Specific neuroprotective effects are unique to each neurosteroid. DHEA acts to regulate brain serotonin and dopamine levels, suppress cortisol, increase hippocampal primed burst potentiation and cholinergic function, decrease amyloid-β protein, inhibit the production of proinflammatory cytokines, and prevent free radical scavenging. DHEA and DHEA-S have both been shown to have a role in glial development and neuronal growth and to promote their survival in animals; the injection of these substances into the brains of mice promoted long-term memory while reversing amnesia. Progesterone is linked to myelinating processes like aiding in the repair of damaged neural myelination. Allopregnanolone contributes to the reduction of contacts during axonal regression.

ROLE OF NEUROSTEROIDS IN MENTAL ILLNESS. Neurosteroids have distinct implications for the maintenance of normal neurologic function and also may contribute to neuropathology. Neurosteroids are differentially regulated in males and females and may affect the manifestation of psychological disorders in these two populations. Specifically, they play a distinct role in depression and anxiety disorders and may be targeted by psychiatric

medications someday soon.

Depression. When compared with nondepressed controls, studies show that depressed patients have lower plasma and CSF concentrations of allopregnanolone. Also, this research has elucidated an inverse relationship between allopregnanolone concentrations and the severity of depressive illness. However, there are no allopregnanolone-based therapies available for humans, so its direct efficacy is unsubstantiated. Antidepressant drugs, specifically fluoxetine (Prozac), have been shown in multiple studies to increase the levels of certain neurosteroids. Nonetheless, there is debate over the therapeutic properties of neurosteroids, prompting the investigation of neurosteroid concentrations in patients undergoing nonpharmacologic therapies. Preliminary results indicate that the lack of modifications in neurosteroid levels during nonpharmacologic treatments supports the validity of the pharmacologic properties of antidepressants, not their therapeutic action, in the elevation of neurosteroid levels in medicated populations.

Anxiety Disorders. In patients with anxiety disorders, the primary mechanism of action is on the GABA receptor. Homeostasis characterized by regular GABAergic activity is restored after panic attacks as neurosteroids are released in response to stress. Allopregnanolone stimulates GABAergic activity with 20 times the strength of benzodiazepines and 200 times the potency of barbiturates. Both positive and negative regulation of the $GABA_A$ *receptor are correlated with anxiolytic and anxiogenic action, respectively.*

Psychotic Disorders. Also, to their primary relevance to the pharmacologic treatment of mood and anxiety disorders, neurosteroids contribute to psychotic, childhood, substance abuse, eating, and postpartum disorders. DHEA and DHEA-S mediate the effect of neurosteroids on psychotic disorders such as schizophrenia. DHEA has been dispensed to decrease anxiety in patients with schizophrenia, as DHEA and DHEA-S suppress GABA inhibition and heighten the neuronal response at the NMDA and sigma receptors. DHEA and DHEA-S levels are typically elevated in the initial episode of a patient with schizophrenia, indicating the onset of psychosis upregulates neurosteroids. Because neurosteroid levels are studied across various illness stages, some questions still exist regarding the role of

neurosteroids in psychosis.

Childhood Mental Illness. In children, the clinical symptomology of ADHD is inversely correlated with DHEA and pregnenolone levels.

Substance Abuse. Alcohol is theorized to regulate the GABA receptor and induce de novo steroid synthesis in the brain, specifically, pregnenolone, allopregnanolone, and allotetrahydrodeoxycorticosterone levels are increased in the brain and periphery in response to increases in peripheral alcohol levels. It is hypothesized that sharp increases in ethanol concentration may mimic the acute stress response and elevate neurosteroid concentrations by the HPA axis. To prevent ethanol dependence, researchers are investigating fluctuations in neurosteroid levels and in vivo neurosteroid responsiveness. Neurosteroids (increased allopregnanolone levels in particular) are associated with drug abuse. However, DHEA-S may check the acquisition of morphine tolerance. Past research has shown that DHEA-S levels were also increased in patients who abstained from cocaine use in a treatment program, and as patients relapsed, DHEA-S concentrations decreased accordingly.

Eating Disorders. Concerning eating disorders, DHEA has been shown to diminish food intake, temper obesity, moderate insulin resistance, and lower lipids in rats with a model of youth-onset, hyperphagic, and genetic obesity. By regulating the serotonergic system, DHEA is hypothesized to promote a reduced caloric load. Although hypothetical, low levels of DHEA and DHEA-S are recorded in young women with anorexia nervosa, and 3 months of oral DHEA supplementation increased bone density and tempered the emotional problems associated with the disorder.

Postpartum and Gynecologic Disorders. Because estrogen and progesterone levels fluctuate during pregnancy and drop markedly after delivery, neurosteroids are thought to contribute to postpartum disorders. Low postpartum DHEA concentrations have been linked to mood instability. Also, allopregnanolone levels correlated with mood disorders during pregnancy and in premenstrual syndrome (PMS). It has been noted that women with the premenstrual dysphoric disorder have higher allopregnanolone/progesterone ratios than normal controls; women treated for this disorder reported

improvement as allopregnanolone levels decreased.

Neurosteroids, Memory Disorders, and Aging. Neurosteroid levels may be irregular in neurodegenerative disorders and aging conditions such as Alzheimer disease and Parkinson disease. DHEA levels at age 70 are only about 20 percent of their maximum value recorded in the late 20s, and some researchers believe DHEA supplementation can prevent or slow the cognitive declines associated with the aging process. However, conflicting studies have indicated that DHEA administration does not improve cognitive measures in patients. Also, in patients with Alzheimer disease, DHEA concentrations are markedly decreased.

PSYCHONEUROENDOCRINOLOGY

The term *psychoneuroendocrinology* encompasses the structural and functional relationships between hormonal systems and the CNS and behaviors that modulate and are derived from both. Classically, *hormones* have been defined as the products of endocrine glands transported by the blood to exert their action at sites distant from their release. Advances in neuroscience have shown, however, that in the CNS, the brain not only serves as a target site for regulatory control of hormonal release but also has secretory functions of its own and serves as an end-organ for some hormonal actions. These complex interrelationships make classic distinctions between the origin, structure, and function of neurons and those of endocrine cells dependent on physiologic context.

Hormone Secretion

Hormone secretion is stimulated by the action of a neuronal secretory product of neuroendocrine transducer cells of the hypothalamus. Examples of hormone regulators (Table 33-6) include corticotropin-releasing hormone (CRH), which stimulates adrenocorticotropin (adrenocorticotropic hormone [ACTH]); TRH, which stimulates the release of TSH; gonadotropin-releasing hormone (GnRH), which stimulates the release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH); and somatostatin (somatotropin release-inhibiting factor [SRIF]) and growth-hormone-releasing hormone (GHRH), which influence growth hormone (GH) release. Chemical signals

cause the release of these neurohormones from the median eminence of the hypothalamus into the portal hypophyseal bloodstream and subsequent transport to the pituitary to regulate the release of target hormones. Pituitary hormones, in turn, act directly on target cells (e.g., ACTH on the adrenal gland) or stimulate the release of other hormones from peripheral endocrine organs. Also, these hormones have feedback actions that regulate secretion and exert neuromodulatory effects in the CNS.

Table 33-6
Examples of Regulating Hormones

Regulating Hormone	Hormone Stimulated (or Inhibited)
Corticotropin-releasing hormone	Adrenocorticotropic hormone
Thyrotropin-releasing hormone	Thyroid-stimulated hormone
Luteinizing hormone-releasing hormone	Luteinizing hormone
Gonadotropin-releasing hormone	Follicle-stimulating hormone
Somatostatin	Growth hormone (inhibited)
Growth hormone-releasing hormone	Growth hormone
Progesterone, oxytocin	Prolactin
Arginine vasopressin	Adrenocorticotropic hormone

Hormones are divided into two general classes: (1) proteins, polypeptides, and glycoproteins, and (2) steroids and steroid-like compounds (Table 33-7); these are secreted by an endocrine gland into the bloodstream and are transported to their sites of action.

Developmental Psychoneuroendocrinology

Hormones can have both organizational and activational effects. Exposure to gonadal hormones during critical stages of neural development directs changes in brain morphology and function (e.g., sex-specific behavior in adulthood). Similarly, thyroid hormones are essential for the normal development of the CNS, and thyroid deficiency during critical stages of postnatal life will severely impair growth and development of the brain, resulting in behavioral disturbances that may be permanent if replacement therapy is not instituted.

Endocrine Assessment

Neuroendocrine function can be studied by assessing baseline measures and by measuring the response of the axis to some neurochemical or hormonal challenge. The first method has two approaches. One approach is to measure

a single time point—for example, morning levels of growth hormone; this approach is subject to significant error because of the pulsatile nature of the release of most hormones. The second approach is to collect blood samples at multiple points or to collect 24-hour urine samples; these measurements are less susceptible to significant errors. The best approach, however, is to perform a neuroendocrine challenge test, in which the person is given a drug or a hormone that perturbs the endocrine axis in some standard way. Persons with no disease show much less variation in their responses to such challenge studies than in their baseline measurements.

Hypothalamic–Pituitary–Adrenal Axis

Since the earliest conceptions of the stress response by Hans Selye and others, investigation of HPA function has occupied a central position in psychoendocrine research. CRH, ACTH, and cortisol levels all rise in response to a variety of physical and psychic stresses and serve as prime factors in maintaining homeostasis and developing adaptive responses to novel or challenging stimuli. The hormonal response depends on the characteristics of the stressor and how one assesses and copes with it. Aside from generalized effects on arousal, distinct effects on sensory processing, stimulus habituation and sensitization, pain, sleep, and memory storage and retrieval have been documented. In primates, social status can influence adrenocortical profiles and, in turn, be affected by exogenously induced changes in hormone concentration.

Pathologic alterations in HPA function have been associated primarily with mood disorders, PTSD, and dementia of the Alzheimer type, although recent animal evidence points toward the role of this system in substance use disorders as well. Disturbances of mood are found in more than 50 percent of patients with Cushing syndrome (characterized by elevated cortisol concentrations), with psychosis or suicidal thought apparent in more than 10 percent of patients studied. Cognitive impairments similar to those seen in major depressive disorder (principally in visual memory and higher cortical functions) are common and relate to the severity of the hypercortisolemia and possible reduction in hippocampal size. In general, reduced cortisol levels normalize mood, and mental status. Conversely, in Addison disease (characterized by adrenal insufficiency), apathy, social withdrawal, impaired

sleep, and decreased concentration frequently accompany prominent fatigue. Replacement of glucocorticoid (but not of electrolyte) resolves behavioral symptomatology.

Similarly, HPA abnormalities are reversed in persons who are treated successfully with antidepressant medications. Failure to normalize HPA abnormalities is a poor prognostic sign. Alterations in HPA function associated with depression include elevated cortisol concentrations, failure to suppress cortisol in response to dexamethasone, increased adrenal size and sensitivity to ACTH, a blunted ACTH response to CRH, and, possibly, elevated CRH concentrations in the brain.

Hypothalamic–Pituitary–Gonadal Axis

The gonadal hormones (progesterone, androstenedione, testosterone, estradiol, and others) are steroids that are secreted principally by the ovary and testes, but significant amounts of androgens arise from the adrenal cortex as well. The prostate gland and adipose tissue, also involved in the synthesis and storage of dihydrotestosterone, contribute to individual variance in sexual function and behavior.

The timing and presence of gonadal hormones play a critical role in the development of sexual dimorphisms in the brain. Developmentally, these hormones direct the organization of many sexually dimorphic CNS structures and functions, such as the size of the hypothalamic nuclei and corpus callosum, neuronal density in the temporal cortex, the organization of language ability, and responsivity in Broca motor speech area. Women with congenital adrenal hyperplasia—a deficiency of the enzyme 21-hydroxylase, which leads to high exposure to adrenal androgens in prenatal and postnatal life, in some studies—are more aggressive and assertive and less interested in traditional female roles than female control subjects. Sexual dimorphisms may also reflect acute and reversible actions of relative steroid concentrations (e.g., higher estrogen levels transiently increase CNS sensitivity to serotonin).

Testosterone. Testosterone is the primary androgenic steroid, with both androgenic (i.e., facilitating linear body growth) and somatic growth functions. Testosterone is associated with increased violence and aggression in animals and correlation studies in humans, but anecdotal reports of

increased aggression with testosterone treatment have not been substantiated in investigations in humans. In hypogonadal men, testosterone improves mood and decreases irritability. Varying effects of anabolic–androgenic steroids on mood have been noted anecdotally. A prospective, placebo-controlled study of anabolic–androgenic steroid administration in normal subjects reported positive mood symptoms, including euphoria, increased energy, and sexual arousal, in addition to increases in the negative mood symptoms of irritability, mood swings, violent feelings, anger, and hostility.

Testosterone is essential for sexual desire in both men and women. In males, muscle mass and strength, sexual activity, desire, thoughts, and intensity of sexual feelings depend on normal testosterone levels, but these functions are not augmented by supplemental testosterone in those with normal androgen levels. Adding small amounts of testosterone to routine hormonal replacement in postmenopausal women has proved, however, to be as beneficial as its use in hypogonadal men.

Dehydroepiandrosterone. DHEA and DHEA sulfate (DHEA-S) are adrenal androgens secreted in response to ACTH and represent the most abundant circulating steroids. DHEA is also a neurosteroid that is synthesized in situ in the brain. DHEA has many physiologic effects, including a reduction in neuronal damage from glucocorticoid excess and oxidative stress. Behavioral interest has centered on its possible involvement in memory, mood, and several psychiatric disorders. *Adrenarche* is the prepubertal onset of adrenal production of DHEA-S and may play a role in human maturation through increasing the activity of the amygdala and hippocampus and promoting synaptogenesis in the cerebral cortex. DHEA has been shown to act as an excitatory neurosteroid and to enhance memory retention in mice, but studies of DHEA administration to humans have not consistently shown any improvement in cognition. Several trials of DHEA administration point to an improvement in well-being, mood, energy, libido, and functional status in depressed individuals. Administration of DHEA to women with adrenal insufficiency (e.g., Addison disease) has repeatedly been demonstrated to enhance mood, energy, and sexual function; effects in men remain to be assessed. Mood, fatigue, and libido improved in human immunodeficiency virus (HIV)-positive patients treated with DHEA in one study, and DHEA and DHEA-S are inversely correlated with severity in

ADHD. Women diagnosed with fibromyalgia have significantly decreased DHEA-S levels, but supplementation does not improve outcomes. Several cases of possible DHEA-induced mania have been reported, and DHEA has been reported to be inversely related to extrapyramidal symptoms (EPS) in patients with schizophrenia who are treated with antipsychotics. DHEA administration, in these cases, improves EPS.

Double-blind treatment studies have shown antidepressant effects of DHEA in patients with major depression, midlife-onset dysthymia, and schizophrenia, although beneficial effects on memory have not been reliably demonstrated. A small, double-blind trial of DHEA treatment of Alzheimer disease failed to reveal significant benefit, although a near-significant improvement in cognitive function was seen after 3 months of treatment.

Animal studies suggest that DHEA may be involved in eating behavior, aggressiveness, and anxiety as well, with its effects resulting from its transformation into estrogen, testosterone, or androsterone from its antiglucocorticoid activity, or direct effects on $GABA_A$, NMDA, and σ receptors. Because of the putative antiglucocorticoid effects, the ratio of cortisol to DHEA levels may be particularly crucial in understanding adaptive responses to stress. Both cortisol and DHEA appear to be involved in fear conditioning, with the cortisol/DHEA ratio hypothesized to be an index of the degree to which an individual is buffered against the adverse effects of stress. This ratio is related to some measures of psychopathology and response to treatment, predicting the persistence of the first episode major depression and being related to the degree of depression, anxiety, and hostility in patients with schizophrenia and response to antipsychotic treatment. Patients with PTSD have higher DHEA levels and lower cortisol/DHEA ratios related to symptom severity, suggesting a role in PTSD recovery. Fear-potentiated startle is more extensive in individuals with high as compared to low cortisol/DHEA-S ratios and is positively associated with cortisol and negatively with DHEA-S. More significant DHEA response to ACTH is related to lower PTSD ratings, and the cortisol/DHEA ratio to negative mood symptoms. A genetic variation in an ACTH receptor promoter has been found to influence DHEA secretion in response to dexamethasone and may underlie some individual differences in stress response.

Estrogen and Progesterone. Estrogens can influence neural activity in

the hypothalamus and limbic system directly through the modulation of neuronal excitability, and they have complex multiphasic effects on nigrostriatal dopamine receptor sensitivity. Accordingly, evidence indicates that the antipsychotic effect of psychiatric drugs can change over the menstrual cycle and that the risk of tardive dyskinesia depends partly on estrogen concentrations. Several studies have suggested that gonadal steroids modulate spatial cognition and verbal memory and are involved in impeding age-related neuronal degeneration. Increasing evidence also suggests that estrogen administration decreases the risk and severity of dementia of the Alzheimer type in postmenopausal women. Estrogen has mood-enhancing properties and can also increase sensitivity to serotonin, possibly by inhibiting monoamine oxidase. In animal studies, long-term estrogen treatment results in a decrease in serotonin 5-HT_1 receptors and an increase in 5-HT_2 receptors. In oophorectomized women, significant reductions in tritiated imipramine binding sites (which indirectly measure presynaptic serotonin uptake) were restored with estrogen treatment.

The association of these hormones with serotonin is hypothetically relevant to mood change in premenstrual and postpartum mood disturbances. In premenstrual dysphoric disorder, a constellation of symptoms resembling major depressive disorder occurs in most menstrual cycles, appearing in the luteal phase and disappearing within a few days of the onset of menses. No definitive abnormalities in estrogen or progesterone levels have been demonstrated in women with the premenstrual dysphoric disorder, but decreased serotonin uptake with premenstrual reductions in steroid levels has been correlated with the severity of some symptoms.

Most psychological symptoms associated with the menopause are reported during perimenopause rather than after complete cessation of menses. Although studies suggest no increased incidence of major depressive disorder, reported symptoms to include worry, fatigue, crying spells, mood swings, diminished ability to cope, and diminished libido or intensity of orgasm. Hormone replacement therapy (HRT) is effective in preventing osteoporosis and reinstating energy, a sense of well-being, and libido; however, its use is very controversial. Studies have shown that combined estrogen–progestin drugs (e.g., Premarin) cause small increases in breast cancer, heart attack, stroke, and blood clots among menopausal women.

Studies of the effects of estrogen alone in women who have had hysterectomies (because estrogen alone increases the risk for uterine cancer) are ongoing.

Hypothalamic–Pituitary–Thyroid Axis

Thyroid hormones are involved in the regulation of nearly every organ system, mainly those integral to the metabolism of food and the regulation of temperature, and are responsible for the optimal development and function of all body tissues. Also, to its prime endocrine function, TRH has direct effects on neuronal excitability, behavior, and neurotransmitter regulation.

Thyroid disorders can induce virtually any psychiatric symptom or syndrome, although no consistent associations of specific syndromes and thyroid conditions are found. Hyperthyroidism is commonly associated with fatigue, irritability, insomnia, anxiety, restlessness, weight loss, and emotional lability; marked impairment in concentration and memory may also be evident. Such states can progress into delirium or mania, or they can be episodic. On occasion, a real psychosis develops, with paranoia as a frequent presenting feature. In some cases, psychomotor retardation, apathy, and withdrawal are the presenting features rather than agitation and anxiety. Symptoms of mania have also been reported following the rapid normalization of thyroid status in hypothyroid individuals and may covary with thyroid level in individuals with episodic endocrine dysfunction. In general, behavioral abnormalities resolve with normalization of thyroid function and respond symptomatically to traditional psychopharmacological regimens.

The psychiatric symptoms of chronic hypothyroidism are generally well recognized (Fig. 33-27). Classically, fatigue, decreased libido, memory impairment, and irritability are noted, but an actual secondary psychotic disorder or dementia-like state can also develop. Suicidal ideation is common, and the lethality of actual attempts is profound. In milder, subclinical states of hypothyroidism, the absence of gross signs accompanying endocrine dysfunction can result in its being overlooked as a possible cause of a mental disorder.

Growth Hormone

Growth hormone deficiencies interfere with growth and delay the onset of puberty. Low GH levels can result from a stressful experience. Administration of GH to individuals with GH deficiency benefits cognitive function in addition to its more obvious somatic effects, but evidence indicates poor psychosocial adaptation in adulthood for children who were treated for GH deficiency. A significant percentage of patients with major depressive disorder and dysthymic disorder may have a GH deficiency. Some prepubertal and adult patients with diagnoses of major depressive disorder exhibit hyposecretion of GHRH during an insulin tolerance test, a deficit that has been interpreted as reflecting alterations in both cholinergic and serotonergic mechanisms. Several GH abnormalities have been noted in patients with anorexia nervosa. Secondary factors, such as weight loss, however, in both major depressive disorder and eating disorders, may be responsible for alterations in the endocrine release.

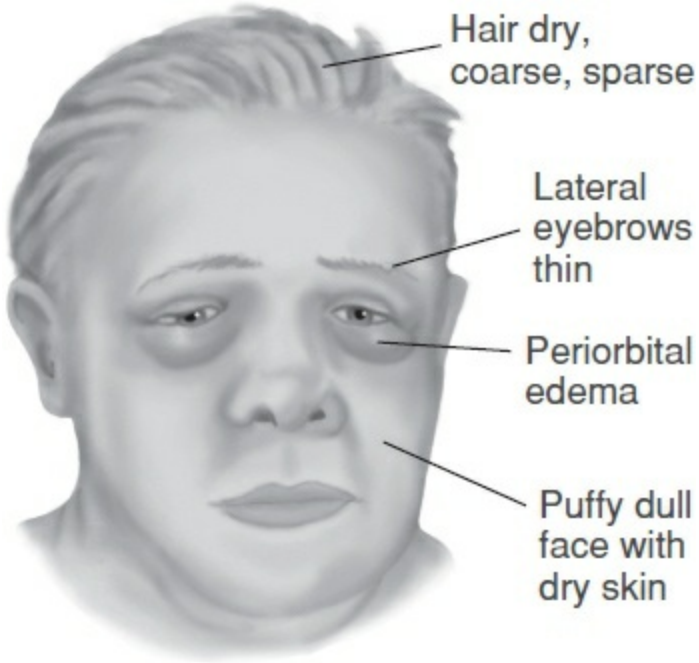

FIGURE 33-27
Myxedema: The patient with severe hypothyroidism (myxedema) has a dull, puffy facies. The edema, often particularly pronounced around the eyes, does not pit with pressure. The hair and eyebrows are dry, coarse, and thinned. The skin is dry. (From Bickley LS, Szilagyi P. *Bates' Guide to Physical Examination and History Taking*, 8th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2003.)

Nonetheless, at least one study has reported that GHRH stimulates food

consumption in patients with anorexia nervosa and lowers food consumption in patients with bulimia. Administration of GH to older men increases lean body mass and improves vigor. GH is released in pulses throughout the day, but the pulses are closer together during the first hours of sleep than at other times.

Prolactin

Since its identification in 1970, the anterior pituitary hormone prolactin has been examined as a potential index of dopamine activity, dopamine receptor sensitivity, and antipsychotic drug concentration in studies of CNS function in psychiatric patients and as a correlate of stress responsivity. The secretion of prolactin is under direct inhibitory regulation by dopamine neurons located in the tuberoinfundibular section of the hypothalamus and is, therefore, increased by classical antipsychotic medications. Prolactin also inhibits its secretion using a short-loop feedback circuit to the hypothalamus. Also, a significant number of prolactin-releasing or prolactin-modifying factors have been identified, including estrogen, serotonin (mainly through the 5-HT_2 and 5-HT_3 receptors), norepinephrine, opioids, TRH, T_4, histamine, glutamate, cortisol, CRH, and oxytocin, with interaction effects possible. For example, estrogen may promote the serotonin-stimulated release of prolactin.

Prolactin is primarily involved in reproductive functions. During maturation, prolactin secretion participates in gonadal development, whereas, in adults, prolactin contributes to the regulation of the behavioral aspects of reproduction and infant care, including estrogen-dependent sexual receptivity and breast-feeding. In female rats, prolactin secretion is strongly stimulated with exposure to pups. In women, basal prolactin levels are elevated in the postpartum period before weaning, and prolactin release is stimulated by suckling. Hyperprolactinemia is associated with low testosterone in men and reduced libido in men and women. In rodents, prolactin level is increased along with corticosterone in response to such stressful stimuli as immobilization, hypoglycemia, surgery, and cold exposure and may be specifically associated with the use of passive coping in the face of a stressor. Prolactin promotes various stress-related behaviors in rats, depending on the condition, such as increasing object-directed exploration while decreasing other exploration.

Patients with hyperprolactinemia often complain of depression, decreased libido, stress intolerance, anxiety, and increased irritability. These behavioral symptoms usually resolve in parallel with decrements in serum prolactin when surgical or pharmacologic treatments are used. In psychotic patients, prolactin concentrations and prolactin-related sexual disturbances have been positively correlated with the severity of tardive dyskinesia. Prolactin levels are also positively correlated with adverse symptoms in schizophrenia.

Melatonin

Melatonin, a pineal hormone, is derived from the serotonin molecule and it controls photoperiodically mediated endocrine events (particularly those of the hypothalamic–pituitary–gonadal axis). It also modulates immune function, mood, and reproductive performance and is a potent antioxidant and free-radical scavenger. Melatonin has a depressive effect on CNS excitability, is an analgesic, and has seizure-inhibiting effects in animal studies. Melatonin can be a useful therapeutic agent in the treatment of circadian phase disorders such as jet lag. Intake of melatonin increases the speed of falling asleep, as well as its duration and quality.

Oxytocin

Oxytocin, also a posterior pituitary hormone, is involved in osmoregulation, the milk ejection reflex, food intake, and female maternal and sexual behaviors. Oxytocin may be released during orgasm, more so in women than in men, and promote bonding between the sexes. It has been used in autistic children experimentally in an attempt to increase socialization.

Insulin

Increasing evidence indicates that insulin may be integrally involved in learning and memory. Insulin receptors occur in high density in the hippocampus and are thought to help neurons metabolize glucose. Patients with Alzheimer disease have lower insulin concentrations in the CSF than controls, and both insulin and glucose dramatically improve verbal memory. Depression is frequent in patients with diabetes, as are indexes of impaired hormonal response to stress. It is not known whether these findings represent the direct effects of the disease or are secondary, nonspecific effects. Some

antipsychotics are known to dysregulate insulin metabolism.

Endocrine Variables in Psychiatric Disorders

Although it is clear that alterations in endocrine regulation are involved in the pathophysiology and treatment responses of many psychiatric disorders, incorporating these findings into clinical diagnostic assessment, and decision-making remains problematic. Large-scale longitudinal or cost-effectiveness studies are rare, despite indications that baseline alterations in glucocorticoid regulation and thyroid status (two of the best-studied abnormalities) may be useful in subtyping psychiatric disorders and prediction of outcome. Alterations in HPA/stress regulation underlie several psychiatric diagnoses and may serve as complementary independent variables in assigning treatment response and course of illness to the classical behavioral categories that have thus far defined psychiatric practice. Studying genetic polymorphisms in factors regulating hormonal response may help us better understand the influence of hormonal variability on the illness and also possible underlying differences in the illness as reflected in these genetic subtypes.

IMMUNE SYSTEM AND CENTRAL NERVOUS SYSTEM INTERACTIONS

Interactions between the immune system and the CNS play a critical role in the maintenance of bodily homeostasis and the development of diseases, including psychiatric disease. Alterations in CNS function brought about by a variety of stressors have been shown to influence both the immune system as well as diseases that involve the immune system. Moreover, many of the relevant hormonal and neurotransmitter pathways that mediate these effects have been elucidated. Of considerable interest is accumulating data that cytokines, which derive from immune cells and microglia, have profound effects on the CNS. The relative role of cytokines and their signaling pathways in the various psychiatric diseases is an area of active investigation, as is the role of infectious and autoimmune diseases in the pathophysiology of psychiatric disorders. These findings highlight the importance of interdisciplinary efforts involving the neurosciences and immunology for gaining new insights into the etiology of psychiatric disorders.

Overview of the Immune System

The immune system can protect the body from the invasion of foreign pathogens, such as viruses, bacteria, fungi, and parasites. Also, the immune system can detect and eliminate cells that have become neoplastically transformed. These functions are accomplished through highly specific receptors on immune cells for molecules derived from invading organisms and a rich intercellular communication network that involves direct cell-to-cell interactions and signaling between cells of the immune system by soluble factors called *cytokines.* The body's absolute dependence on the efficient functioning of the immune system is illustrated by the less than 1-year survival rate of untreated infants born with severe combined immunodeficiency disease and the devastating opportunistic infections and cancers that arise during untreated acquired immunodeficiency syndrome (AIDS).

Behavioral Conditioning

The fact that learning processes are capable of influencing immunologic function is an example of interactions between the immune system and the nervous system. Several classical conditioning paradigms have been associated with suppression or enhancement of the immune response in various experimental designs. The conditioning of immunologic reactivity provides further evidence that the CNS can have significant immunomodulatory effects.

Some of the first evidence for immunologic conditioning was derived from the serendipitous observation that animals undergoing extinction in a taste-aversion paradigm with cyclophosphamide, an immunosuppressive agent, had unexpected mortality. In that taste-aversion paradigm, animals were simultaneously exposed to an oral saccharin solution (the conditioned stimulus) and an intraperitoneal injection of cyclophosphamide (unconditioned stimulus). Because the animals experienced considerable physical discomfort from the cyclophosphamide injection, through the process of conditioning, they began to associate the ill effects of cyclophosphamide with the taste of the oral saccharin solution. If given a choice, the animals avoided the saccharin solution (taste aversion). Conditioned avoidance can be eliminated or extinguished if the saccharin is

repeatedly presented in the absence of cyclophosphamide. However, it was observed that animals undergoing extinction of cyclophosphamide-induced taste aversion died unexpectedly, leading to the speculation that the oral saccharin solution had a specific conditioned association with the immunosuppressive effects of cyclophosphamide. Repeated exposure to the saccharin-associated conditioned immunosuppression during extinction might explain the unexpected death of animals. To test that hypothesis, researchers conditioned the animals with saccharin (conditioned stimulus) and intraperitoneal cyclophosphamide (unconditioned conditioned stimulus) and then immunized them with sheep red blood cells. At different times after immunization, the conditioned animals were re-exposed to saccharin (conditioned stimulus) and examined. The conditioned animals exhibited a significant decrease in mean antibody titers to sheep red blood cells when compared to the control animals. Thus, the evidence demonstrated that immunosuppression of humoral immunity was occurring in response to the conditioned stimulus of saccharin alone.

Stress and the Immune Response

Interest in the effects of stress on the immune system grew out of a series of animal and human studies suggesting that stressful stimuli can influence the development of immune-related disorders, including infectious diseases, cancer, and autoimmune disorders. Although stress has been historically associated with suppression of immune function, recent data indicate that such a conclusion oversimplifies the complexities of the mammalian immune response to environmental perturbation and that stress may also activate certain aspects of the immune system, particularly the innate immune response.

Stress and Illness. Experiments conducted on laboratory animals in the late 1950s and the early 1960s indicated that a wide variety of stressors—including isolation, rotation, crowding, exposure to a predator, and electric shock—increased morbidity and mortality in response to several types of tumors and infectious diseases caused by viruses and parasites. However, as research progressed, it became increasingly clear that “stress” is too variegated a concept to have singular effects on immunity and that the effects

of stress on immunity depend on several factors. Chief among these factors is whether a stressor is acute or chronic. Other critical variables include stressor severity and type, as well as the timing of stressor application and the type of tumor or infectious agent investigated. For example, mice subjected to electric grid shock 1 to 3 days before the infection of Maloney murine sarcoma virus-induced tumor cells exhibited decreased tumor size and incidence. In contrast, mice exposed to grid shock 2 days after tumor cell injection exhibited an increase in tumor size and number.

The relevance of the effects of stress on immune-related health outcomes in humans has been demonstrated in studies that have shown an association between chronic stress and increased susceptibility to the common cold, reduced antibody responses to vaccination, and delayed wound healing. Also, stress, as well as depression, through their effects on inflammation, has been linked to increased morbidity and mortality in infectious diseases, such as HIV infection, autoimmune disorders, neoplastic diseases, as well as diabetes and cardiovascular disorders, which are increasingly being recognized as diseases in which the immune system, inflammation, in particular, plays a pivotal role (Fig. 33-28).

Effects of Chronic Stress. When challenged with a medical illness or chronic psychological stressor, complex interactions between the immune and nervous systems promote a constellation of immune-induced behavioral changes, alternatively referred to as “sickness syndrome” or “sickness behavior.” These behavioral changes include dysphoria, anhedonia, fatigue, social withdrawal, hyperalgesia, anorexia, altered sleep–wake patterns, and cognitive dysfunction. Although seen in response to infection, the full syndrome can be reproduced in humans and laboratory animals by the administration of innate immune cytokines. Blocking cytokine activity diminishes or prevents the development of sickness behavior in laboratory animals, even when such behavior develops as a result of psychological stress. Evidence that cytokine-induced behavioral toxicity is related to significant depression comes in part from studies showing that in humans and laboratory animals, antidepressants can abolish or attenuate the development of sickness behavior in response to cytokine administration.

Inflammation and disease. IL, interleukin; TNF, tumor necrosis factor; NF-kB, nuclear factor κB; C RP, C-reactive protein. (From Cowles MK, Miller AH. Stress cytokines and depressive illness. In: Squire LR, ed. *The New Encyclopedia of Neuroscience*. Academic Press; 2009:521, with permission.)

Relevance of Immune System–CNS Interactions to Psychiatric Disorders

Major Depression. The neuropsychiatric disorder that has been best characterized in terms of the influence of the brain on the immune system and vice versa is major depression. For many years major depression was seen as the quintessential example of how stress-related disorders may decrease immunocompetence. More recently, however, it has become evident that stress also activates inflammatory pathways, even while suppressing measures of acquired immunity. Not surprisingly, studies now indicate that, in addition to immunosuppression, major depression is also frequently associated with inflammatory activation. Recent research showing that proinflammatory cytokines are capable of suppressing many of the immune measures examined in major depression may provide a mechanism to account for how chronic stress-induced inflammatory activity may give rise to depression-related suppression of in vitro functional assays, such as

lymphocyte proliferation.

Bipolar Disorder. Patients with bipolar disorder evince many of the immune alterations frequently observed in the context of unipolar depression. Several studies have observed that bipolar patients, particularly when manic, demonstrate increased plasma concentrations of inflammatory cytokines. Other studies indicate that treatments for mania, such as lithium, lower plasma concentrations of several cytokines. Of interest, the available literature seems to suggest that patients in the manic phase of the disorder may be more likely than depressed patients to demonstrate increased inflammatory markers. It should not be surprising that mania—which seems the phenomenologic opposite of depression—should be associated with increased inflammation, given that mania and depression have also been reported to show identical neuroendocrine and autonomic abnormalities, such as dexamethasone non suppression and increased sympathetic activity, both of which would be expected to promote inflammatory activity.

Schizophrenia. There has been growing interest in the idea that infectious agents, particularly viruses, may underlie at least some cases of schizophrenia. Although it is well established that viral encephalitis can present clinically as psychosis, the primary focus of the "viral hypothesis" for schizophrenia has been on infections during neurodevelopment, given its congruence with the emerging consensus that prenatal or early postnatal insult is implicated in the causality of schizophrenia. Several lines of indirect evidence suggest that viral infection during CNS development may be involved in the pathogenesis of schizophrenia. The data include: (1) an excess number of patient births in the late winter and early spring, suggesting possible exposure to viral infection in utero during the fall and winter peak of viral illnesses, (2) an association between exposure to viral epidemics in utero and the later development of schizophrenia, (3) higher prevalence of schizophrenia in crowded urban areas, which have conditions that are particularly conducive to the transmission of viral pathogens, and (4) seroepidemiologic studies indicating a higher infection rate for certain viruses in schizophrenia patients or their mothers.

Also, schizophrenia has been associated with indices of immune activation, including elevations in cytokines. Although these immune findings in

patients with schizophrenia may indicate evidence of immune system activation secondary to an infection, it should be noted that they might also indicate that an autoimmune process is involved in the disorder. Despite the plethora of studies pointing to abnormalities in cellular and humoral immunity in schizophrenia, the data have not been uniform or conclusive, and there is a need for more studies that account for confounding variables such as medication status and tobacco use. Moreover, attempts to isolate infectious agents from schizophrenic brain tissue or to detect viral nucleic acids in the CNS or peripheral blood of patients with schizophrenia have generally yielded negative results.

Because the initial neuronal abnormalities in schizophrenia have been proposed to arise during neurodevelopment, a perinatal viral infection could insidiously disrupt development and then be cleared by the immune system before clinical diagnosis. In such a scenario, host factors such as cytokines could be responsible for causing the developmental abnormality by interacting with growth factors or adhesion molecules. Recent animal models have identified that maternal immune activation with resultant production of interleukin 6 (IL-6) critically affects behavioral and transcriptional changes in offspring. Behavioral changes, including deficits in prepulse inhibition and latent inhibition, are consistent with behavioral abnormalities in animal models of both schizophrenia and autism. Various animal models using influenza virus, Borna disease virus, or lymphocytic choriomeningitis virus in rodents have demonstrated that prenatal or postnatal viral infections can lead to neuroanatomical or behavioral alterations that are somewhat reminiscent of schizophrenia in humans. As mentioned earlier, epidemiologic studies also support the link between infection with a teratogenic virus and the development of psychotic disorders later in life. Associations have been observed between maternal infection with rubella or influenza during gestation and the development of a schizophrenia spectrum disorder in the offspring. Similarly, maternal antibodies to the herpes simplex virus that develops during pregnancy are correlated with increased rates of psychosis during adulthood in the offspring.

Non-HIV retroviruses might also play a role in the pathogenesis of schizophrenia. Retroviruses integrate into host DNA and can disrupt the function of adjacent genes. Moreover, the genomes of all humans contain sequences of “endogenous retroviruses” that hold the capacity to alter the

transcriptional regulation of host genes. If genes controlling the development or function of the brain undergo transcriptional disruption by retroviral effects, then this might lead to a cascade of biochemical abnormalities, eventually giving rise to schizophrenia.

Autism. Although a convincing case can be made for a significant immune component in autism, the relationship of immune abnormalities to the neurobehavioral symptoms of the disease remains controversial. Recent epidemiologic studies have not substantiated the claim that childhood vaccines trigger autism, and immune-based therapies for autism have not been reliably effective. Thus, although it is tempting to speculate that the immune system holds a clue to a cure for autism, there is currently not enough data to determine whether immune anomalies cause autism, are *caused by* autism or are just adventitiously associated with the disease.

Alzheimer Disease. Although Alzheimer disease is not considered an inflammatory disease primarily, emerging evidence indicates that the immune system may contribute to its pathogenesis. The discovery that amyloid plaques are associated with acute-phase proteins, such as complement proteins and C-reactive protein, suggests the possibility of an ongoing immune response. The idea that inflammatory processes are involved in Alzheimer disease has been bolstered by recent studies showing that long-term use of nonsteroidal anti-inflammatory drugs (NSAIDs) is negatively correlated with the development of Alzheimer disease.

HIV AIDS. AIDS is an immunologic disease associated with a variety of neurologic manifestations, including dementia. HIV encephalitis results in synaptic abnormalities and loss of neurons in the limbic system, basal ganglia, and neocortex.

Multiple Sclerosis. Multiple sclerosis (MS) is a demyelinating disease characterized by disseminated inflammatory lesions of white matter. Considerable progress has been made in elucidating the immunopathology of myelin destruction that occurs in MS and the animal model for the disease, experimental allergic encephalomyelitis. Although the initial step in lesion formation has not been determined, disruption of the BBB and infiltration of

T cells, B cells, plasma cells, and macrophages appear to be associated with lesion formation.

Other Disorders. Finally, several disorders are seen in which neural-immune interactions are suspected but not well documented. *Chronic fatigue syndrome* is an illness with a controversial etiology and pathogenesis. Also, to persistent fatigue, symptoms frequently include depression and sleep disturbances. Tests of immune function have found indications of both immune activation and immunosuppression. Neuroendocrine assessments indicate that patients with chronic fatigue syndrome may be hypocortisolemic because of impaired activation of the HPA axis. Although an acute viral infection frequently precedes the onset of chronic fatigue syndrome, no infectious agent has been causally associated with it.

In contrast, *Lyme disease,* in which sleep disturbances and depression are also common, is caused by infection with the tick-borne spirochete *Borrelia burgdorferi,* which can invade the CNS and cause encephalitis and neurologic symptoms. Lyme disease is remarkable because it appears to produce a spectrum of neuropsychiatric disorders, including anxiety, irritability, obsessions, compulsions, hallucinations, and cognitive deficits. Immunopathology of the CNS may be involved because symptoms can persist or reappear even after a lengthy course of antibiotic treatment, and the spirochete is frequently difficult to isolate from the brain. *Gulf War syndrome* is a controversial condition with inflammatory and neuropsychiatric features. The condition has been attributed variously to combat stress, chemical weapons (e.g., cholinesterase inhibitors), infections, and vaccines. Given the impact of stress on neurochemistry and immune responses, these pathogenic mechanisms are not mutually exclusive.

Therapeutic Implications

The bidirectional nature of CNS–immune system interactions implies the therapeutic possibility that agents known to alter stress system activity positively might benefit immune functioning and, conversely, that agents that modulate immune functioning may be of potential benefit in the treatment of neuropsychiatric disturbance, especially in the context of medical illness. Increasing evidence supports both hypotheses.

Antidepressants and the Immune System. Emerging data indicate that in animals and humans, antidepressants attenuate or abolish behavioral symptoms induced by inflammatory cytokine exposure. For example, pretreatment of rats with either imipramine or fluoxetine (a TCA and SSRI, respectively) for 5 weeks before endotoxin administration significantly attenuated endotoxin-induced decrements in saccharine preference (commonly accepted as a measure for anhedonia), as well as weight loss, anorexia, and reduced exploratory, locomotor, and social behavior. Similarly, several studies in humans suggest that antidepressants can ameliorate mood disturbances in the context of chronic cytokine therapies, especially if given prophylactically before cytokine exposure. For example, the SSRI paroxetine significantly decreased the development of major depression in patients receiving high doses of interferon-α (IFN-α) for malignant melanoma.

Behavioral Interventions and Immunity. It has been known for years that psychosocial factors can mitigate or worsen the effects of stress, not only on immune functioning but also on the long-term outcomes of medical conditions in which the immune system is known to play a role. Therefore, behavioral interventions aimed at maximizing protective psychosocial factors might be predicted to have a beneficial effect, not only in terms of mitigating the effect of stress on immune functioning but perhaps also on diminishing emotional disturbances that arise in the context of immune system dysregulation.

Two factors that have been repeatedly identified as protective against stress-induced immune alterations are social support and the ability to see stressors as being to some degree under the individual's control. One study used a genome-wide scan to assess gene expression activity in socially isolated versus nonisolated individuals. It found that social isolation was associated with increased activation of several proinflammatory cytokine-related pathways and reduced activity in anti-inflammatory cytokine pathways, as well as in the glucocorticoid receptor, which plays an essential role in the neuroendocrine control of inflammatory processes. Of interest, the two types of psychotherapy most often examined in illnesses associated with immune dysregulation are group therapy, which provides social support, and cognitive behavioral therapy, which provides cognitive reframing techniques aimed at enhancing one's sense of agency (and hence control).

NEUROGENETICS

Starting from the rediscovery of Gregor Mendel's basic concepts at the turn of the 20th century, the field of genetics has matured into an essential cornerstone not only of the biologic sciences but of all of medicine. The discovery of the basic structure and properties of DNA in the middle of the century led to an exponential acceleration in our understanding of all aspects of the life sciences, including deciphering the complete sequence of the human genome and those of myriad other species. Massive databases of such sequences now provide 21st-century biologists with the task of decoding the functional significance of all this information. In particular, researchers are trying to determine how to sequence variations contributing to the phenotypic variation between species and individuals within a species. In humans, we hope that discoveries about the relationship between genotypes and phenotypes will revolutionize our understanding of why and how some individuals but not others develop common diseases. This hope is particularly vital for psychiatry, as our knowledge of the pathogenic mechanisms of the psychiatric disease remains sparse.

Genetic mapping studies aim to identify the genes implicated in heritable diseases, based on their chromosomal location. These studies are carried out by investigating affected individuals and their families through two approaches, linkage, and association (Fig. 33-29). It is now straightforward to genetically map Mendelian traits (traits for which a specific genotype at one particular locus is both necessary and sufficient to cause the trait). Psychiatric diseases, however, do not follow simple Mendelian inheritance patterns but rather are examples of etiologically complex traits. Etiologic complexity may be due to many factors, including incomplete penetrance (expression of the phenotype in only some of the individuals carrying the disease-related genotype), the presence of phenocopies (forms of the disease that are not caused by genetic factors), locus heterogeneity (different genes associated with the same disease in different families or populations), or polygenic inheritance (risk for the disease only increases if susceptibility variants at multiple genes act in concert). Mapping a complex disorder involves several component steps, including the definition of the phenotype to be studied, epidemiologic studies to determine the evidence for genetic transmission of that phenotype, choice of an informative study population, and determination

of the appropriate experimental and statistical approaches.

Genetic Epidemiologic Approaches

Genetic epidemiologic investigations provide quantitative evidence regarding the degree to which given trait aggregates in families and can suggest to what degree such aggregation reflects a genetic contribution to the etiology of the trait. Family studies compare the aggregation of disease among the relatives of affected individuals compared to control samples. Because these studies do not differentiate between genetic and environmental contributions to such familial aggregation, they provide only indirect evidence regarding the heritability of a trait. Often these studies measure the relative risk (λ), defined as the rate of occurrence of disease among specified categories of relatives of an affected individual divided by the rate of occurrence of the disease for the general population. A relative risk of >1 suggests a genetic etiology, and the magnitude of the measure gives an estimate of the genetic contribution to the disease. Relative risks can be calculated for sibling pairs, parent–offspring pairs, and various other types of family relationships. Likely modes of transmission can be assessed by comparing the degree of relative risk for each type of relationship. Multiple family studies have been carried out for many of the major psychiatric disorders, including major depression, bipolar disorder, schizophrenia, and OCD. Although these studies have consistently reported familial aggregation for all of these disorders, the degree of such aggregation has varied substantially across studies, mainly reflecting differences in phenotype definition and how study samples were ascertained and assessed.

Gene Mapping Strategies

	Linkage Analysis		Genome Wide Association	
	Pedigree Analysis	Affected Sib Pair Analysis	Case-Control	Family-Trios
				
Study Subjects	Multigenerational families with multiple affected individuals	Two or more affected siblings	Affected individuals and matched unaffected controls sampled from population	Affected individual and parents
Basic Idea	Identify genetic markers that cosegregate with disease phenotype	Identify chromosomal regions shared by siblings concordant for disease.	Tests for statistical association of alleles and disease in cases versus controls.	Tests for association using nontransmitted parental chromosome as control.
Strengths	1) Can detect rare variants of large effect. 2) Gains power by incorporating information about familial relationships into the model.	1) Robust to differences in genetic composition of study population. 2) Easier to collect clinical samples compared to special pedigrees. 3) Allows incorporation of enviromental data.	1) Can detect common variants of small effect. 2) Does not require collection of family data.	1) Can detect common variants of small effect. 2) Robust to problems of population stratification.
Limitations	1) Limited power to identify common variants of small effect. 2) Cost intensive.	1) Limited power to identify common variants of small effect.	1) Increased false-positive rate in the presence of population stratification. 2) Requires large sample sizes.	1) About two-thirds as powerful as case-control designs. 2) Difficult to collect samples for late-onset diseases.

FIGURE 33-29
Comparison of gene-mapping strategies. Genetic mapping approaches can be divided into those that rely on linkage analysis and those that rely on association analysis. Linkage studies can be further categorized as either focused on investigation of pedigrees or focused on investigation of sib pairs. Association studies can be categorized as either case–control or family-based. Some of the key features as well as advantages and disadvantages of these different approaches are shown. (From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2009:321.)

Twin studies examine the concordance rates of a particular disorder (the percentage of twin pairs where both twins have the disorder) in monozygotic (MZ) and dizygotic (DZ) twins. For a disorder that is strictly determined by genetic factors, the concordance rate should be 100 percent in MZ twin pairs (who share 100 percent of their genetic material) and 25 or 50 percent in DZ twin pairs (who are no more closely related than any siblings), depending on whether the disease is recessive or dominant, respectively. For a disorder where genetic factors play a role in disease causation but are not the exclusive cause of disease, the concordance rates should be more significant for MZ twins than those for DZ twins. The higher the degree of concordance of MZ twins, the higher the trait heritability or the evidence for a genetic

contribution to disease risk. When genetic factors do not play a role, the concordance rates should not differ between the twin pairs, under the simplifying assumption that the environment for MZ twin pairs is no more similar than that for DZ twin pairs. Several twin studies that have been conducted for traits such as autism, bipolar disorder, and schizophrenia have consistently suggested high heritability and have therefore spurred efforts to map loci for each of these conditions genetically. Different twin studies may, however, generate varying point estimates for the heritability of any given disorder. When evaluating the results of twin studies, it is, therefore, essential to scrutinize how the phenotype was ascertained because, as with family studies, the different heritability estimates are likely due to differences in the mode of assessing and defining phenotypes. For example, early twin studies of psychiatric disorders often relied on their phenotypes on unstructured interviews by a single clinician.

In contrast, modern studies generally utilize standardized assessments and a review of diagnostic material by a panel of expert clinicians. Similarly, part of the apparent variation in heritability between different twin studies can be attributed to the fact that some studies employ narrow definitions of affectedness for a given phenotype. Other studies employ broader phenotype definitions (e.g., considering a twin with major depressive disorder to be phenotypically concordant with a co-twin diagnosed with bipolar disorder). Because of such differences in approach across studies, it is usually prudent to view such investigations as providing a rough estimate of the genetic contribution to trait variability. Nevertheless, even such estimates are useful in deciding which traits are likely to be mappable.

Basic Concepts of Gene Mapping

Recombination and Linkage. Once genetic epidemiologic studies of particular phenotypes have suggested that these phenotypes are heritable, genetic mapping studies are conducted to identify the specific genetic variants that contribute to the risk of the disorder. All genetic mapping methods aim to identify disease-associated variants based on their chromosomal position and the principle of genetic linkage. All cells contain two copies of each chromosome (called homologs), one inherited from the mother and one inherited from the father. During meiosis, the parental

homologs cross over, or recombine, creating unique new chromosomes that are then passed on to the progeny. Genes that are physically close to one another on a chromosome are genetically linked, and those that are farther apart or are on different chromosomes are genetically unlinked. Unlinked genes will recombine at random (i.e., there is a 50 percent chance of recombination with each meiosis). Genetic loci that are linked will recombine less frequently than expected by random segregation, with the degree of recombination proportional to the physical distance between them. The principle of linkage underlies the use of genetic markers, segments of DNA of known chromosomal locations that contain variations or polymorphisms (described in more detail later). Strategies to map disease genes are based on identifying genetic marker alleles that are shared—to a greater extent than expected by chance—by affected individuals. It is presumed that such sharing reflects linkage between a disease locus and a marker locus, that is, the alleles at both loci are inherited "identical by descent" (IBD), from a common ancestor, and that this linkage pinpoints the chromosomal site of the disease locus.

The evidence for linkage between two loci depends on the recombination frequency between them. Recombination frequency is measured by the recombination fraction (Θ). It is equal to the genetic distance between the two loci (1 percent recombination equals 1 centimorgan [cM] in the genetic distance and, on average, covers a physical distance of about 1 megabase [mB] of DNA). A recombination fraction of 0.5 or 50 percent indicates that two loci are not linked but rather that they are segregating independently. A LOD (logarithm of the odds) score is calculated to determine the likelihood that two loci are linked at any particular genetic distance. The LOD score is calculated by dividing the likelihood of acquiring the data if the loci are linked at a given recombination fraction by the likelihood of acquiring the data if the loci are unlinked ($\Theta = 0.5$). This step gives an odds ratio, and the log (base 10) of this odds ratio is the LOD score. A LOD score can be obtained for various values of the recombination fraction, from $\Theta = 0$ (completely linked) to $\Theta = 0.5$ (unlinked). The value of Θ that gives the largest LOD score is considered to be the best estimate of the recombination fraction between the disease locus and the marker locus. This recombination fraction can then be converted into a genetic map distance between the two loci.

Linkage Disequilibrium. Linkage disequilibrium (LD) is a phenomenon that is used to evaluate the genetic distance between loci in populations rather than in families. When alleles at two loci occur together in the population more often than would be expected given the allele frequencies at the two loci, those alleles are said to be in LD. When strong LD is observed between two loci, it usually indicates that the two loci are sited in very close physical proximity to one another on a given chromosome and is useful in mapping disease susceptibility loci because one locus can be used to predict the presence of another locus. This predictability is vital because current gene-mapping strategies can sample only a subset of the estimated 10 million common human polymorphisms. Because of the existence of LD, one can use data from a subset of genotyped polymorphisms to infer genotypes at nearby loci. Clusters of alleles that are in LD and inherited as a single unit are termed haplotypes. Thus LD mapping "consolidates" genomic information by identifying haplotypes in populations that can then be used to infer IBD sharing among unrelated individuals.

There are several methods to measure the extent of LD. One of the most commonly used measures of LD is r^2, a measure of the difference between observed and expected haplotype probabilities. Unlike D', another widely used measure of LD, r^2 values do not depend on the allele frequencies of the loci being assessed. A considerable r^2 value indicates that the observed frequency of association between two alleles is more significant than that expected by chance; that is, the alleles are in LD. LD studies have traditionally been used to complement traditional pedigree analyses, for example, to hone in on a locus that has been mapped by linkage analysis. However, LD-based association analysis has become the method of choice for whole-genome screens, particularly for diseases where traditional linkage studies have been unsuccessful. These studies have one great advantage over a traditional family analysis. Because affected individuals are chosen from an entire population, the only limit to the number of potential subjects is the population size and disease frequency. Maximizing the potential number of affected individuals that can be included in the analysis is extremely important for disorders where genetic heterogeneity or incomplete penetrance is likely to be a factor.

Genetic Markers. Mapping studies, regardless of their type, depend on the availability of genetic markers. The most widely used markers are microsatellite markers (also called simple tandem repeats [STRs], or simple sequence length polymorphisms [SSLPs]) and SNPs. SSLPs are stretches of variable numbers of repeated nucleotides two to four base pairs in length. These markers are highly polymorphic, as the number of repeat units at any given STR locus varies substantially between individuals. SNPs, as the name implies, are single base pair changes at a specific nucleotide; they are the most common form of sequence variation in the genome. SNPs are widely used for genetic mapping studies because they are distributed so widely across the genome and because they can be assessed in a high-throughput, automated fashion. Other forms of genetic variation that have been investigated for use as genetic markers include small insertion or deletion polymorphisms, termed indels, that generally range between 1 and 30 base pairs and copy number variations (CNVs), which can refer to either deletions or duplications. Recent genome-wide surveys have revealed that CNVs are common and can range in length from several base pairs to several million base pairs. CNVs may contribute to chromosomal recombination and rearrangements, thereby playing an essential role in generating genetic diversity. Also, as many of these variants are sizable, it is hypothesized that they may significantly influence the expression of genes that encompass or are adjacent to the variant.

Mapping Strategies

The genetic variants that contribute to disease susceptibility can be roughly categorized into those that are highly penetrant and those that are of low penetrance. High-penetrance variants, by definition, have a large effect on phenotype, and therefore identifying these variants usually provides fundamental insights into pathobiology. Because individuals carrying high-penetrance variants have a high probability of expressing a disease phenotype, such variants tend to be rare and to segregate in families and are generally most powerfully mapped using pedigree-based approaches (see Fig. 33-29). In contrast, low-penetrance variants have a relatively weak effect on phenotype, and therefore identification of individual low-penetrance variants may, at least initially, provide relatively little new biologic knowledge.

However, because of their small effects, such variants are typically frequent, and identifying them may add to our understanding of disease risk. Because we do not expect these variants to segregate strongly with the disease phenotype in pedigrees, efforts to identify them focus on population samples.

Pedigree Analysis. A pedigree analysis, which is conducted in multigenerational families, consists of scanning the genome or a portion of the genome with a series of markers in one or more affected pedigrees, calculating a LOD score at each marker position, and identifying the chromosomal regions that show a significant deviation from what would be expected under independent assortment. The primary goal of the pedigree analysis is to determine if two or more genetic loci (i.e., a genetic marker of known location and the unknown disease loci) are cosegregating within a pedigree.

Following the successful application of pedigree analysis to map Mendelian disorders such as Huntington disease, many investigators adopted this strategy for mapping psychiatric disease genes with, at best, mixed success. In the late 1980s and mid-1990s, several pedigree-based studies reported the mapping of susceptibility loci for Alzheimer disease, bipolar disorder, and schizophrenia. Although the linkage findings for three Alzheimer disease loci were relatively quickly replicated, the findings reported for bipolar disorder and schizophrenia were ultimately determined to have been false positives. Several different explanations have been proposed for the failure of pedigree-based approaches to map psychiatric loci; however, most investigators now recognize that these studies were generally drastically underpowered, considering the apparent etiologic complexity of psychiatric disorders.

Pedigree analysis in psychiatry has increasingly turned toward an application that is more appropriately powered, namely, the mapping of quantitative trait loci (QTLs). QTLs are defined as genetic loci that contribute to the variation in continuously varying traits (as opposed to categorical traits such as disease diagnoses). QTLs are typically loci of small effect that only contribute to a portion of the observed variance of a trait in the population. It is now generally accepted that using analytical methods developed in the late 1990s, it may be possible to use pedigree studies to map a wide range of quantitative traits that are relevant for understanding psychiatric disorders.

Several such studies are now being undertaken, typically with multiple phenotypes being assessed in each individual in the pedigree.

Sib-Pair Analysis. Affected sib-pair (ASP) analysis became widely used during the 1990s for the genetic mapping of complex traits, including many psychiatric disorders. Sib-pair analysis examines the frequency with which sibling pairs concordant for a trait share a particular region of the genome compared with the frequency that is expected under random segregation.

Sib-pair analysis is based on the fact that siblings share approximately 50 percent of their genomes IBD. Therefore, if a set of unrelated sib pairs affected with a given trait shares a particular area of the genome at a frequency significantly more significant than 50 percent (the proportion of sharing expected under conditions of random segregation), then that area of the genome is likely to be linked to the trait in question. In this method, siblings are genotyped, and population frequencies and parental genotypes are used to estimate the proportion of genes shared IBD at each site for each sib-pair. The linkage analysis then compares those pairs concordant and discordant for each locus.

Like pedigree studies, ASP studies have more power to locate genes of a large effect than genes of small effect. This limitation can be partially addressed by a two-tiered design that incorporates additional markers or family members after an initial linkage study in affected siblings or by an increased sample size. It generally requires less effort to identify and assess even large sets of affected sibs than to identify and assess all members of extended pedigrees, mainly when investigators can take advantage of data repositories that include samples and phenotype data from sib pairs ascertained from multiple sites. For example, the U.S. National Institute of Mental Health (NIMH) maintains such repositories for sizable collections of sib pairs affected with schizophrenia, bipolar disorder, autism, and Alzheimer disease. An additional benefit of the ASP design is that it allows for the incorporation of epidemiologic information, permitting the simultaneous examination of environmental and gene–environment interactions.

Association Studies. In the last few years, there has been increasing acceptance of the notion that association studies are more powerful than linkage approaches for mapping the loci of relatively small effects that are

thought to underlie much of the risk for complex disorders. Whereas linkage studies attempt to find cosegregation of a genetic marker and a disease locus within a family or families, association studies examine whether a particular allele occurs more frequently than expected in affected individuals within a population. As noted previously in this chapter, mapping of genes using association studies is based on the idea that specific alleles at markers closely surrounding a disease gene will be in LD with the gene; that is, these alleles will be carried in affected individuals more often than expected by random segregation, because they are inherited IBD.

There are two common approaches to association studies (see Fig. 33-29), case-control designs, and family-based designs, which typically investigate trios (mother, father, and an affected offspring). In a case-control study, allele frequencies are compared between a group of unrelated affected individuals and a matched control sample. This design is generally more powerful than a family-based design because large samples of cases and controls are more straightforward to collect than trios and are less expensive since they require the genotyping of fewer individuals. Case-control samples may be the only practical design for traits with a late age of onset (such as Alzheimer disease) for which parents of affected individuals are typically unavailable. The main drawback of the case-control approach is the potential problem of population stratification; if the cases and controls are not carefully matched demographically, then they may display substantial differences in allele frequency that reflect population differences rather than associations with the disease.

Family-based association studies are designed to ameliorate the problem of population stratification. In this design, the nontransmitted chromosomes (the copy of each chromosome that is not passed from parent to child) are used as control chromosomes, and differences between allele frequencies in the transmitted and nontransmitted chromosomes are examined, eliminating the problem of stratification, as the comparison group is by definition genetically similar to the case group. Although more robust to population stratification than a case-control study, family-based studies are only about two-thirds as powerful using the same number of affected individuals, as noted previously.

Until recently, it was not practical to conduct association studies on a genome-wide basis, as relatively few SNPs were available. Therefore, association studies focused on testing one or a few markers in candidate

genes chosen based on their hypothesized function with a given disease. Recently, however, as a result of international efforts that have identified millions of SNPs distributed relatively evenly across the genome and that have developed technology for genotyping them relatively inexpensively, genome-wide association (GWA) studies are now a reality. Such studies hold much promise for the identification of common variants contributing to common diseases. While few GWA studies of psychiatric disorders have been completed, such studies have already reported remarkable findings for complex traits such as rheumatoid arthritis, inflammatory bowel disease, and type 2 diabetes. The successful studies of these diseases have made use of extensive samples (in some cases up to several thousand cases and controls), providing further support for the hypothesis that underpowered study designs bear much of the responsibility for the disappointing results to date of psychiatric genetic investigations.

Statistical Considerations. Scientists in other biomedical research fields are often surprised by the high level of statistical evidence that geneticists require to consider a linkage or association result to be significant. This requirement can be imagined in terms of the very low expectation that any two loci are either linked or associated with one another. The likelihood that any two given loci are linked (i.e., the prior probability of linkage) is expected to be approximately 1:50, based on the genetic length of the genome. To compensate for this low prior probability of linkage and bring the posterior (or overall) probability of linkage to about 1:20, which corresponds to the commonly accepted significance level of $p = 0.05$, a conditional probability of 1,000:1 odds in favor of linkage is required, corresponding to the traditionally accepted LOD score threshold of 3. This generally provides an acceptable false-positive rate (Fig. 33-30), but some false-positive findings have exceeded even this threshold.

Geneticists generally expect that the chance that any two loci in the genome are associated with one another is even lower than that of their being in linkage. Typically a *p*-value of less than about 10^{-7} is considered to indicate “genome-wide significance.” This standard essentially discounts the prior probability that some investigators assign to variants in candidate genes chosen based on their hypothesized functional relevance to a given disorder or trait. GWA studies are now replicating associations with very low *p*-values

for a wide range of complex traits, whereas most candidate gene associations (which usually report as significant much higher *p*-values) remain unreplicated. It is, therefore, increasingly apparent that genome-wide levels of significance are appropriately applied to all initial association studies for a given trait.

Number of false positives expected in a whole genome scan for a given threshold of logarithm of odds (LOD) score. *Solid line* represents the expectation for a perfect genetic map. *Symbols* represent the results for 100 sib pairs using genetic maps with markers spaced every .1 cM (*circles*), every 1 cM (*squares*), and every 10 cM (*triangles*). The *dotted line* indicates the 5 percent genome-wide significance level. (Courtesy of Dr. Eric Lander.)

Defining Phenotypes for Mapping Studies

The generally disappointing results of psychiatric genetic mapping studies have focused increasing attention on the problem of defining and assessing phenotypes for such studies. Most psychiatric mapping studies to date have relied on categorical disease diagnoses, as exemplified by the *Diagnostic and*

Statistical Manual (DSM-5) classification scheme. Criticisms of this approach rest on two arguments. First, diagnosis of the psychiatric disease depends on subjective clinical evaluation, a fact that underscores the difficulty in ascertaining individuals who can be considered affected with a given disease. Second, even when a psychiatric diagnosis can be established unambiguously, the menu-based system used for psychiatric classification provides the possibility that any two individuals affected with a given disorder may display mostly nonoverlapping sets of symptoms, likely reflecting distinct etiologies. Concern that the diagnosis-based approach to phenotyping may represent one of the chief obstacles to the genetic mapping of psychiatric phenotypes has generated considerable interest in mapping heritable traits known to demonstrate continuous variation in the population. Continuous measures that are hypothesized to be related to psychiatric disorders include biochemical measures (e.g., serum or CSF levels of neurotransmitter metabolites or hormones), cognitive measures, personality assessments, structural or functional brain images, biophysical markers such as responses to evoked potentials, or molecular assays such as gene expression profiles. Critical features of categorical and continuous phenotyping strategies are shown in Figure 33-31, and each is discussed in more detail below.

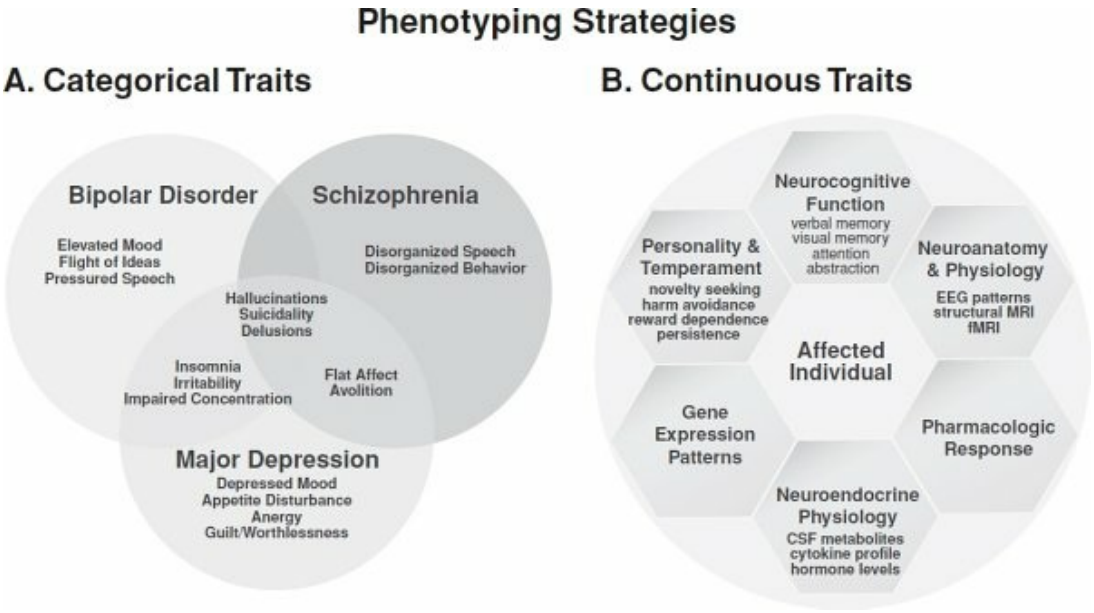

FIGURE 33-31
Two alternate schemes for conceptualizing psychiatric phenotypes. **A:** Categorical Traits as conceptualized by the *Diagnostic and Statistical Manual*

(DSM-5) represent a “menu-based” approach to psychiatric disorders. Individuals are assessed for a checklist of signs and symptoms that are then used to categorize the individual as “affected” according to a specific diagnosis. Not all symptoms are present in samples of individuals who carry a particular DSM diagnosis, and many of these symptoms occur across diagnostic boundaries, as illustrated in this Venn diagram. DSM phenotypes therefore probably represent etiologically heterogeneous categories, and this fact may help to explain the limited progress thus far of genetic mapping investigations focused on these phenotypes. **B:** Alternatively, in the Continuous Traits model, “affectedness” can be conceptualized in terms of an expectation that an individual will demonstrate extreme values on a set of continuous measures that correlate with psychopathology and thus are hypothesized to underlie the disorder (as illustrated by examples of six different types of measures shown in the hexagon). Such measures may also be associated with particular components of categorical phenotypes, such as those depicted in the Venn diagram in Figure 33-31A. The justification for using continuous measures as the phenotypes for genetic mapping studies is that they are considered etiologically simpler and more reliably assessed compared to categorical phenotypes. In addition, mapping such traits combines information from all members of the study population (affected and unaffected individuals alike), which adds considerably to power. (From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock’s Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2009:325.)

Categorical Phenotypes. The most commonly used categorical phenotypes in psychiatry are DSM diagnoses. Some studies focus on a single DSM diagnosis, whereas other studies include individuals with a range of different diagnoses. The latter approach is typically used for disorders that are hypothesized to represent a single disease spectrum, such as mood disorders. The categorical approach is designed to help us classify subjects as unambiguously as possible. Several strategies are used to accomplish this goal. The first strategy involves deciding on the appropriate diagnostic criteria for the study in question and deciding how these criteria will be applied to individuals in the study. One way of standardizing the procedures used to identify and assess potential study subjects is to use only experienced clinicians in the diagnostic process and to train them in the administration of the instruments and the diagnostic criteria to be employed. Also, a “best estimate” procedure or a consensus diagnosis is frequently used. The best estimate process involves making use of every piece of available information, including medical records, interviews, and videotapes, to arrive at a diagnosis. For a consensus diagnosis, two or more diagnosticians independently review the material and make a diagnosis for each individual. The diagnoses are then compared, and individuals for whom an agreement in

diagnosis cannot be reached are not entered as “affected” into the study.

A well-designed study makes use of all available information about the genetic epidemiology of the disorder to choose a sample of affected individuals to study. It is often the case that a subset of families carries the disorder in what appears to be a simple Mendelian pattern, whereas the inheritance pattern is less clear for other families or groups. In a disorder where there are likely to be multiple genes contributing to the phenotype, it makes sense, to begin with, a study sample where there may be significant loci. Redefining the disease phenotype can often simplify the mapping process by identifying such groups or families. For example, in the search for a genetic defect for Alzheimer disease, the process was advanced enormously by limiting the study population to those individuals who had an early age of onset (before age 65); the early-onset trait segregated in an autosomal dominant fashion. Other ways of redefining the phenotype include focusing on factors such as ethnic background, age of onset, treatment response, symptom severity, or the presence of comorbid disorders.

Narrowing the phenotype using the approaches discussed earlier may increase the chances of finding a genetic defect in complex diseases, but it can also significantly reduce the power of the study by limiting the number of available affected individuals. For this reason, it has been argued that for some disorders broadening the phenotype is an appropriate strategy. The suggestion is that for some complex diseases, the phenotype of interest may represent the end of a spectrum and that other phenotypes within the spectrum must also be included to have enough power to map genes. For example, mapping studies of bipolar disorder might include affected individuals with major depressive disorder as well as those individuals diagnosed with bipolar disorder.

Although the two approaches of narrowing the disease phenotype and broadening the disease phenotype may seem to be mutually exclusive, many groups studying complex disorders have incorporated both approaches into their study designs. One way to do this is to create stratified diagnostic categories, ranging from a narrow diagnostic category to a broad diagnostic category, and test for genetic linkage under each of these schemas. Some investigators argue that for complex diseases that are part of a spectrum, this strategy decreases the rate of false negatives, that is, of missing an existing linkage because of misspecification. Others argue that using several models

and picking the one that gives the highest scores dramatically increases the rates of false positives, that is, of identifying an area of linkage where none exists. One problem that exists with the use of multiple diagnostic categories is that as more models are used (and therefore more statistical tests are performed), increasingly stringent levels of evidence are required to consider a result significant.

While categorical phenotypes remain the mainstay of psychiatric genetic studies, the limitations of DSM nosology as the basis of phenotyping for genetic studies are becoming apparent. Genetic investigations are focusing increasingly on traits that may be components of one or more DSM diagnostic categories. For example, there is growing evidence that genetic susceptibility to psychosis, broadly defined, contributes to both severe bipolar disorder and schizophrenia, and several investigative approaches are being employed to attempt to identify genes that underlie such susceptibility and even to explore possible etiologic relationships between psychiatric and nonpsychiatric disorders. For example, bioinformatics models have been employed to investigate medical records databases and have uncovered extensive pairwise correlations among a diverse list of psychiatric disorders, neurologic disorders, autoimmune disorders, and infectious diseases. Eventually, the results of such model-fitting experiments may provide a framework to design more powerful linkage and association studies that can search for alleles that contribute to susceptibility to multiple disorders.

Continuous Phenotypes. Because of the difficulties experienced in genetic mapping of categorical diagnoses, neurobehavioral geneticists are increasingly focused on investigating quantitative traits that are hypothesized to underlie a particular psychiatric diagnosis, and that may be simpler to map genetically. The rationale for efforts to map such alternative phenotypes or endophenotypes is that the genes identified through such efforts may provide clues regarding the biologic pathways that are relevant to understanding a particular disorder. Several features characterize useful endophenotypes. First, they should be state-independent; that is, they should not fluctuate as a function of the disease course or medication treatment and should show adequate test–retest stability. Second, they should be heritable; that is, there should be evidence that genetic factors are responsible for a substantial proportion of the variability of the trait within the population. Third, the

endophenotype should be correlated with the disease under investigation; that is, different values of the trait measure are observed in patients compared to unrelated control subjects.

Measures of brain structure and function provide most of the traits now under investigation as endophenotypes for psychiatric disorders. For example, several features of brain morphometry (as assessed by MRI) are highly heritable (in the range of 60 to 95 percent), including total brain volume, cerebellar volume, gray and white matter density, amygdala and hippocampal volume, and regional cortical volume. Several studies show that brain structural features that are correlated in clinical samples with disorders such as schizophrenia or bipolar disorder are also abnormal in relatives of affected individuals. Physiologic measures of brain activity that have been employed as candidate endophenotypes for psychiatric disorders include electroencephalography (EEG) patterns. Several "pencil and paper" assessments have been employed to measure endophenotypes relating to neurocognitive function and temperament.

Animal Models. In contrast to categorical phenotypes, endophenotypes can be more straightforwardly related to phenotypes that can be assessed in animal models. Studies of genetic variations that affect circadian rhythms provide a good example. Variations in circadian rhythms have long been recognized as prominent features of mood disorders, and quantitative assessments of activity patterns have been proposed as endophenotypes for such disorders. Numerous studies in animal models have demonstrated that genetically controlled biologic clocks determine circadian activity and that variations in clock genes are associated with variations in such activity from bacteria to humans. Genetic mapping efforts in fruit flies starting in the early 1970s resulted in the identification of at least seven "clock genes," beginning with a *period.* Subsequent studies showed that the homologs of several of these genes play essential roles in regulating mammalian circadian rhythms. Genetic mapping studies in mice also have identified previously unknown circadian rhythm genes, beginning with the discovery and characterization in the early 1990s of a *clock.* These genetic discoveries have not only explicated the cellular networks and neurophysiologic circuits responsible for the control of mammalian circadian rhythms. However, they have also generated animal models that may shed light on the pathobiology of psychiatric

syndromes such as bipolar disorder. For example, mice carrying a targeted mutation in the *clock* demonstrate abnormal activity patterns, such as hyperactivity and decreased sleep, which is modified by the administration of lithium.

Progress in the Genetics of Specific Disorders

The progress in identifying susceptibility genes for psychiatric disorders has been disappointing compared to that observed for nonpsychiatric disorders. Alzheimer disease represents the most successful application of gene-mapping strategies to complex neurobehavioral disorders, and the section on this disease provides an example of how genetic linkage studies add to the understanding of the pathogenesis of a complex trait. An overview section on autism describes genetic investigations of syndromes that have features of autism but have relatively simple inheritance patterns and discusses how these studies have provided starting points for investigations of more complex ASDs. Finally, the frustrating search for unequivocal gene findings for bipolar disorder and schizophrenia is used to illustrate the challenges that are motivating new approaches in the field of neurobehavioral genetics.

Alzheimer Disease. Alzheimer disease provides an excellent example of the power of genetics to elucidate the complex biology of a neuropsychiatric disorder. Alzheimer disease is a well-defined form of dementia characterized by progressive impairment of memory and intellectual functioning. The clinical signs and symptoms, although characteristic, are not limited to Alzheimer disease; they are also found in several other types of dementia. For this reason, the diagnosis of Alzheimer disease can only be confirmed histopathologically at autopsy. The presence of senile plaques (made up of a core of β-amyloid fibrils surrounded by dystrophic neurites), tau-rich neurofibrillary tangles, and congophilic angiopathy in the brain parenchyma and associated blood vessels are pathognomonic for Alzheimer disease.

A variable age of onset has been noted for Alzheimer disease, ranging from as early as age 35 to as late as age 95. The concordance rate for Alzheimer disease in MZ twin pairs is about 50 percent, indicating a moderately substantial genetic contribution to disease risk. It is now evident from a wide range of genetic studies that Alzheimer disease can be divided

into two broad categories. These are the familial forms, which account for a tiny minority of Alzheimer disease cases and are characterized by early onset and autosomal dominant inheritance with high penetrance; and sporadic forms, in which the genetic contribution is hypothesized to be similar to that characterizing other common neuropsychiatric diseases.

The search for the genetic basis of familial Alzheimer disease began with traditional linkage studies. First, an investigation of a candidate locus on chromosome 21 in humans identified mutations in the *amyloid precursor protein* (*APP*) gene in a small number of families in which significant linkage had previously been observed to markers from this region. Transgenic mice with different *APP* mutations were created and have been shown to produce β-amyloid deposits and senile plaques as well as to show synapse loss, astrocytosis, and microgliosis, all part of the pathology of Alzheimer disease. Mutations in the genes that encode β-APP all lead to an increase in the extracellular concentration of longer fragments of β-amyloid (Aβ42). Most of the strains of transgenic mice with mutations in APP exhibit increased rates of behavioral changes and impairment in several memory tasks, indicating dysfunction in object-recognition memory and working memory, among others. These findings represent striking evidence that mutations in the β-amyloid gene are indeed responsible for at least some of the histopathologic elements of Alzheimer disease.

Even as the preceding findings were being reported, it was clear that mutations in the β-amyloid gene could not wholly explain the etiology and pathology of Alzheimer disease, not least because it was shown that linkage to chromosome 21 was excluded in most early-onset Alzheimer disease families. Also, no neurofibrillary tangles are observed in most of the different β-amyloid transgenic mice. The subsequent search for the genetic underpinnings of Alzheimer disease using genome-wide linkage analysis of early-onset Alzheimer disease families resulted in the identification of two additional Alzheimer disease susceptibility genes: *presenilin-1* (*PS-1*) on chromosome 14q24.3 and *presenilin-2* (*PS-2*) on chromosome 1q. PS-1 and PS-2 are integral transmembrane proteins with at least seven transmembrane domains. Although their function has not yet been completely elucidated, they are involved in the pathogenesis of Alzheimer disease. Inactivation of *presenilins* in mice leads to neurodegeneration and behavioral manifestations of memory loss. Biochemical and cellular studies have implicated presenilins

in several critical pathways, including apoptosis (programmed cell death) and protein processing in the endoplasmic reticulum.

These findings emphasize one of the strengths of using family-based linkage analysis. Pedigree-based studies are especially suited to identify highly penetrant disease genes that serve essential roles in critical biologic processes. Although mutations in *APP* and *presenilin* are rare, research into the biology of the expressed proteins has provided vital insights into the pathophysiology of dementia. Because these highly penetrant mutations elucidate essential biologic functions, they also provide a firm ground to design therapeutic interventions. For example, amyloid-β "vaccines" designed to induce an immunogenic response to pathogenic amyloid are now in advanced clinical trials. Unlike the current psychopharmacological treatments for Alzheimer disease that nonspecifically target cholinergic and glutaminergic neuronal systems, the amyloid-β vaccines may specifically treat the causes of Alzheimer disease by generating an immune response that may reverse the deposition of senile plaques.

SPORADIC AND LATE-ONSET ALZHEIMER DISEASE. Mutations in *APP, PS-1,* or *PS-2* are present in a majority of familial cases of early-onset Alzheimer disease but do not account for sporadic or familial late-onset Alzheimer disease. For this reason, investigators turned to other approaches to search for evidence of linkage in a large number of small families with late-onset Alzheimer disease. In 1991, the results of a nonparametric linkage study using 36 markers in late-onset Alzheimer disease families provided evidence for a susceptibility gene on the long arm of chromosome 19. In 1993, association studies revealed that the e4 allele of the *apolipoprotein E* gene was strongly associated with late-onset Alzheimer disease and that this association almost certainly was responsible for the previously observed linkage signal on chromosome 19. There are three known alleles of this gene —e2, e3, and e4. In most populations, the e3 allele is the most common. However, in familial late-onset Alzheimer disease, the incidence of e4 is approximately 50 percent, and in sporadic late-onset Alzheimer disease, it is 40 percent, compared with about 16 percent in normal controls. Epidemiologic studies suggest that between 30 and 60 percent of late-onset Alzheimer disease cases have at least one *apoE-e4* allele. The e4 genotype appears to be a more important risk factor for Alzheimer disease in

populations of European and Asian origin when compared with populations of African origin. Overall, the association of *apoE-e4* with Alzheimer disease remains probably the most robust association yet identified for a common human disease.

The establishment of *apoE-e4* as a susceptibility allele for late-onset Alzheimer disease has led to the search for additional alleles that might interact with *apoE-e4* to modify disease risk. In 2007, investigators used GWA strategies (in histologically confirmed cases and controls) to identify *GAB2* (GRB-associated binding protein 2) as an additional risk allele in *apoE-e4* carriers (but not in Alzheimer disease patients who were not e4 carriers). Initial studies suggest that carriers of both *apoE-e4* and *GAB2* risk alleles have an almost 25-fold more significant risk for Alzheimer disease than individuals who do not carry either risk allele. Larger-scale GWA studies of Alzheimer disease are in progress and will likely yield further associations; however, it is unlikely that any will have as strong an effect as *apoE.*

Autism. Autism is a severe neurodevelopmental disorder that is characterized by three primary features: impaired language and communication; abnormal or impaired social interaction; and restricted, repetitive, and stereotyped patterns of behavior. Understanding the etiology of autism has proceeded slowly, but there is convincing evidence that alterations in specific cellular and molecular neurodevelopmental pathways are essential in its etiology. In comparison with other neuropsychiatric disorders, there is particularly strong evidence for a genetic contribution to the risk of autism and ASDs. The sibling recurrence risk for autism or ASD is between 2 and 6 percent. Given a population prevalence of about 1 in 2,000 (0.04 percent), this means that the siblings of autistic individuals are approximately 50 to 100 times more likely to develop autism than a person in the general population. Twin studies of autism show extraordinarily high heritability (as demonstrated by MZ twin concordance of 80 to 92 percent) but also demonstrate the genetic complexity of these disorders, with the DZ twin concordance rate of 1 to 10 percent suggesting a highly multigenic mode of inheritance.

Increasing interest is now focused on the possibility that individuals affected with autism may display more considerable numbers of large-scale

chromosomal aberrations (5 to 10 percent in some studies) than unaffected individuals. Also, to such gross abnormalities, several recent studies have suggested that autism is associated with an unusually high prevalence of submicroscopic CNVs. For example, in 2007, the Autism Genome Project Consortium applied microarray strategies to almost 8,000 individuals from about 1,500 families, each with at least two affected family members, and found that about 10 percent of the ASD families carried CNVs, with an average size of more than 3 million base pairs, mostly consisting of duplications rather than deletions. Although the design of this study did not permit assessment of whether the frequency of CNVs is higher in patients with autism than that in controls, another study found a de novo CNV incidence of 10 percent in sporadic (no family history) cases of autism compared to an incidence of 1 percent in controls. These results, while exciting, are still considered preliminary. Even before the demonstration of high rates of de novo mutations in autism, epidemiologic studies had strongly suggested that the genetic basis of this disorder is likely complex. For example, although the risk of autism in first-degree relatives of autistic probands is high, there is a substantial falloff for second- and third-degree relatives of such probands, suggesting that multiple genetic variants must interact to increase susceptibility to this syndrome. Segregation analyses of autism also support the hypothesis that it is a heterogeneous disorder that reflects the actions of multiple genetic variants of small effect. A latent class analysis performed to study possible modes of transmission suggested an epistatic model with up to about 10 interacting loci, whereas other studies have estimated that as many as 15 such loci may be involved. Genetic studies of autism have included whole-genome screens, candidate gene studies, chromosome rearrangement studies, mutation analyses, and, most recently, comparative genomic hybridization studies. Taken together and recognizing that most findings still await adequate replication, these studies have contributed to an emerging picture of autism susceptibility that includes genes involved in three major systems: those involving synapse formation and maintenance, those involving cell migration, and those involving the excitatory/inhibitory neurotransmitter networks. Figure 33-32 shows a schematic of the currently known potential candidate genes for autism and their molecular relationships with one another.

SYNAPSE FORMATION AND MAINTENANCE. Perhaps the most significant breakthroughs in identifying susceptibility genes for autism have come from studies of disorders that display clinical features associated with autism or ASDs but with simpler inheritance patterns, including fragile X syndrome, tuberous sclerosis, and Rett syndrome. In general, the genetic defects associated with these disorders affect synapse formation and maintenance. Fragile X, which accounts for 3 to 4 percent of autism cases, is caused by an unstable trinucleotide repeat in the 5′ region of the fragile X mental retardation 1 (*FMR1)* gene at Xq27.3. This repeat expands as it is transmitted to succeeding generations, resulting in abnormal methylation and inhibition of expression of *FMR1*. *FMR1* produces an RNA-binding protein that acts as a chaperone for the transport of RNA from the nucleus to the cytoplasm and is involved in messenger RNA (mRNA) translation at the synapse. Abnormalities in dendritic spine density (increased over normal) and anatomy (longer and thinner than normal) have been reported in individuals with fragile X as well as in mouse models of this disorder. Tuberous sclerosis, which accounts for perhaps 2 to 10 percent of autism cases (the rate of tuberous sclerosis is higher among autistic individuals with seizure disorders), results from mutations in one of two tumor suppressor genes, *TSC1* on 9q34, and *TSC2* on 16p13, both of which are involved in guanosine triphosphatase (GTPase) inactivation. Loss of a single copy of *TSC1* in mice has been shown to disrupt cytoskeletal dynamics and dendritic spine structure.

Although somewhat less well understood, the genetics of Rett syndrome, an X-linked pervasive developmental disorder (the first with a known genetic etiology), also point to abnormalities in synapse formation and maintenance in ASD and ASD-like disorders. Mutations in *MeCP2* cause Rett syndrome. The gene makes a methylated-DNA-binding protein that regulates gene expression and chromatin structure. Although little is known about the exact role of *MeCP2* in the development of Rett syndrome, the pattern of normal early development and later regression suggests that this gene is more likely to be involved in synapse maintenance and remodeling than in synapse development.

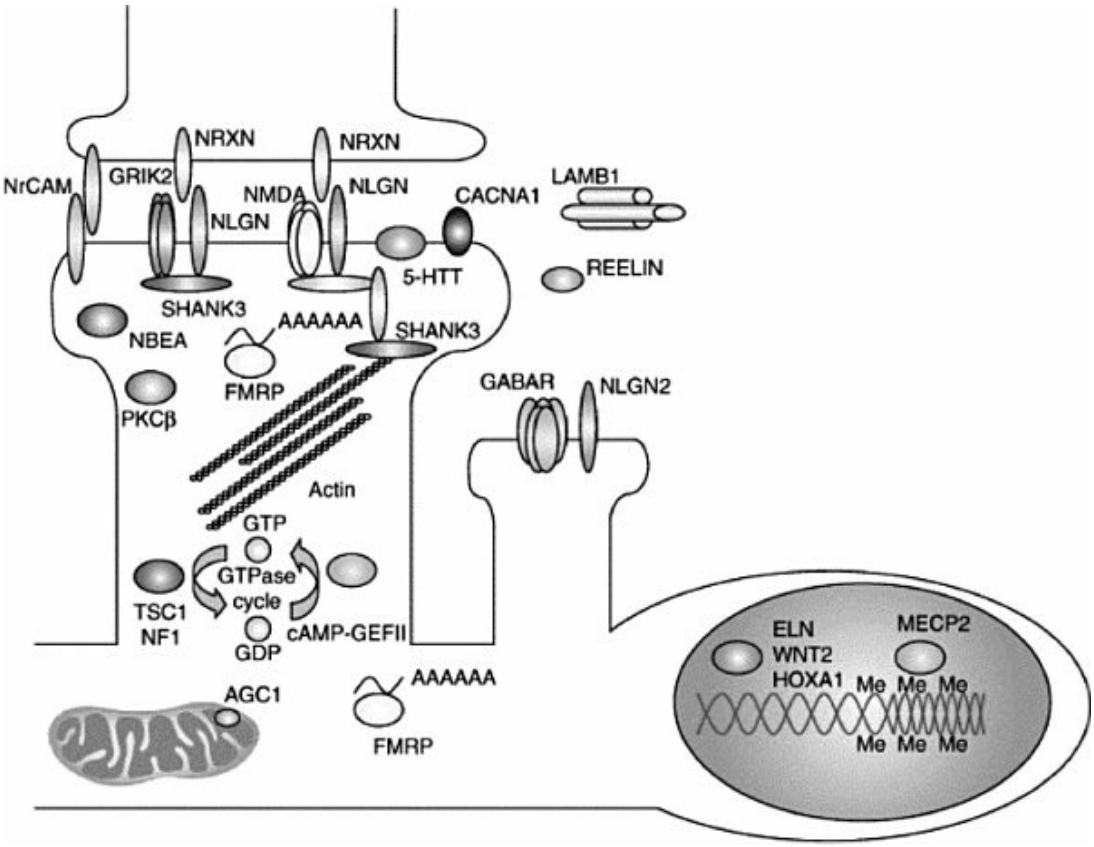

FIGURE 33-32
Schematic of the cell biology of proteins expressed from genes identified through mapping studies of autism spectrum disorders. The function of each gene product falls into three broad functional categories. Proteins involved in synapse formation and maintenance include FMR1, TSC1, TSC2, MeCP2, NLGN 3 and 4, and SHANK3. Another set of proteins is involved in neuronal migration and cell fate including REELIN, WNT2, LAMB1, and NrCAM. Proteins involved in neurotransmitter systems are also altered in some individuals with autism and include 5-HTT (serotonin transporter encoded by SLC6A4), GABAR, and the NMDA subunit encoded by GRIN2A. See text for details. (From Persico AM, Bourgeron T. Searching for ways out of the autism maze: genetic, epigenetic and environmental clues. *Trends Neurosci*. 2006;29:349, with permission.)

Neuroligin (*NLGN*) 3 and 4 and *SHANK3,* additional genes that appear to play a role in synapse formation, may be affected by chromosomal rearrangements observed in some individuals affected with autism. The neuroligin genes, sited on the X chromosome, produce cell adhesion molecules that are located on postsynaptic glutamatergic neurons. When mutated in rodents, these genes show defective trafficking and synapse induction. In nonmutated form, their expression induces the formation of normal, presynaptic terminals in axons. *SHANK3* is a binding partner of the

neuroligins and regulates the structural organization of dendritic spines. Mutations in *SHANK3* have been identified in ASD-affected members of at least three families to date, and a comparative genomic hybridization study of autistic individuals, their family members, and controls recently identified a large deletion in chromosome 22q13, the region containing *SHANK3*, in at least one individual with autism.

CELL MIGRATION. Of the regions highlighted by a genome screen in autism families, chromosome 7q has provided the most consistent evidence for linkage, albeit over an extensive region. Known chromosomal rearrangements in this region in individuals affected with autism add to its interest. The linkage region on chromosome 7q contains several genes that are strong candidates for autism, most notably *RELN*, which maps to chromosome 7q22. *RELN* codes for reelin, a signaling protein secreted by Cajal–Retzius cells located in the marginal zone of the developing brain. It plays a vital role in neuronal migration as well as in the development of neural connections. Reeler mice, which have spontaneous deletions of *RELN*, have cytoarchitectonic alterations in their brains during development that are similar to those that have been described in autistic brains. The complete absence of *RELN* in humans leads to a more severe phenotype with lissencephaly and severe mental retardation but not autism. Individuals with autism show reduced levels of reelin mRNA and protein in brain and blood serum, suggesting that mutations leading to reduced expression of *RELN* rather than its absence may be significant in ASD. Genetic association studies with *RELN* have been equivocal, suggesting that if *RELN* does contribute to the development of autism, then it may play such a role in a small subset of affected individuals. *WNT2* (wingless-type MMTV integration site family member 2) is another gene identified as a potential candidate for autism based on linkage studies. *WNT2* is located on 7q31 and is part of a family of genes that encode secreted signaling proteins implicated in several developmental processes, including the regulation of cell fate and patterning during embryogenesis. At least two families have been identified in which nonconservative coding sequence variants in *WNT2* segregate with autism. LD between an SNP in the 3′ untranslated region of *WNT2* and autism is also present in families with severe language abnormalities that accounted for most of the evidence for linkage on chromosome 7q in one of the original

genome screens.

EXCITATORY/INHIBITORY NEUROTRANSMITTER SYSTEMS. Although there is little current evidence that mutations in genes encoding neurotransmitter transporters or receptors are directly responsible for the development of autism, there is some evidence that such genes might act as modifiers or susceptibility factors for autism spectrum phenotype. The evidence is perhaps most robust for the role of the GABA receptors in the development and expression of autistic disorders. These receptors occur in a cluster on chromosome 15q11–13, and duplications of this region are the most common cytogenetic abnormalities seen in autism cases (up to 6 percent of cases). GABA is an important inhibitory neurotransmitter in the CNS and is responsible for controlling excitability in mature brains. Chromosome 15q11–13 is one of the most complex regions of the genome. It has a high rate of genomic instability, including frequent duplication and deletion events, and imprinting plays a vital role in the expression of genes in this region. The 15q11–13 region is the critical region for Angelman and Prader–Willi syndromes, neurologic disorders due to deletions or mutations in this region that occur on maternally and paternally inherited chromosomes, respectively.

Despite the high rate of duplications of 15q11–13 among autistic individuals, genome screens have not shown strong support for linkage or association to this region. Candidate gene studies continue, however, in part because a rate of 6 percent of autistic individuals with duplications in this region is hard to ignore.

Bipolar Disorder. The search for the genetic basis of bipolar disorder has been fraught with missteps and partial answers. The history of genetic mapping attempts for bipolar disorder illustrates not only the extreme complexity of psychiatric disorders but also the evolution of genetic approaches to such diseases. Bipolar disorder is an episodic illness characterized by recurrent periods of both mania and depression. Psychotic symptoms are often a part of the clinical picture, particularly in more severely affected individuals.

Numerous genetic epidemiologic investigations conducted over several decades have strongly supported a genetic contribution to risk for bipolar

disorder. The definition of the bipolar disorder phenotype in these studies has varied substantially, resulting in a wide range of heritability estimates. This problem is typical of many psychogenetic studies. For example, many early studies into the genetic basis of mood disorders did not distinguish between unipolar and bipolar mood disorders. Furthermore, the diagnostic methodology used in such early studies differs substantially from that employed in current-day genetic studies. For example, a Danish twin study that suggested a very high heritability for bipolar disorder and thereby had a substantial influence on the design of initial genetic mapping studies of mood disorders employed only unstructured diagnostic interviews by a single clinician rather than the structured assessments used in current studies, which have suggested somewhat lower heritabilities.

Current estimates of the concordance for bipolar disorder range between 65 and 100 percent in MZ twins and 10 and 30 percent in DZ twins. This ratio indicates that the disorder is highly heritable (between about 60 and 80 percent). Several studies have shown that bipolar disorder is substantially more heritable than unipolar major depression, which has an estimated heritability between 30 and 40 percent.

Early family studies suggested that bipolar disorder segregation patterns were compatible with single-gene inheritance of a locus of significant effect. However, although some bipolar disorder pedigrees may segregate such a locus, mounting evidence indicates that if such pedigrees exist, they must be quite rare. Furthermore, the fact that genetic linkage studies have failed to uncover such a locus with unequivocal evidence in any pedigrees argues against this possibility. The observed rapid decrease in recurrence risk for bipolar disorder from monozygotic co-twins to first-degree relatives is also not consistent with single-gene inheritance models but instead suggests models of multiple interacting genes.

EARLY LINKAGE STUDIES. Tremendous excitement followed the first reports of linkage to bipolar disorder on chromosomes X and 11 in 1987. Investigators noted that in several families, bipolar disorder and other affective disorders appeared to be inherited in an X-linked fashion. Likewise, these disorders appeared to cosegregate in several Israeli families with color blindness and G6PD deficiency, which map to the X chromosome. Linkage studies in these pedigrees, using color blindness or G6PD deficiency as marker loci, gave

LOD scores between 4 and 9. Early studies of chromosome 11 were similar to those for chromosome X in that they reported significant linkage after testing only a few markers in a single region, in this case, in an extended Old Order Amish pedigree heavily loaded for bipolar disorder.

Not surprisingly, these findings generated a great deal of interest. Both studies showed high LOD scores and seemed to provide clear evidence for linkage. However, replication studies in other populations failed to produce positive results for either the X chromosome or chromosome 11, and evidence for linkage virtually disappeared in both chromosomal regions in the samples in which linkage was initially reported when the pedigrees were extended to include additional affected individuals and when additional markers were typed in the putative linkage regions. The most likely explanation in each case is that the original linkage results were false-positive findings and may have reflected over-optimistic interpretation of evidence that, in retrospect, was relatively scanty.

GENOME-WIDE SCREENS. The early linkage studies of bipolar disorder evaluated only a few markers because they were all that were available. With the construction of genetic linkage maps of the genome in the 1990s, linkage studies of most complex traits, including bipolar disorder, began to search genome-wide. The advantage of genome-wide mapping studies is that they do not require *a priori* knowledge of the biologic underpinnings of a particular phenotype. Complete genome screens provide an opportunity to evaluate the evidence of linkage at all points in the genome without bias. Although genome-wide studies had greater power to detect accurate linkage than studies focused on only a few markers in arbitrary locations or around a few candidate genes, these investigations have also generally had disappointing results. The challenge of achieving replicated significant linkage results for bipolar disorder and other complex traits is apparent when one reviews the many gene-mapping studies that have suggested—but not demonstrated unequivocally—bipolar disorder susceptibility loci on chromosome 18.

CHROMOSOME 18. The first report of linkage came from a partial genome screen that examined 11 markers on chromosome 18 and identified suggestive linkage near the centromere. Because the inheritance patterns for

bipolar disorder are unknown, the results were analyzed using both recessive and dominant models. Some of the markers were positive under a recessive model in some families, some were positive under a dominant model in other families, and some markers gave positive LOD scores in a subset of families under both models. Attempts to replicate this finding in other populations have been mixed. So far, at least two groups have found no evidence for linkage to the pericentromeric region of chromosome 18 in their samples, although one other group has found evidence to support linkage to this region. Other studies have found suggestive evidence for linkage on chromosome 18, including a complete genome screen in two large Costa Rican pedigrees that gave evidence for linkage on chromosome 18q22–23 as well as in an area on 18p. The combined evidence of these several studies, although somewhat contradictory and confusing, points to at least two different susceptibility loci on chromosome 18: one on 18p and one on 18q.

IMPROVING STUDY POWER. The equivocal findings represented by the attempts to pinpoint susceptibility loci on chromosome 18 have led investigators to implement several new strategies to map bipolar disorder genes. One such strategy is a meta-analysis, which involves combining data across multiple individual investigations to increase statistical power, and in some cases, the combined analysis points to loci not initially found in the individual studies. Several meta-analytical techniques have been used to explore gene-mapping studies for bipolar disorder. The multiple scan probability (MSP) and genome scan meta-analysis (GSMA) methods require only linkage statistics and *p*-values from each study to examine combined data. MSP was used to combine chromosomal regions with *p*-values less than 0.01 from 11 independent bipolar disorder studies and provided evidence for susceptibility loci on chromosomes 13q and 22q. Although the MSP and GSMA methods have the advantage of requiring only linkage significance data, they are not able to account for study-specific issues that will limit the extent to which multiple studies can be compared. Combining original genotype data from multiple studies can circumvent this problem. With this method, the largest meta-analysis to date combined 11 bipolar disorder genome-wide linkage scans consisting of 5,179 individuals from 1,067 families. Access to the original genotype data allowed the construction of a standardized genetic map in which the markers of each respective study were

mapped onto one standard gender-averaged map. The results of this meta-analysis identified two susceptibility loci with genome-wide significance on 6q and 8q.

Another strategy that has been used to increase the power of gene-mapping studies in the formation of consortia that combine data across multiple clinical sites. A consortium combining data from the UK and Ireland led to support for linkage at 9p21 and 10p14–21. Likewise, combining data from Spanish, Romanian, and Bulgarian families provided additional support for findings on chromosomes 4q31 and 6q24. Investigators can also increase power by standardizing marker sets and clinical evaluation protocols between independent studies to permit direct comparisons between such studies. This approach was used to identify a bipolar disorder susceptibility locus on chromosome 5q31–33. The region showed suggestive nonparametric linkage results in pedigrees from the Central Valley of Costa Rica. With identical genetic markers and diagnostic criteria, the same region was highlighted in an independent analysis of a set of Colombian families who have a genetic background similar to that of the Costa Rican families. A follow-up study using additional markers in an expanded set of Colombian and Costa Rican families confirmed genome-wide significant evidence to a candidate region of 10 cM in 5q31–33. This finding is especially impressive given that the linkage peak in the bipolar studies overlaps with linkage regions for schizophrenia and psychosis, identified in a previous study of 40 families from the Portuguese Islands. These results contribute to a growing opinion that there may be substantial genetic overlap between different DSM disorders.

Schizophrenia. In the past decade we have seen exciting advances in the genetic studies of schizophrenia. Much of these are due to the several large consortia formed to investigate the disorder. These collaborative efforts allow for large samples with sufficient power to investigate the disorder.

Before these studies, family studies established a heritability of between 60 and 80 percent, however we lacked any meaningful genome-wide studies. In 2009 several of the consortia combined samples and identified an SNP in the MHC on chromosome 6p22 as a risk locus. What followed were several elegant studies, including a landmark 2016 paper from the Schizophrenia Working Group of the Psychiatric Genomics Consortium, which focused on

the C4 alleles and demonstrated their role in synaptic pruning during critical developmental period. This supports the hypothesis that schizophrenia is the result of abnormalities of neurodevelopment.

Before this work, various candidate genes emerged. They spawned a diverse range of basic and clinical investigations aiming to elucidate their functional significance, for example, using mouse gene targeting and functional MRI.

The early identification of chromosome 6p24–22 as implicated in schizophrenia led to the proposal of *Dysbindin* (*DTNB1*) as a candidate gene for schizophrenia. Additional association studies of *Dysbindin* have been equivocal.

Linkage studies subsequently pointed to a region on chromosome 1 containing the candidate genes *DISC 1* and *DISC 2* (*disrupted in schizophrenia 1* and *2*) located on chromosome 1q21–22 and 1q32–42. These genes were initially identified in a large Scottish pedigree in the early 1990s. A balanced translocation between chromosomes 1 and 11 segregated in this pedigree and was possibly associated with severe mental illness. *DISC 1* and *2* were identified in the original Scottish family because of their location near the chromosomal translocation breakpoint. As with *Dysbindin,* follow-up studies of *DISC 1* and *2* have been equivocal.

Genome screens, including a screen focused on extended Icelandic kindreds, have identified a schizophrenia candidate region on chromosome 8p21–22. Fine mapping of the region narrowed the search and eventually led to the proposal of *neuregulin 1* (*NRG1*) as a schizophrenia candidate gene. Association studies again provided equivocal and difficult-to-interpret results.

Despite the equivocal genetic studies, significant resources have been channeled into molecular and neurophysiologic investigations of the functional products of *dysbindin, DISC 1* and *2,* and *neuregulin.* Mutant mice for each of the three genes are now available and have been used to demonstrate interesting biologic findings. For example, *dysbindin* is expressed in the hippocampus and dorsolateral prefrontal cortex. The dysbindin protein binds to B-dystrobrevin and has been implicated in synaptic structure and signaling. *DISC 1* has been shown to influence neurite formation in cellular studies, and mutant mice for *DISC 1* show impairments in a wide variety of tests, including learning, memory, and sociability.

Neuregulin belongs to a family of growth factors that mediate numerous functions, including synapse formation, neuronal migration, and neurotransmission. Targeted disruption of *erbB4*, the postsynaptic target of neuregulin, leads to synaptic glutamatergic hypofunction. Despite the exciting biology uncovered, it remains unclear whether and to what extent any of these genes contribute to the etiology of schizophrenia in humans, and many geneticists have been cautious in their endorsement of the legitimacy of the mutant mice generated from the current list of candidate genes as models of psychiatric disorders.

APPLIED ELECTROPHYSIOLOGY

EEG is the recording of the electrical activity of the brain. It is used in clinical psychiatry principally to evaluate the presence of seizures, particularly temporal lobe, frontal lobe, and petit mal seizures (absence seizures), which can produce complex behaviors. EEG is also used during ECT to monitor the success of the stimulus in producing seizure activity and as a critical component of polysomnography used in the evaluation of sleep disorders. Quantitative electroencephalography (QEEG) and cerebral evoked potentials (EPs) represent newer EEG-based methods that provide improved research and clinical insights into brain functioning.

Electroencephalography

A brain wave is a transient difference in electrical potential (greatly amplified) between any two points on the scalp or between some electrode placed on the scalp and a reference electrode located elsewhere on the head (i.e., ear lobe or nose). The difference in electrical potential measured between any two EEG electrodes fluctuates or oscillates rapidly, usually many times per second. It is this oscillation that produces the characteristic "squiggly line" that is recognized as the appearance of "brain waves."

Brain waves reflect a change by becoming faster or slower in frequency or lower or higher in voltage, or perhaps some combination of these two responses. A routine EEG can never constitute positive proof of the absence of brain dysfunction. Even in diseases with established brain pathophysiology, such as multiple sclerosis, deep subcortical neoplasm, some seizure disorders, and Parkinson disease and other movement disorders, a

substantial incidence of patients with normal EEG studies may be encountered. Nonetheless, a normal EEG can often provide convincing evidence for excluding certain types of brain pathology that may present with behavioral or psychiatric symptoms. More often, information from the patient's symptoms, clinical course and history, and other laboratory results identifies a probable cause for the EEG findings. EEG studies are often ordered when a pathophysiologic process is already suspected, or a patient experiences a sudden, unexplained change in mental status.

Electrode Placement. The electrodes usually used to record the EEG are attached to the scalp with a conductive paste. A standard array consists of 21 electrodes. The placement of the electrodes is based on the 10/20 International System of Electrode Placement (Fig. 33-33). This system measures the distance between readily identifiable landmarks on the head and then locates electrode positions at 10 percent or 20 percent of that distance in an anterior–posterior or transverse direction. Electrodes are then designated by an uppercase letter denoting the brain region beneath that electrode and a number, with odd numbers used for the left hemisphere and with even numbers signifying the right hemisphere (the subscript Z denotes midline electrodes). Thus, the O_2 electrode is placed over the right occipital region, and the P_3 lead is found over the left parietal area.

In particular circumstances, other electrodes may be used. Nasopharyngeal (NP) electrodes can be inserted into the NP space through the nostrils and can be closer to the temporal lobe than scalp electrodes. No actual penetration of tissue occurs. These electrodes may be contraindicated with many psychiatric patients displaying behaviors, such as confusion, agitation, or belligerence, which could pull the leads out, possibly lacerating the nasal passage. Sphenoidal electrodes use a hollow needle through which a fine electrode that is insulated, except at the tip, is inserted between the zygoma and the sigmoid notch in the mandible until it is in contact with the base of the skull lateral to the foramen ovale.

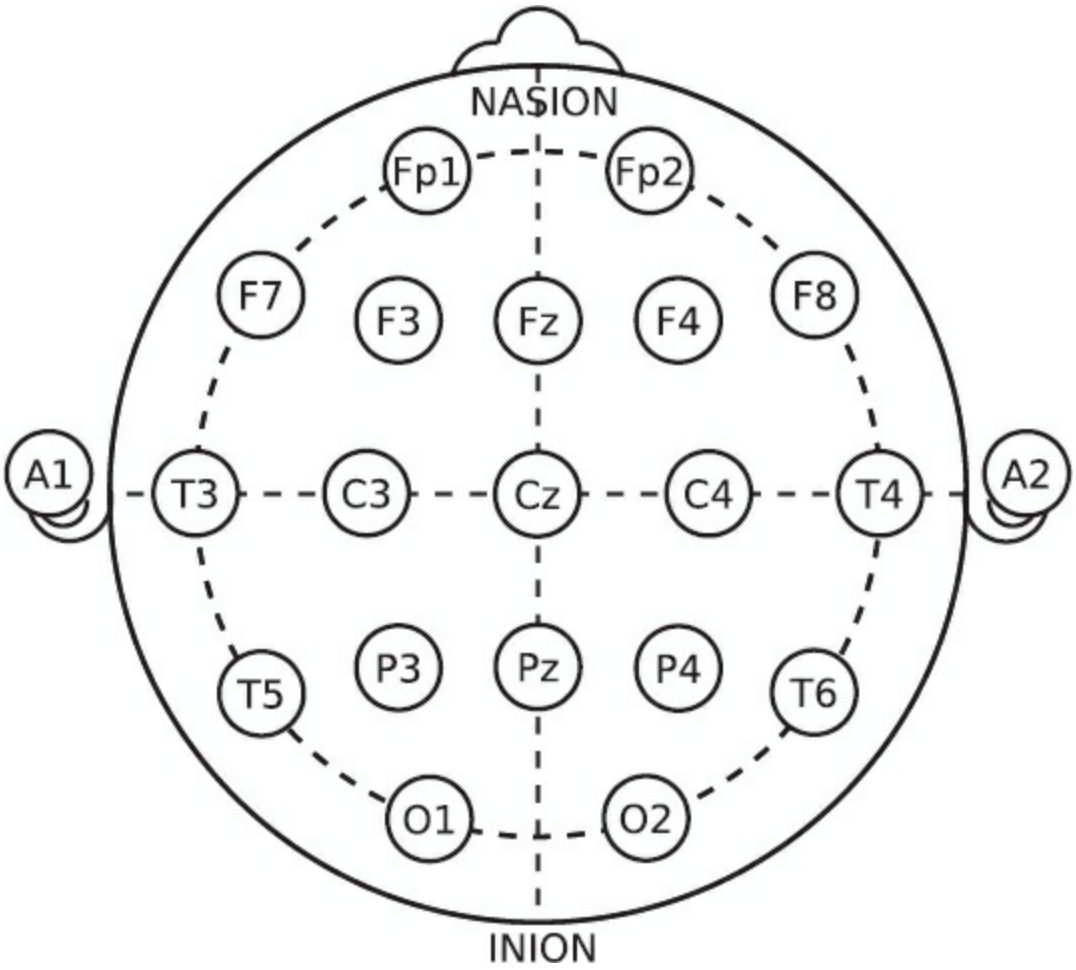

FIGURE 33-33
International 10–20 Electrode Placement System.

Activated EEG. Specific activating procedures are used to increase the probability that abnormal discharges, particularly spike or spike-wave seizure discharges, will occur. Strenuous hyperventilation is one of the most frequently used activation procedures. While remaining reclined with the eyes closed, the patient is asked to over breathe through the open mouth with deep breaths for 1 to 4 minutes, depending on the laboratory (3 minutes is standard). In general, hyperventilation is one of the safest EEG-activating procedures, and, for most of the population, it presents no physical risk. It can pose a risk for patients with cardiopulmonary disease or risk factors for cerebral vascular pathophysiology, however. Photic stimulation (PS) generally involves placing an intense strobe light approximately 12 inches in front of the subject's closed eyes and flashing at frequencies that can range from 1 to 50 Hz, depending on how the procedure is carried out. Retinal

damage does not occur because each strobe flash, although intense, is too brief in duration to harm the patient. When the resting EEG is normal, and a seizure disorder or behavior that is suspected to be a manifestation of a paroxysmal EEG dysrhythmia is suspected, PS can be a valuable activation method to use. EEG recording during sleep, natural or sedated, is now widely accepted as an essential technique for eliciting a variety of paroxysmal discharges, when the wake tracing is normal, or for increasing the number of abnormal discharges to permit a more definitive interpretation. It has been shown that the CNS stress produced by 24 hours of sleep deprivation alone can lead to the activation of paroxysmal EEG discharges in some cases.

Normal EEG Tracing

The normal EEG tracing (Fig. 33-34) is composed of a complex mixture of many different frequencies. Discrete frequency bands within the broad EEG frequency spectrum are designated with Greek letters.

Awake EEG. The four basic waveforms are alpha, beta, delta, and theta. Highly rhythmic *alpha waves* with a frequency range of 8 to 13 Hz constitute the dominant brain wave frequency of the normal eyes-closed awake EEG. Alpha frequency can be increased or decreased by a wide variety of pharmacologic, metabolic, or endocrine variables. Frequencies that are faster than the upper 13 Hz limit of the alpha rhythm are termed *beta waves*, and they are not uncommon in average adult waking EEG studies, particularly over the frontal-central regions. *Delta waves* (≤3.5 Hz) are not present in the normal waking EEG but are a prominent feature of deeper stages of sleep. The presence of significant generalized or focal delta waves in the awake EEG is strongly indicative of a pathophysiologic process. Waves with a frequency of 4.0 to 7.5 Hz are collectively referred to as *theta waves.* A small amount of sporadic, arrhythmic, and isolated theta activity can be seen in many normal waking EEG studies, particularly in frontal-temporal regions. Although theta activity is limited in the waking EEG, it is a prominent feature of the drowsy and sleep tracing. Excessive theta in awake EEG, generalized, or focal, suggests the operation of a pathologic process.

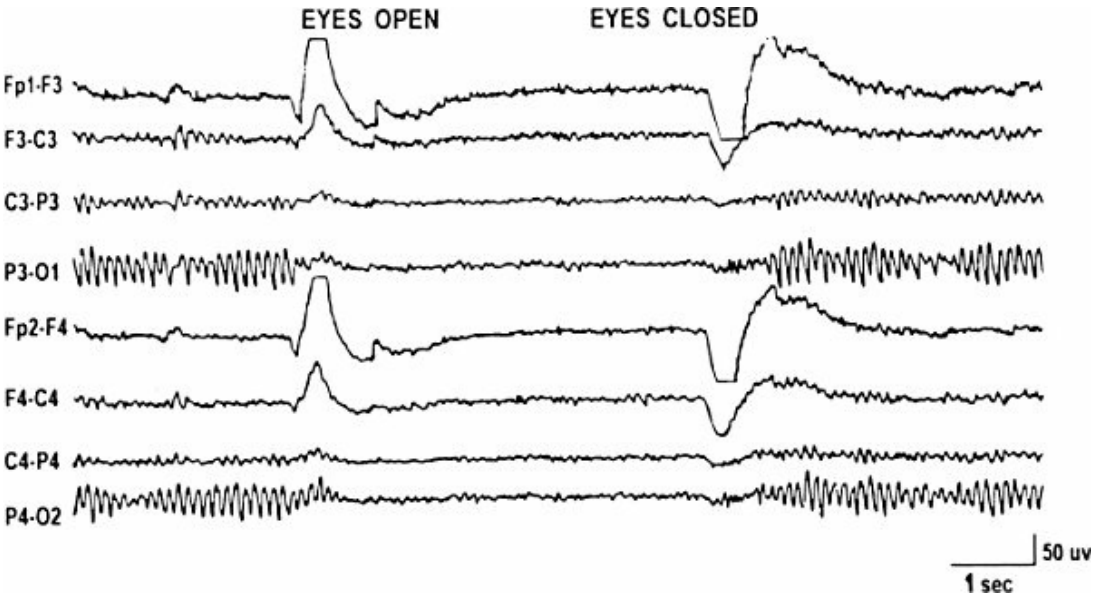

FIGURE 33-34
Normal electroencephalogram (EEG) tracings in an awake 28-year-old man. (Reprinted from Emerson RG, Walesak TS, Turner CA. EEG and evoked potentials. In: Rowland LP, ed. *Merritt's Textbook of Neurology*. 9th ed. Baltimore, MD: Lippincott Williams & Wilkins; 1995:68, with permission.)

With maturation, EEG activity gradually goes from a preponderance of irregular medium- to high-voltage delta activity in the tracing of the infant, to greater frequency and more rhythmic pattern. Rhythmic activity in the upper theta-lower alpha range (7 to 8 Hz) can be seen in posterior areas by early childhood, and, by mid-adolescence, the EEG essentially has the appearance of an adult tracing.

Sleep EEG. The EEG patterns that characterize drowsy and sleep states are different from the patterns seen during the awake state. The rhythmic posterior alpha activity of the waking state subsides during drowsiness and is replaced by irregular low-voltage theta activity. As drowsiness deepens, slower frequencies emerge, and sporadic vertex sharp waves may appear at central electrode sites, particularly among younger persons. Finally, the progression into sleep is marked by the appearance of 14-Hz sleep spindles (also called *sigma waves*), which, in turn, gradually become replaced by high-voltage delta waves as deep sleep stages are reached.

EEG Abnormalities

Apart from some of the apparent indications for an EEG study (i.e., suspected seizures), EEG studies are not routinely performed as part of a diagnostic work-up in psychiatry. EEG, however, is a valuable assessment tool in clinical situations in which the initial presentation or the clinical course appears to be unusual or atypical (Table 33-8). Table 33-9 summarizes some common types of EEG abnormalities.

Some psychotropic medications and recreational or abused drugs produce EEG changes, yet, except for the benzodiazepines and some compounds with a propensity to induce paroxysmal EEG discharges, little, if any, the clinically relevant effect is noted when the medication is not causing toxicity. Benzodiazepines, which always generate a significant amount of diffuse beta activity, have EEG-protective effects so that they can mask alterations caused by concomitant medications (Table 33-10).

Medical and neurologic conditions produce a wide range of abnormal EEG findings. EEG studies, thus, can contribute to the detection of unsuspected organic pathophysiology influencing a psychiatric presentation (Fig. 33-35). Table 33-11 lists EEG alterations in medical disorders, and Table 33-12 lists EEG alterations associated with psychiatric disorders.

Table 33-8
Warning Signs of the Presence of Covert Medical or Organic Factors Causing or Contributing to Psychiatric Presentation

Atypical age of onset (i.e., anorexia nervosa beginning at mid-adulthood)
Complete lack of positive family history of the disorder when a positive family history is expected
Any focal or localized symptoms (i.e., unilateral hallucinations)
Focal neurologic abnormalities
Catatonia
Presence of any difficulty with orientation or memory (in general, Mini Mental State Examination should be normal)
Atypical response to treatment
Atypical clinical course

Note: Clinicians should have a high index of suspicion for underlying medical conditions and a

low threshold for initiating appropriate workups.

Table 33-9
Common Electroencephalography (EEG) Abnormalities

Diffuse slowing of background rhythms	Most common EEG abnormality; nonspecific and is present in patients with diffuse encephalopathies of diverse causes
Focal slowing	Suggests localized parenchymal dysfunction and focal seizure disorder; seen with focal fluid collection, such as hematomas
Triphasic waves	Typically consist of generalized synchronous waves occurring in brief runs; approximately one-half of patients with triphasic waves have hepatic encephalopathy, and the remainder have other toxic–metabolic encephalopathies
Epileptiform discharges	Interictal hallmark of epilepsy; strongly associated with seizure disorders
Periodic lateralizing epileptiform discharges	Suggest the presence of an acute destructive cerebral lesion; associated with seizures, obtundation, and focal neurologic signs
Generalized periodic sharp waves	Most commonly seen following cerebral anoxia; recorded in about 90% of patients with Creutzfeldt–Jakob disease

Table 33-10
Electroencephalography (EEG) Alterations Associated with Medication and Drugs

Drug	Alterations

Benzodiazepines	Increased beta activity
Clozapine (Clozaril)	Nonspecific change
Olanzapine (Zyprexa)	Nonspecific change
Risperidone (Risperdal)	Nonspecific change
Quetiapine (Seroquel)	No significant changes
Aripiprazole (Abilify)	No significant changes
Lithium	Slowing or paroxysmal activity
Alcohol	Decreased alpha activity; increased theta activity
Opioids	Decreased alpha activity; increased voltage of theta and delta waves; in overdose, slow waves
Barbiturates	Increased beta activity; in withdrawal states, generalized paroxysmal activity and spike discharges
Marijuana	Increased alpha activity in frontal area of brain; overall slow alpha activity
Cocaine	Similar to marijuana
Inhalants	Diffuse slowing of delta and theta waves
Nicotine	Increased alpha activity; in withdrawal, marked decrease in alpha activity
Caffeine	In withdrawal, increase in amplitude or voltage of theta activity

Topographic Quantitative Electroencephalography (QEEG)

Unlike standard EEG interpretation, which relies on waveform recognition, QEEG involves computer analysis of data extracted from the EEG. Findings are compared with an extensive population database of subjects without any known neurologic or psychiatric disorder as well as QEEG profiles that may be characteristic of some defined diagnostic group. In QEEG, the analog-based electrical signals are processed digitally and converted to graphic, colored topographical displays. These images are sometimes called "brain maps."

Table 33-11
Electroencephalography (EEG) Alterations Associated with Medical Disorders

Seizures	Generalized, Hemispheric, or Focal Spike, Spike-Wave Discharge, or Both
Structural lesions	Focal slowing, with possible focal spike activity
Closed head injuries	Focal slowing (sharply focal head trauma) Focal delta slowing or more widespread slowing (subdural hematomas)
Infectious disorders	Diffuse, often synchronous, high voltage slowing (acute phase of encephalitis)
Metabolic and endocrine disorders	Diffuse generalized slowing of wake frequencies Triphasic waves: 1.5–3.0 per second high-voltage slow waves, with each slow wave initiated by a blunt or rounded spike-like transient (hepatic encephalopathy)
Vascular pathophysiology	Slowed alpha frequency and increased generalized theta slowing (diffuse atherosclerosis) Focal or regional delta activity (cerebrovascular accidents)

QEEG remains primarily a research method, but it holds considerable

clinical potential for psychiatry, mainly in establishing neurophysiologic subtypes of specific disorders and for identifying electrophysiologic predictors of response. Examples of some of the more promising results of QEEG research include the identification of subtypes of cocaine dependence and the subtype most likely to be associated with sustained abstinence; identification of subtypes of OCD that predict clinical responsiveness or lack of responsiveness to SSRIs; and the differentiation between normals, attention-deficit disorder and ADHD, and learning disability subpopulations. QEEG findings in ADHD show that increased theta abnormality frontally may be a strong predictor of response to methylphenidate and other psychostimulants and that favorable clinical responses may be associated with a normalization of the EEG abnormality.

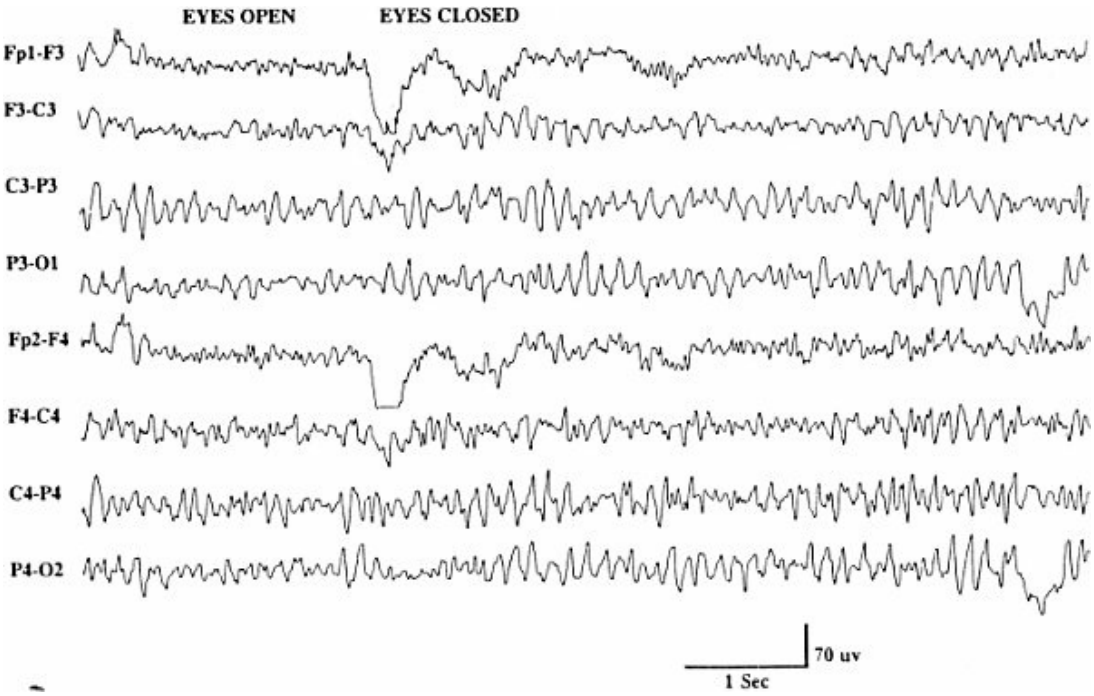

FIGURE 33-35
Diffuse slowing in a 67-year-old patient with dementia. Six- to seven cycles per second (cps) activity predominates over the parieto-occipital regions. Although reactive to eye closure, the frequency of this rhythm is abnormally slow. (Reprinted from Emerson RG, Walesak TS, Turner CA. EEG and evoked potentials. In: Rowland LP, ed. *Merritt's Textbook of Neurology*. 9th ed. Baltimore, MD: Lippincott Williams & Wilkins; 1995:68, with permission.)

Table 33-12
Electroencephalography (EEG) Alterations Associated with

Psychiatric Disorders	
Panic disorder	Paroxysmal EEG changes consistent with partial seizure activity during attack in one-third of patients; focal slowing in about 25% of patients
Catatonia	Usually normal, but EEG indicated in new patient presenting with catatonia to rule out other causes
Attention-deficit/hyperactivity disorder (ADHD)	High prevalence (up to 60%) of EEG abnormalities versus normal controls; spike or spike-wave discharges
Antisocial personality disorder	Increased incidence of EEG abnormalities in those with aggressive behavior
Borderline personality disorder	Positive spikes: 14 and 6 per second seen in 25% of patients
Chronic alcoholism	Prominent slowing and periodic lateralized paroxysmal discharges
Alcohol withdrawal	May be normal in patients who are not delirious; excessive fast activity in patients with delirium
Dementia	Rarely normal in advanced dementia; may be helpful in differentiating pseudodementia from dementia

Cerebral Evoked Potentials

Cerebral EPs are a series of surface (scalp) recordable waves that result from brain visual, auditory, somatosensory, and cognitive stimulation. They are abnormal in many psychiatric conditions, including schizophrenia and Alzheimer disease, thus creating difficulty in using cerebral EPs for differential diagnosis purposes.

CHRONOBIOLOGY

Chronobiology is the study of biologic time. The rotation of the Earth about its axis imposes a 24-hour cyclicity on the biosphere. Although it is widely accepted that organisms have evolved to occupy geographical niches that can be defined by the three spatial dimensions, it is less appreciated that organisms have also evolved to occupy temporal niches that are defined by the fourth dimension—time. Much like light represents a small portion of the electromagnetic spectrum, the 24-hour periodicity represents a small time domain within the spectrum of temporal biology. A broad range of frequencies exist throughout biology, ranging from millisecond oscillations in ocular field potentials to the 17-year cycle of emergence seen in the periodic cicada (*Magicicada* spp.). Although these different periodicities all fall within the realm of chronobiology, *circadian* (Latin: *circa*, about; *dies*, day) rhythms that have a period of about one day are among the most extensively studied, and best understood biologic rhythms.

A defining feature of circadian rhythms is that they persist in the absence of time cues and are not driven merely by the 24-hour environmental cycle. Experimental animals housed for several months under constant darkness, temperature, and humidity continue to exhibit robust circadian rhythms. Maintenance of rhythmicity in a "timeless" environment points to the existence of an internal biologic timing system that is responsible for generating these endogenous rhythms.

The site of the primary circadian oscillator in mammals, including humans, is the suprachiasmatic nucleus (SCN), located in the anterior hypothalamus. The mean circadian period generated by the human SCN is approximately 24.18 hours. Like a slightly slow watch, an individual with such a period gradually comes out of synchrony with the astronomical day. In slightly more than 3 months, an ordinarily diurnal human would be in antiphase to the day–night cycle and thus would become transiently nocturnal. Therefore, a circadian clock must be reset regularly to be effective at maintaining the proper phase relationships of behavioral and physiologic processes within the context of the 24-hour day.

Although factors such as temperature and humidity exhibit daily fluctuations, the environmental parameter that most reliably corresponds to the period of Earth's rotation around its axis is the change in illuminance

associated with the day–night cycle. Organisms have evolved to use this daily change in light levels as a time cue or *zeitgeber* (German: *zeit,* time; *geber,* giver) to reset the endogenous circadian clock. Regulation of the circadian pacemaker through the detection of changes in illuminance requires a photoreceptive apparatus that communicates with the central oscillator. This apparatus is known to reside in the eyes because surgical removal of the eyes renders an animal incapable of resetting its clock in response to light.

The circadian clock drives many rhythms. These include rhythms in behavior, core body temperature, sleep, feeding, drinking, and hormonal levels. One such circadian-regulated hormone is the indoleamine, melatonin. Melatonin synthesis is controlled through a multisynaptic pathway from the SCN to the pineal gland. Serum levels of melatonin become elevated at night and return to baseline during the day. The nocturnal rise in melatonin is a convenient marker of circadian phase. Exposure to light elicits two distinct effects on the daily melatonin profile. First, light acutely suppresses elevated melatonin levels, immediately decreasing them to baseline levels. Second, light shifts the phase of the circadian rhythm of melatonin synthesis. Because melatonin can be assayed easily, it provides a convenient window into the state of the circadian pacemaker. Any perturbation of the clock is reflected in the melatonin profile; thus, melatonin offers an output that can be used to study the regulation of the central circadian pacemaker.

Sleep and Circadian Rhythms

Sleep Regulation. Restful consolidated sleep is most appreciated when sleep disturbances are experienced. Sleep is the integrated product of two oscillatory processes. The first process frequently referred to as the *sleep homeostat,* is an oscillation that stems from the accumulation and dissipation of sleep debt. The biologic substrates encoding sleep debt are not known, although adenosine is emerging as a primary candidate neuromodulator of the sleep homeostat. The second oscillatory process is governed by the circadian clock and controls a daily rhythm in sleep propensity or, conversely, arousal. These interacting oscillations can be dissociated by housing subjects in a timeless environment for several weeks.

The circadian cycle in arousal (wakefulness) steadily increases throughout the day, reaching a maximum immediately before the circadian increase in

plasma melatonin (Fig. 33-36). Arousal subsequently decreases to coincide with the circadian trough in core body temperature. Experiments imposing forced sleep schedules throughout the circadian day have shown that an uninterrupted 8-hour bout of sleep can only be obtained if sleep is initiated approximately 6 hours before the temperature nadir. This nadir typically occurs at approximately 5:00 AM to 6:00 AM. In healthy individuals, initiating sleep between 11:00 PM and 12:00 AM affords the highest probability of getting eight solid hours of sleep.

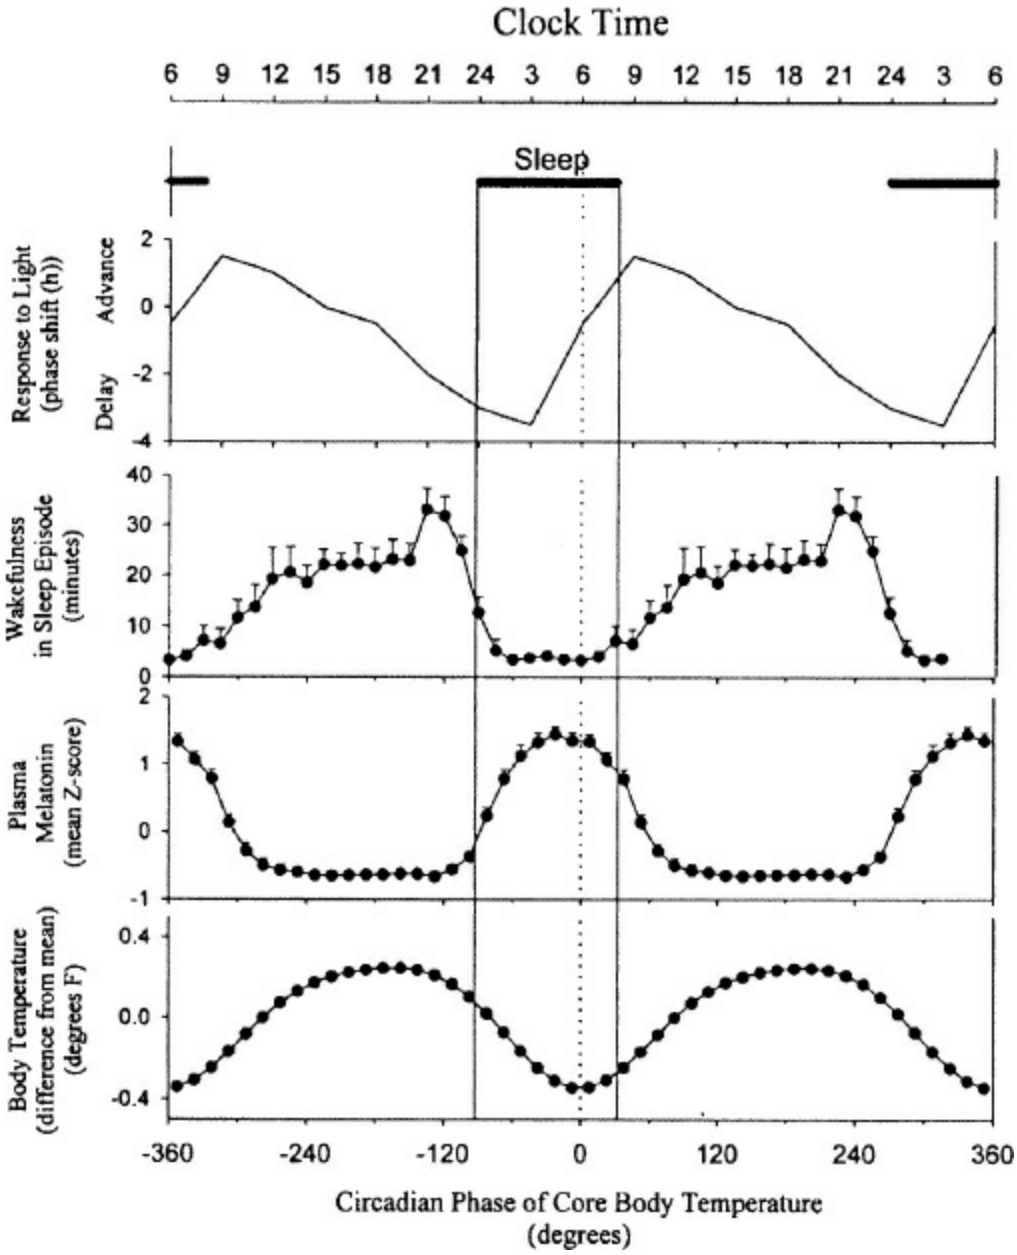

FIGURE 33-36

Relative phase relationship of sleep in young adults to other circadian phase markers. (From Dijk D-J, Lockley SW. Invited review: integration of human sleep-wake regulation and circadian rhythmicity. *J Appl Physiol*. 2002;92:852, with permission.)

It should be stressed that diurnal preference varies among individuals as a function of age, endogenous circadian periods, and other factors. This variability is paralleled by physiology. Clinically, diurnal preference can be quantified using the Horne-Östberg (HO) Morningness-Eveningness Questionnaire (MEQ). In qualitative terms, *morning people* or *morning larks* tend to awaken earlier and experience the core body temperature minimum at an earlier clock time relative to *night people* or *night owls.* Sleep deprivation studies have shown that the homeostatic component of sleep is remarkably similar among individuals of similar age. (It should be noted that there is a well-established age-dependent decline in sleep need.) Therefore, diurnal preference is dictated almost exclusively by the circadian component of sleep regulation.

Circadian Sleep Disorders. Advanced sleep phase syndrome (ASPS) is a pathologic extreme of the morning lark phenotype. An autosomal-dominant familial form of ASPS (FASPS) has been genetically characterized. Afflicted family members exhibit a striking 4-hour advance of the daily sleep–wake rhythm. They typically fall asleep at approximately 7:30 PM and spontaneously awaken at approximately 4:30 AM. Affected individuals have an SNP in the gene encoding hPER2, the human homolog of the mouse *Per2* clock gene. This adenine-to-guanine nucleotide polymorphism results in serine-to-glycine amino acid substitution that causes the mutant protein to be inefficiently phosphorylated by casein kinase Iε, an established component of the circadian molecular clockwork. Similarly, delayed sleep phase syndrome (DSPS) is influenced by genetics. A length polymorphism in a repeat region of the *hPER3* gene appears to be associated with diurnal preference in patients with DSPS, the shorter allele being associated with evening preference.

The advent of the light bulb extended the human day into night. This encroachment on the night, although increasing productivity, affects our sleep patterns (Fig. 33-37). The typical use of artificial lights results in a single, consolidated bout of sleep lasting approximately 8 hours. This pattern of

sleep is uncommon among most other mammals, which typically experience more fractured sleep. Human sleep under more natural photoperiods, where the duration of the night is longer than in artificial settings, becomes decompressed. Specifically, a bimodal distribution of sleep is observed; bouts of sleep occur early and late at night. Periods of *quiet wakefulness* are interspersed between the two primary bouts of sleep. This natural sleep pattern is more similar to the sleep patterns of other mammals.

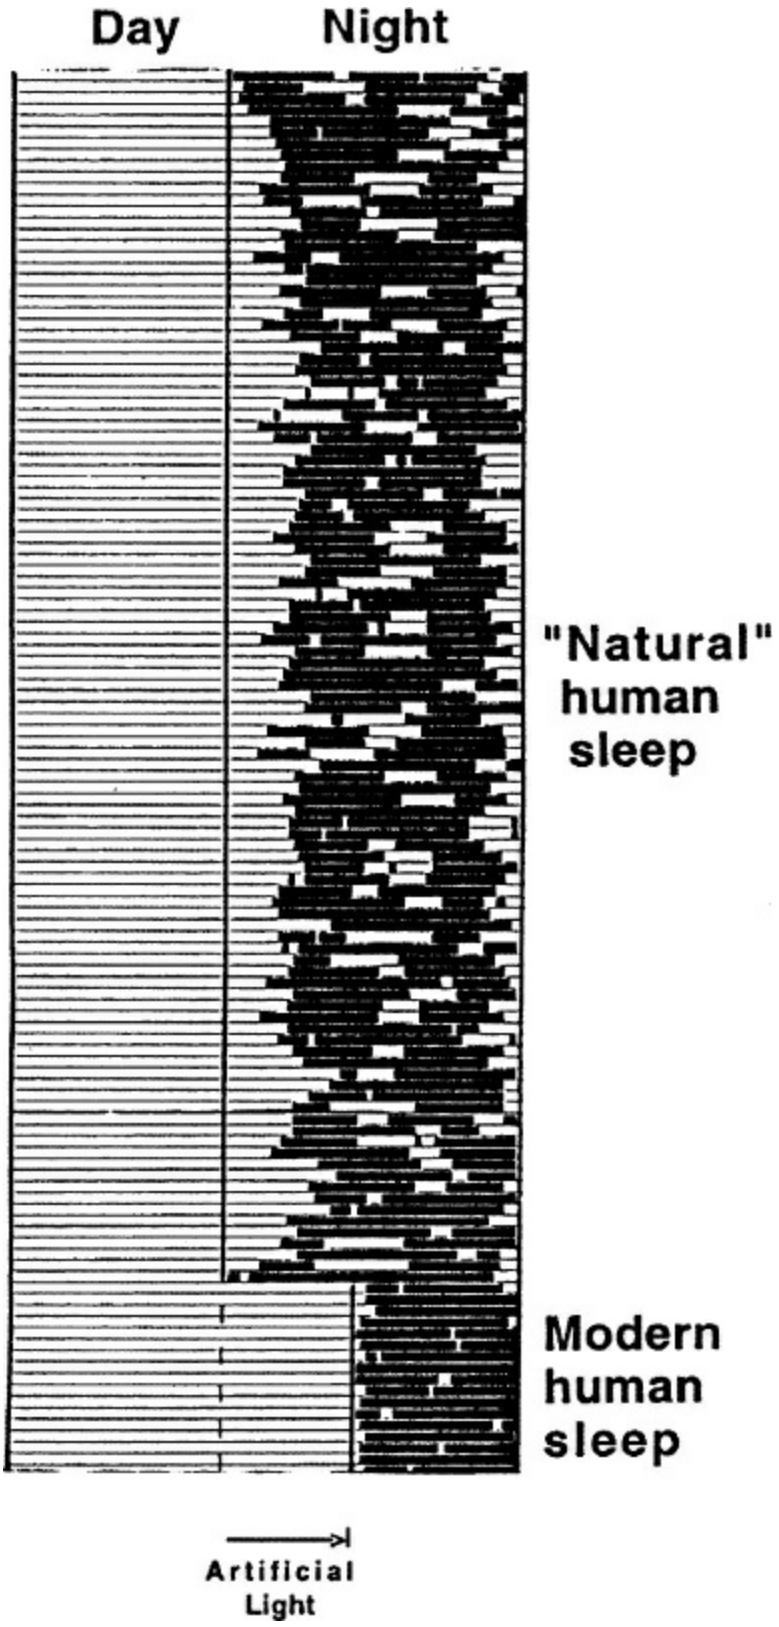

FIGURE 33-37
Change in sleep structure in response to artificial lighting. Total sleep time is reduced, and periods of quiet wakefulness are abolished by extending daytime

into nighttime through artificial lighting. (From Wehr TA, Moul DE, Barbato G, Giesen HA, Seidel JA, Barker C, Bender C. Conservation of photoperiod-responsive mechanisms in humans. *Am J Physiol*. 1993;265:R846, with permission.)

Seasonality

The 24-hour period of the Earth's rotation around its axis is unchanging. However, the Earth's axis is tilted 23.45 degrees from the plane of its orbit around the sun (the ecliptic). The relative day to night proportion within day varies as the Earth proceeds through its orbit of the sun. Many organisms are capable of synchronizing physiology to the seasonal cycle to maximize survival. For example, precise seasonal cycles in reproduction are seen throughout the plant and animal kingdoms. Large mammals that typically have long gestation periods, such as sheep, conceive in the fall when the nights are long and the days are short, so birth occurs during the relatively mild season of spring. These animals are referred to as *short-day breeders.*

Conversely, mammals with gestation periods of only a few weeks, such as hamsters, conceive and give birth during spring and summer, when the days are long and the nights are short. Hence, these animals are referred to as *long-day breeders.* Like circadian rhythms, many of these yearly (circannual) rhythms tend to persist in the absence of seasonal cues with endogenous periods of approximately 1 year.

Melatonin and Seasonality. The most reliable environmental parameter providing a faithful representation of the solar day is the day–night cycle. Similarly, the most reliable environmental parameter reflecting the progression through the seasons is the change in day length, the fraction of the 24-hour day between sunrise and sunset. In seasonally breeding animals, day length is physiologically encoded through the melatonin profile. As described previously, melatonin levels are elevated during the night. A long night, such as that experienced during the short day lengths of winter, results in an elevated melatonin profile of a relatively long duration. A short summer night, by contrast, results in a short duration of elevated melatonin. This seasonal signal is interpreted by the reproductive axis, resulting in an appropriate reproductive response. Melatonin's role in transducing day length was elucidated by pinealectomizing seasonally breeding animals, thereby

removing the primary endogenous source of melatonin. Melatonin was then infused in profiles mimicking long days or short days. The duration of elevated melatonin was the primary determinant of seasonal reproductive status, even when the infused profile was administered under a conflicting day length. Variations in other parameters, such as the amplitude of the melatonin profile, the amount of total melatonin synthesized, or the phase relationship of the profile to the light-dark cycle, are of limited importance in producing a humoral signal that transduces day length.

Reproductive responses to changing day length can be dramatic. A male Siberian hamster (*Phodopus sungorus*) maintained in long days is reproductively competent and typically has a testicular weight of approximately 250 mg per testis. Under short days, however, the testes regress to approximately 15 mg per testis, representing a 94 percent decrease in testicular mass. The same degree of regression is observed in response to melatonin infusions that mimic short days. Communication of the hormonally transduced day length to the reproductive axis is likely to be mediated, at least partially, through melatonin receptors in the *pars tuberalis* of the pituitary gland. The exact mechanism remains unknown, but activation of these receptors is hypothesized to regulate an unidentified factor putatively named tuberalin indirectly. Tuberalin, in turn, controls gene expression and prolactin release from lactotrophs in the adenohypophysis of the pituitary.

Seasonality in Humans. Whether humans are truly seasonal is still a point of considerable debate. Several lines of evidence exist that suggest the presence of a residual tendency toward seasonality. A peak in the rate of suicide occurs in the summer; this peak is cross-cultural. Birth rates also tend to show a seasonal variation; a small but distinguishable peak in the rate of births occurs in spring and summer. This pattern, however, is itself variable and is heavily influenced by unknown cultural and geographic factors. Of interest, the amplitude of the spring–summer birth rate peak has diminished as societies have become industrialized.

The decompressed bimodal structure of human sleep during long nights indicates that the length of natural sleep is related to the length of the night. Potentially, a two-oscillator system could function to maintain proper sleep patterns during changing photoperiods. Such a proposed system would consist of an evening oscillator that tracks the transition from day to night

(dusk) and a morning oscillator that tracks the transition from night to day (dawn). The relative phase differences between these oscillators may encode the changing day lengths associated with the passing of the seasons. Biologic evidence for a two-oscillator system exists in rodents and humans.

The melatonin profile of many vertebrates, including some humans, is bimodal, with evening and morning peaks. In rodents, metabolic and electrophysiologic studies of the SCN typically have been done in brain slices cut in the coronal plane. Results of electrophysiologic studies conducted in brain slices cut in the horizontal plane have provided new insights. The action potential frequency in SCN neurons from horizontally cut preparations is bimodal, with peaks in the early and late subjective day. Furthermore, the interpeak interval varies as a function of the photoperiod in which the animal was housed. These studies lend credence to long-standing suspicions that the SCN of seasonally breeding mammals and, perhaps, nonseasonal mammals harbor a morning and evening oscillator that interact to convey day-length information.

Effect of Aging. In general, as humans age, the circadian period shortens, the circadian phase advances resulting in earlier waking times and bedtimes, the amplitudes of most circadian rhythms decrease, and dramatic phase shifts such as those caused by jet-lag are less tolerated. Again, a mouse model has provided an interesting insight into the interaction of the aging process and the circadian clock. The effect of chronic jet-lag on aged mice has dramatic consequences on mortality. About half of aged mice forced to phase advance 6 hours once per week survive this treatment compared with an 83 percent survival rate in unshifted age-matched mice. Aged mice subjected to weekly 6-hour phase delays show an intermediate survival of 68 percent. These profound effects of phase-shifting are not observed in younger mice. The pathogenesis of chronic jet-lag remains to be determined. Of interest, these mice did not have an increased rate of tumorigenesis. It is likely that in humans, as in mice, the internal desynchrony of oscillators that result from a rotating light schedule may have dire consequences that may be exacerbated by aging.

Circadian Rhythms and Pharmacotherapy

Circadian rhythmicity can be affected by drugs, and conversely, the circadian clock can modulate the efficacy of drugs throughout the day. A better understanding of these interactions will lead to more effective pharmacotherapies. Some of the best-studied interactions between medications and the circadian clock have included the circadian effects of antidepressants. Elevated nocturnal body temperature is a common feature among depressed patients. This effect may be due to reduced amplitude of the master circadian oscillator in the hypothalamus that drives body temperature. TCAs and SSRIs reduce elevated nocturnal body temperature while simultaneously enhancing circadian amplitude. Similarly, many depressed patients exhibit a dampened amplitude in daily activity rhythms. Like body temperature, the amplitude in daily activity cycles of depressed individuals may be augmented by TCA or SSRI therapy.

The use of lithium to treat bipolar disorder has been long established. However, lithium also affects the circadian system, resulting in a lengthening of the circadian period. The molecular mechanism by which this occurs remains unknown. Glycogen synthase kinase 3β (GSK3β) has been implicated in participating within the molecular clock mechanism. Of interest, GSK3β is inhibited by lithium. In cell culture, GSK3β has been shown to stabilize the negative clockwork regulator REV-ERBα via phosphorylation. REV-ERBα typically represses the transcription of the *BMAL1* gene. With lithium, however, GSK3β is inhibited, thereby preventing the phosphorylation and stabilization of REV-ERBα, which is then targeted for proteasomal degradation. The degradation of REV-ERBα results in the de-repression of *BMAL1* transcription. Whether lithium's influence on circadian behavior is attributable to its inhibitory effect on *GSK3*β-mediated stabilization of REV-ERBα remains to be determined.

Short-acting benzodiazepines (e.g., triazolam [Halcion] and brotizolam [Lendormin]) also exert chronobiologic effects. In hamsters, triazolam or brotizolam administered during the middle of the subjective day induces circadian phase advances in activity. Brotizolam has been shown to reduce the light-induced expression of clock genes *Per1* and *Per2* in the SCN. Although benzodiazepines are allosteric modulators of γ-aminobutyric acid A receptors ($GABA_A$), several lines of evidence indicate that the circadian effects of short-acting benzodiazepines require an intact serotonergic system.

When the 5-$HT_{1A/7}$ receptor agonist 8-hydroxy-2-(di-*n*-propylamino)-tetralin (8-OH-DPAT) is injected into hamsters at subjective midday, phase advances in locomotor behavior and SCN neuronal activity are observed in addition to a reduction in *Per1* and *Per2* gene expression in the SCN. Recreational drugs of abuse also affect the circadian system. 3,4-Methylenedioxymethamphetamine (MDMA), or "ecstasy," can act as a serotonin neurotoxin. Hamsters treated with MDMA showed reduced triazolam-induced phase shifts in circadian locomotor activity and a diminished ability to re-entrain rhythms posttreatment. MDMA-treated animals exhibited a reduction of serotonergic axonal terminals in the SCN, again emphasizing the importance of an intact serotonergic system in the regulation of the circadian axis. Recreational use of methamphetamine has increased dramatically. Chronic administration of methamphetamine disorganizes rodent activity rhythms. However, the administration of methamphetamine to rodents rendered arrhythmic through ablation of the SCN results in a reemergence of rhythmicity. The mechanism involved in the rescue of rhythmicity or site of action remains unknown.

The efficacy and toxicity of many pharmacotherapeutics vary as a function of the circadian phase. Daily variations in fixed-dose lethal toxicity have been appreciated in rodents for years. Many anticancer drugs, ranging in mechanism from antimetabolites to DNA intercalators to mitotic inhibitors, have 2- to 10-fold changes in tolerability in rodents over the day. Much of this difference is attributed to circadian variations in the body's ability to absorb, distribute, metabolize, and eliminate toxic compounds. These four processes are affected by underlying circadian rhythms in physiologic processes such as daily variations in gastric pH, gastrointestinal mobility, glomerular filtration rate, and membrane viscosity. The rhythmic intake of food during traditionally timed meals also influences how the body handles therapeutic drugs. It is becoming clear that to maximize efficacy and minimize the toxicity of drugs, the circadian phase of administration must be considered. Appropriate circadian timing of the administration of multiple drugs can be a daunting challenge to infirmed individuals or their caretakers. The development of small implanted programmable pumps that can be directed to administer anticancer drugs or other therapeutics at particular times of day may provide a limited solution to this challenge. The emergence

of the field of chronotherapy reflects our increased understanding of the circadian system's impact on pharmacologic treatment efficacy.

34

Contributions from the Behavioral and Social Sciences

The underpinnings of psychiatry span many disciplines. The previous chapter covered the neuroscience foundations of psychiatry. However, there are also contributions from the psychosocial sciences, the sociocultural sciences, and many more areas of scientific pursuit. Also, many theories and models of the mind have grown from the psychoanalytic and other theoretical schools that have had a vital influence on the practice of psychiatry, both historically and currently.

This chapter provides a brief tour through some of the significant fields that, along with the neurosciences, have helped psychiatry to grow from a purely empirical practice into a robust and evidence-based branch of medicine. Along the way, it also provides some brief biographies of some of the greatest thinkers and researchers in these fields.

34.1 Contributions from the Psychosocial Sciences

JEAN PIAGET AND COGNITIVE DEVELOPMENT

Jean Piaget (1896–1980) is considered one of the greatest thinkers of the 20th century. His contributions to the understanding of cognitive development had a paradigmatic influence in developmental psychology and had significant implications for interventions with children, both educational and clinical.

Piaget was born in Neuchatel, Switzerland, where he studied at the university and received a doctorate in biology at 22. Interested in psychology, he studied and researched several centers, including the Sorbonne in Paris, and he worked with Eugen Bleuler at the Burghöltzli Psychiatric Hospital.

Piaget created a broad theoretical system for the development of cognitive abilities; in this sense, his work was similar to that of Sigmund Freud, but Piaget emphasized how children think and acquire knowledge.

Widely renowned as a child (or developmental) psychologist, Piaget referred to himself primarily as a *genetic epistemologist;* he defined genetic epistemology as the study of the development of abstract thought based on a biologic or innate substrate. That self-designation reveals that Piaget's central project was more than articulating *developmental child psychology*, as this term is generally understood; it was an account of the progressive development of human knowledge.

Cognitive Development Stages

According to Piaget, the following four major stages lead to the capacity for adult thought (Table 34-1): (1) sensorimotor, (2) preoperational thought, (3) concrete operations, and (4) formal operations. Each stage is a prerequisite for the following one, but the rate at which different children move through different stages varies with their native endowment and environmental circumstances.

Sensorimotor Stage (Birth to 2 Years). Piaget used the term *sensorimotor* to describe the first stage: infants begin to learn through sensory observation, and they gain control of their motor functions through activity, exploration, and manipulation of the environment. Piaget divided this stage into six substages, listed in Table 34-2.

From the outset, biology and experience blend to produce learned behavior. For example, infants are born with a sucking reflex, but a type of learning occurs when infants discover the location of the nipple and alter the shape of their mouths. A stimulus is received, and a response results, accompanied by a sense of awareness that is the first schema, or elementary concept. As infants become increasingly mobile, one schema is built on another, and new and more complex schemata are developed. Infants' spatial,

visual, and tactile worlds expand during this period; children interact actively with the environment and use previously learned behavior patterns. For example, having learned to use a rattle, infants shake a new toy as they did the rattle they had already learned to use. Infants also use a rattle in new ways.

The critical achievement of this period is the development of *object permanence* or the *schema of the permanent object.* This phrase relates to a child's ability to understand that objects have an existence independent of their involvement. Infants learn to differentiate themselves from the world and maintain a mental image of an object, even when it is not visible. When an object is dropped in front of infants, they look down to the ground to search for the object; that is, they behave for the first time as though they have a reality outside themselves.

At about 18 months, infants begin to develop mental symbols and to use words, a process known as *symbolization.* Infants can create a visual image of a ball or a mental symbol of the word *ball* to stand for, or signify, the real object. Such mental representations allow children to operate on new conceptual levels. The attainment of object permanence marks the transition from the sensorimotor stage to the preoperational stage of development.

Stage of Preoperational Thought (2 to 7 Years). During the stage of preoperational thought, children use symbols and language more extensively than in the sensorimotor stage. Thinking and reasoning are intuitive; children learn without the use of reasoning. They cannot think logically or deductively, and their concepts are primitive; they can name objects but not classes of objects. Preoperational thought is midway between socialized adult thought and the completely autistic Freudian unconscious. Events are not linked by logic. Early in this stage, if children drop a glass that breaks, they have no sense of cause and effect. They believe that the glass was ready to break, not that they broke the glass. Children in this stage cannot grasp the sameness of an object in different circumstances: the same doll in a carriage, a crib, or a chair is perceived to be three different objects. During this time, things are represented in terms of their function. For example, a child defines a bike as "to ride" and a hole as "to dig."

Table 34-1

Stages of Intellectual Development Postulated by Piaget

Age (yr)	Period	Cognitive Developmental Characteristics
0–1.5 (to 2)	Sensorimotor	Divided into six stages, characterized by: 1. Inborn motor and sensory reflexes 2. Primary circular reaction 3. Secondary circular reaction 4. Use of familiar means to obtain ends 5. Tertiary circular reaction and discovery through active experimentation 6. Insight and object permanence
2–7	Preoperations subperiod[a]	Deferred imitation, symbolic play, graphic imagery (drawing), mental imagery, and language
7–11	Concrete operations	Conservation of quantity, weight, volume, length, and time based on reversibility by inversion or reciprocity; operations; class inclusion and seriation
11–end of adolescence	Formal operations	Combinatorial system, whereby variables are isolated and all possible combinations are examined; hypotheticodeductive thinking

[a]This subperiod is considered by some authors to be a separate developmental period.

In this stage, children begin to use language and drawings in more elaborate ways. From one-word utterances, two-word phrases develop, made up of either a noun and a verb or a noun and an objective. A child may say, “Bobby eat,” or “Bobby up.”

Table 34-2
Piaget’s Sensorimotor Period of Cognitive Development

Age	Characteristics
Birth–2 mo	Uses inborn motor and sensory reflexes (sucking, grasping, looking) to interact and accommodate to the external world
2–5 mo	Primary circular reaction: Coordinates activities of own body and five senses (e.g., sucking thumb); reality remains subjective—does not seek stimuli outside of its visual field; displays curiosity
5–9 mo	Secondary circular reaction: Seeks out new stimuli in the environment; starts both to anticipate consequences of own behavior and to act purposefully to change the environment; beginning of intentional behavior
9 mo–1 yr	Shows preliminary signs of object permanence; has a vague concept that objects exist apart from itself; plays peek-a-boo; imitates novel behaviors
1 yr–18 mo	Tertiary circular reaction: Seeks out new experiences; produces novel behaviors
18 mo–2 yr	Symbolic thought: Uses symbolic representations of events and objects; shows signs of reasoning (e.g., uses one toy to reach for and get another); attains object permanence

Children in the preoperational stage cannot deal with moral dilemmas,

although they feel good and bad. For example, when asked, “Who is more guilty, the person who breaks one dish on purpose or the person who breaks ten dishes by accident?” a young child usually answers that the person who breaks ten dishes by accident is more guilty because more dishes are broken. Children in this stage have a sense of *immanent justice;* the belief that punishment for bad deeds is inevitable.

Children in this developmental stage are *egocentric:* they see themselves as the center of the universe; they have a limited point of view, and they cannot take the role of another person. Children cannot modify their behavior for someone else; for example, children are not negativistic when they do not listen to a command to be quiet because their brother has to study. Instead, egocentric thinking prevents an understanding of their brother’s point of view.

During this stage, children also use magical thinking, called *phenomenalistic causality,* in which events that occur together are thought to cause one another (e.g., thunder causes lightning, and bad thoughts cause accidents). Also, children use *animistic thinking,* which is the tendency to endow physical events and objects with life-like psychological attributes, such as feelings and intentions.

SEMIOTIC FUNCTION. The semiotic function emerges during the preoperational period. With this new ability, children can represent something—such as an object, an event, or a conceptual scheme—with a signifier, representing a representative function (e.g., language, mental image, symbolic gesture). That is, children use a symbol or sign to stand for something else. Drawing is a semiotic function initially done as a playful exercise but eventually signifying something else in the real world.

Stage of Concrete Operations (7 to 11 Years). The stage of concrete operations is so named because, in this period, children operate and act on the concrete, real, and perceivable world of objects and events. Egocentric thought is replaced by *operational thought,* which involves dealing with a wide array of information outside the child. Therefore, children can now see things from someone else’s perspective.

Children in this stage begin to use limited logical thought processes and can serialize, order, and group things into classes based on common

characteristics. *Syllogistic reasoning,* in which a logical conclusion is formed from two premises, appears during this stage; for example, all horses are mammals (premise); all mammals are warm-blooded (premise); therefore, all horses are warm-blooded (conclusion). Children can reason and follow the rules and regulations. They can regulate themselves, and they begin to develop a moral sense and a code of values.

Children who become overly invested in rules may show obsessive-compulsive behavior; children who resist a code of values often seem willful and reactive. The most desirable developmental outcome in this stage is that a child attains healthy respect for rules and understands that there are legitimate exceptions to rules.

Conservation is the ability to recognize that, although the shape of objects may change, the objects still maintain or conserve other characteristics that enable them to be recognized as the same. For example, if a ball of clay is rolled into a long, thin sausage shape, children recognize that each form contains the same amount of clay. An inability to conserve (which is characteristic of the preoperational stage) is observed when a child believes there is more clay in the sausage-shaped piece because it is longer. *Reversibility* is the capacity to understand the relation between things and realize that one thing can turn into another and back again—for example, ice and water.

The most critical sign that children are still in the preoperational stage is that they have not achieved conservation or reversibility. The ability of children to understand concepts of quantity is one of Piaget's most influential cognitive developmental theories. Measures of quantity include measures of substance, length, number, liquids, and area (Fig. 34-1).

The 7- to 11-year-old child must organize and order occurrences in the real world. Dealing with the future and its possibilities occur in the formal operational stage.

Stage of Formal Operations (11 through the End of Adolescence). The stage of formal operations is so named because young persons' thinking operates in a formal, highly logical, systematic, and symbolic manner. This stage is characterized by the ability to think abstractly, to reason deductively, and to define concepts, and also by the emergence of skills for dealing with permutations and combinations; young persons can grasp the concept of

probabilities. Adolescents attempt to deal with all possible relations and hypotheses to explain data and events during this stage. Language use is complex; it follows formal rules of logic and is grammatically correct. Abstract thinking is shown by adolescents' interest in various issues—philosophy, religion, ethics, and politics.

HYPOTHETICODEDUCTIVE THINKING. Hypotheticodeductive thinking, the highest organization of cognition, enables persons to make a hypothesis or proposition and to test it against reality. *Deductive reasoning* moves from the general to the particular and is a more complicated process than *inductive reasoning,* which moves from the particular to the general.

Because young persons can reflect on their own and other persons' thinking, they are susceptible to self-conscious behavior. As adolescents attempt to master new cognitive tasks, they may return to egocentric thought, but on a higher level than in the past. For example, adolescents may think that they can accomplish everything or can change events by thought alone. Not all adolescents enter the stage of formal operations at the same time or to the same degree. Depending on individual capacity and intervening experience, some may not reach the stage of formal operational thought at all and may remain in the concrete operational mode throughout life.

Psychiatric Applications

Piaget's theories have many psychiatric implications. Hospitalized children in the sensorimotor stage have not achieved object permanence and, therefore, have separation anxiety. They do best if their mothers are allowed to stay with them overnight. Children at the preoperational stage, who cannot deal with concepts and abstractions, benefit more from role-playing proposed medical procedures and situations than by having them described in detail. For example, a child who receives intravenous therapy is helped by acting out the procedure with a toy intravenous set and dolls.

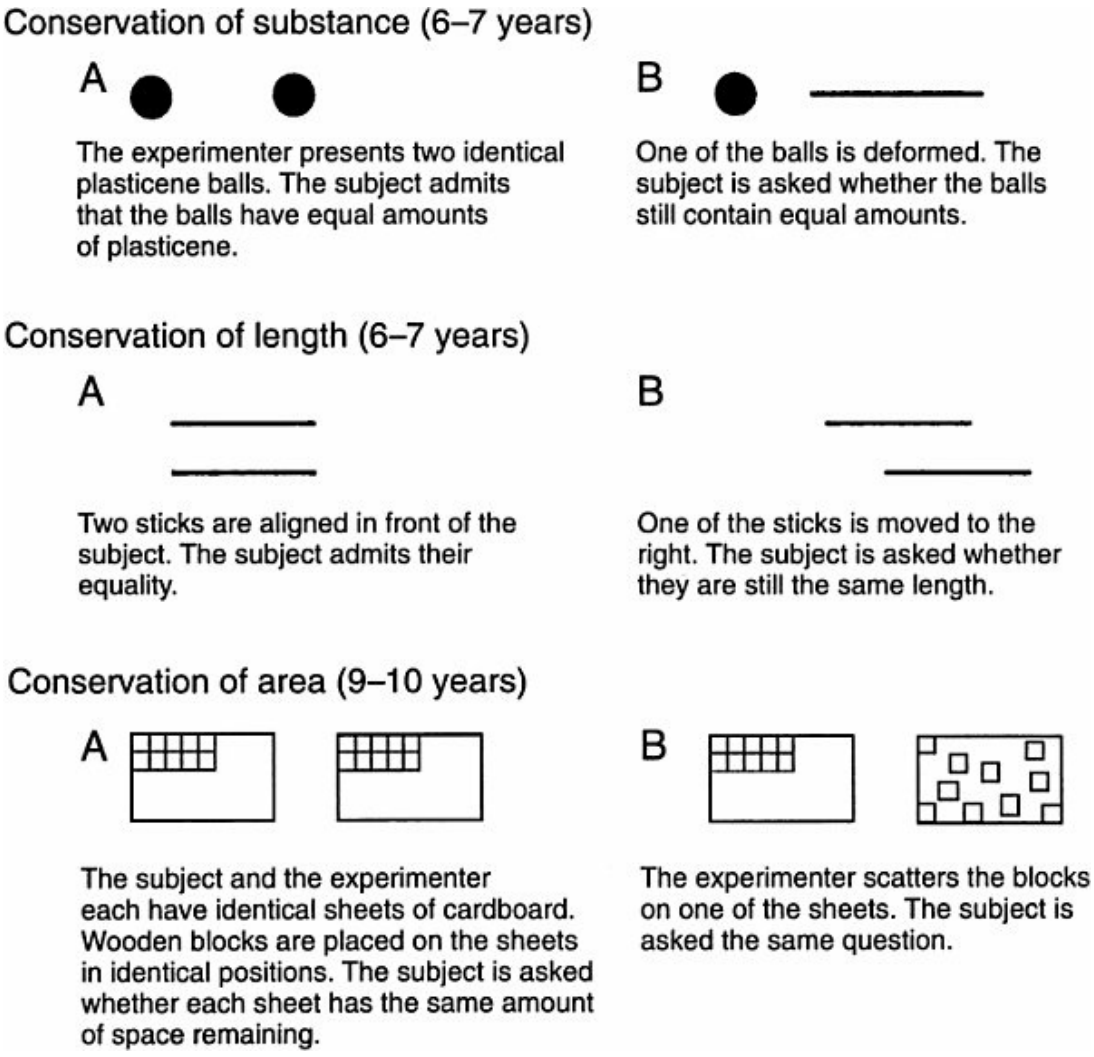

FIGURE 34-1
Some simple tests for conservation, with approximate ages of attainment. When the sense of conservation is achieved, the child answers that **B** contains the same quantity as **A**. (Modified from Lefrancois GR. *Of Children: An Introduction to Child Development*. Belmont, CA: Wadsworth; 1973:305, with permission.)

Because children at the preoperational stage do not understand cause and effect, they may interpret physical illness as punishment for bad thoughts or deeds. Because they have not yet mastered the capacity to conserve and do not understand the concept of reversibility (which usually occurs during the concrete operational stage), they cannot understand that a broken bone mends or that blood loss in an accident can be replaced.

Adolescents' thinking, during the stage of formal operations, may appear overly abstract when it is, in fact, a normal developmental stage. Adolescent turmoil may not herald a psychotic process but may well result from a typical

adolescent's coming to grips with newly acquired abilities to deal with the unlimited possibilities of the surrounding world.

Adults under stress may regress cognitively as well as emotionally. Their thinking can become preoperational, egocentric, and sometimes animistic.

Implications for Psychotherapy. Piaget was not an applied psychologist and did not develop the implications of his cognitive model for psychotherapeutic intervention. Nevertheless, his work formed one of the foundations of the *cognitive revolution* in psychology. One aspect of this revolution was an increasing emphasis on the cognitive components of the therapeutic endeavor. In contrast to classical psychodynamic therapy, which focused primarily on drives and affects, and in contrast to behavior therapy, which focused on overt actions, cognitive approaches to therapy focused on thoughts, including automatic assumptions, beliefs, plans, and intentions. By including "theory theory" and "script theory," we can see additional applications to psychotherapy.

Cognitive development theory has influenced psychotherapeutic approaches in multiple ways. Some therapists have taken developmental notions from Piaget's work and developed intervention techniques. Others have developed cognitive models of treatment independent of Piaget but with heavy reliance on cognition. Others have included Piaget's concepts in a broader set of constructs to undergird new developmental approaches to psychotherapy.

First, some psychotherapists applied Piagetian notions directly to child interventions. Susan Harter, for example, discussed techniques for helping young children become aware of divergent or contradictory emotions and to integrate these complex emotions within a more abstract or higher class of emotions. One of Harter's techniques is to ask the young child to make a drawing that shows different and conflicting feelings in one person. This technique represents an application of the concrete operation of class inclusion to the realm of the emotions. Harter's work applied Piagetian findings to the common therapeutic problem of helping children to recognize, tolerate, and integrate mixed or ambivalent affects within stable object relations.

As such, it drew on cognitive theory and psychodynamic theory. Similar techniques are important in work with children who have been exposed to

trauma or sexual abuse. It is an essential component of such work to assist them in labeling, differentiating, and accepting the full range of emotions stemming from these experiences.

Second, other psychotherapists developed treatment models that, although not directly dependent on Piagetian psychology, emphasized core ideas quite similar to those Piaget discovered in his naturalistic observations of cognitive development. These models are even more closely aligned with recent developments in "theory theory." Aaron Beck, for example, developed an entire school of cognitive therapy that focuses on the role of cognitions in causing or maintaining psychopathology. Cognitive therapy is an effective treatment for problems as diverse as depression, anxiety disorders, and substance use disorders.

A core idea in cognitive therapy is that the patient has developed certain core beliefs, aspects of the self-schema, and conditional probability beliefs as a result of developmental experiences, and these contribute to emotional or behavioral problems. For example, depressed persons may have the core belief, "I am unlovable." Addicted persons may have the belief, "Unless I drink, I cannot feel happy." In cognitive therapy, the person can be assisted in identifying the negative automatic thoughts and underlying dysfunctional attitudes or beliefs that contribute to emotional distress or addictive behavior. The critical therapeutic process after identification of the maladaptive thoughts is to help the patient view these thoughts more objectively, not unquestioningly take them as veridical. Here, cognitive therapy emphasizes evidence, consistent both with Piagetian theory and "theory theory." The patient is assisted in seeking out evidence to test negative thinking; active involvement, rather than passive listening, is required.

What the cognitive therapist accomplishes through such techniques as Socratic questioning and asking if there are other ways to look at the same event is similar to what the talented teacher does in guiding children to a more adequate, more intelligent understanding of operational tasks. The notion of equilibration is relevant in both instances. By helping the individual see that previous cognitive structures are inadequate, the therapist or teacher disturbs the old cognitive structure, and the patient or student experiences a disruption that leads to the search for more-adequate structures. The compensation for external disturbance is what Piaget termed *equilibration.* New structures can be constructed only through a process of accommodation,

enabling the subject to assimilate a more comprehensive array of data, a new perspective, or more complex information.

Because it requires *thinking about thinking*, cognitive therapy seems to require formal operational thinking, although this has not been empirically tested. At the least, it requires the ability to recognize and articulate affects, to recognize and label events that give rise to affects, and to translate into thought the mediating process that occurs rapidly between the event and the affect. Cognitive-behavioral models of psychotherapy include cognitive techniques and more behavioral, interactive techniques, such as increasing pleasant activities and improving communication and problem-solving skills. It is possible that the less-cognitive, more-behavioral techniques, although requiring a lower level of cognitive development, can also lead to the garnering of evidence and modification of specific expectancies, attributions, and self-schemata.

Because "script theory" or narrative approaches to cognition in psychotherapy are empirically based, generated by repetitive experiences rather than by reflective abstraction, and domain-specific, they may have even more general application to psychotherapy than classic Piagetian theories or "theory theory." For example, in dialectical behavior therapy, patients provide a "chain analysis" of events, feelings, thoughts, situational stimuli, and interpersonal factors that led to negative or self-damaging behavior. This narrative provides guidance to the patient and the therapist about where and how to intervene to prevent similar behavior.

Developmentally Based Psychotherapy. Developmentally based psychotherapy, developed by Stanley Greenspan, M.D., integrates cognitive, affective, drive, and relationship-based approaches with a new understanding of the stages of human development. The clinician first determines the level of the patient's ego or personality development and the presence or absence of deficits or constrictions. For example, can the person regulate activity and sensations, relate to others, read nonverbal affective symbols, represent experience, build bridges between representations, integrate emotional polarities, abstract feelings, and reflect on internal wishes and feelings?

From a developmental point of view, the integral parts of the therapeutic process include learning how to regulate experience; to engage more fully and deeply in relationships; to perceive, comprehend, and respond to

complex behaviors and interactive patterns; and to be able to engage in the ever-changing opportunities, tasks, and challenges during life (e.g., adulthood and aging) and, throughout, to observe and reflect on one's own and others' experiences. These processes are the foundation of the ego, and more broadly, the personality. Their presence constitutes emotional health and their absence, emotional disorder. The developmental approach describes how to harness these core processes and assist the patients in mobilizing their growth.

ATTACHMENT THEORY

Attachment and Development

Attachment can be defined as the emotional tone between children and their caregivers and is evidenced by an infant's seeking and clinging to the caregiving person, usually the mother. By their first month, infants usually have begun to show such behavior, designed to promote proximity to the desired person.

Attachment theory originated in the work of John Bowlby, a British psychoanalyst (1907–1990). In his studies of infant attachment and separation, Bowlby pointed out that attachment constituted a central motivational force and that mother–child attachment was an essential medium of human interaction that had significant consequences for later development and personality functioning. Being monotropic, infants tend to attach to one person; but they can form attachments to several persons, such as the father or a surrogate. Attachment develops gradually; it results in an infant's wanting to be with a preferred person, who is perceived as stronger, wiser, and able to reduce anxiety or distress. Attachment thus gives infants feelings of security. The interaction between mother and infant facilitates the process; the amount of time together is less critical than the activity between the two.

The term *bonding* is sometimes used synonymously with attachment, but the two are different phenomena. Bonding concerns the mother's feelings for her infant and differs from attachment. Mothers generally do not rely on their infants as a source of security, as is the case in attachment behavior. Much research reveals that the bonding of mother to infant occurs when there is

skin-to-skin contact between the two or when other types of contact, such as voice and eye contact, are made. Some workers have concluded that a mother who has skin-to-skin contact with her baby immediately after birth shows a stronger bonding pattern and may provide more attentive care than a mother who does not have this experience. Some researchers have even proposed a critical period immediately after birth, during which such skin-to-skin contact must occur if bonding is to occur. This concept is much disputed: many mothers are bonded to their infants and display excellent maternal care even though they did not have skin-to-skin contact immediately postpartum. Because human beings can develop representational models of their babies in utero and even before conception, this representational thinking may be as crucial to the bonding process as skin, voice, or eye contact.

Ethologic Studies. Bowlby suggested a Darwinian evolutionary basis for attachment behavior; namely, such behavior ensures that adults protect their young. Ethologic studies show that nonhuman primates and other animals exhibit attachment behavior patterns that are presumably instinctual and are governed by inborn tendencies. An example of an instinctual attachment system is *imprinting*. Certain stimuli can elicit innate behavior patterns during the first few hours of an animal's behavioral development; thus, the animal offspring becomes attached to its mother at a critical period early in its development. A similar sensitive or critical period during which attachment occurs has been postulated for human infants. The presence of imprinting behavior in humans is highly controversial, but bonding and attachment behavior during the first year of life closely approximate the critical period; in humans, however, this period occurs over years rather than hours.

HARRY HARLOW. Harry Harlow's work with monkeys is relevant to attachment theory. Harlow demonstrated the emotional and behavioral effects of isolating monkeys from birth and keeping them from forming attachments. The isolates were withdrawn, unable to relate to peers, unable to mate, and incapable of caring for their offspring.

Phases of Attachment

In the first attachment phase, sometimes called the *preattachment stage* (birth

to 8 or 12 weeks), babies orient to their mothers, follow them with their eyes over a 180-degree range, and turn toward and move rhythmically with their mother's voice. In the second phase, sometimes called *attachment in the making* (8 to 12 weeks to 6 months), infants become attached to one or more persons in the environment. In the third phase, sometimes called *clear-cut attachment* (6 through 24 months), infants cry and show other signs of distress when separated from the caretaker or mother; this phase can occur as early as 3 months in some infants. On being returned to the mother, the infant stops crying and clings to gain further assurance of the mother's return. Sometimes, seeing the mother after a separation is sufficient for crying to stop. In the fourth phase (25 months and beyond), the mother figure is seen as independent, and a more complex relationship between the mother and the child develops. Table 34-3 summarizes the development of standard attachment from birth through 3 years.

Mary Ainsworth. Mary Ainsworth (1913–1999) was a Canadian developmental psychologist from the University of Toronto. She described three main types of insecure attachment: insecure-avoidant, insecure-ambivalent, and insecure-disorganized. The insecure-avoidant child, having experienced brusque or aggressive parenting, tends to avoid close contact with people and lingers near caregivers rather than approaching them directly when faced with a threat. The insecure-ambivalent child finds exploratory play difficult, even in the absence of danger, and clings to his or her inconsistent parents. Insecure-disorganized children have parents who are emotionally absent with a parental history of abuse in their childhood. These children tend to behave in bizarre ways when threatened. According to Ainsworth, disorganization is a severe form of insecure attachment and a possible precursor of severe personality disorder and dissociative phenomena in adolescence and early adulthood.

Table 34-3
Normal Attachment

Birth to 30 days
Reflexes at birth
Rooting

- Head turning
- Sucking
- Swallowing
- Hand-mouth
- Grasp
- Digital extension
- Crying—signal for particular kind of distress
- Responsiveness and orientation to mother's face, eyes, and voice
- 4 days—anticipatory approach behavior at feeding
- 3–4 wk—infant smiles preferentially to mother's voice

Age 30 days through 3 mo
- Vocalization and gaze reciprocity further elaborated from 1 to 3 mo; babbling at 2 mo, more with the mother than with a stranger
- Social smile
- In strange situation, increased clinging response to mother

Age 4 through 6 mo
- Briefly soothed and comforted by sound of mother's voice
- Spontaneous, voluntary reaching for mother
- Anticipatory posturing to be picked up
- Differential preference for mother intensifies
- Subtle integration of responses to mother

Age 7 through 9 mo
- Attachment behaviors further differentiated and focused specifically on mother
- Separation distress, stranger distress, strange-place distress

Age 10 through 15 mo
- Crawls or walks toward mother
- Subtle facial expressions (coyness, attentiveness)
- Responsive dialogue with mother clearly established
- Early imitation of mother (vocal inflections, facial expression)
- More fully developed separation distress and mother preference
- Pointing gesture
- Walking to and from mother
- Affectively positive reunion responses to mother after separation

or, paradoxically, short-lived, active avoidance or delayed protest
Age 16 mo through 2 yr
Involvement in imitative jargon with mother (12–14 mo)
Head-shaking “no” (15–16 mo)
Transitional object used during the absence of mother
Separation anxiety diminishes
Mastery of strange situations and persons when mother is near
Evidence of delayed imitation
Object permanence
Microcosmic symbolic play
Age 25 mo through 3 yr
Able to tolerate separations from mother without distress when familiar with surroundings and given reassurances about mother’s return
Two- and three-word speech
Stranger anxiety much reduced
Object consistency achieved—maintains composure and psychosocial functioning without regression in absence of mother
Microcosmic play and social play; cooperation with others begins

Based on material by Justin Call, M.D.

Mary Ainsworth expanded on Bowlby’s observations and found that the interaction between the mother and her baby during the attachment period significantly influences the baby’s current and future behavior. Patterns of attachments vary among babies; for example, some babies signal or cry less than others. Sensitive responsiveness to infant signals, such as cuddling a crying baby, causes infants to cry less in later months, rather than reinforcing crying behavior. Close bodily contact with the mother when the baby signals for her is also associated with the growth of self-reliance, rather than a clinging dependence, as the baby grows older. Unresponsive mothers produce anxious babies; these mothers often have lower intelligence quotients (IQs) and are emotionally more immature and younger than responsive mothers.

Table 34-4
The Strange Situation

Episode[a]	Persons Present	Change
1	Parent, infant	Enter room
2	Parent, infant, stranger	Unfamiliar adult joins the dyad
3	Infant, stranger	Parent leaves
4	Parent, infant	Parent returns, stranger leaves
5	Infant	Parent leaves
6	Infant, stranger	Stranger returns
7	Parent, infant	Parent returns, stranger leaves

[a]All episodes are usually 3 minutes long, but episodes 3, 5, and 6 can be curtailed if the infant becomes too distressed, and episodes 4 and 7 are sometimes extended.

Reprinted from Lamb ME, Nash A, Teti DM, Bornstein MH. Infancy. In: Lewis M, ed. *Child and Adolescent Psychiatry: A Comprehensive Textbook*. 2nd ed. Philadelphia, PA: Williams & Wilkins; 1996:256, with permission.

Ainsworth also confirmed that attachment serves to reduce anxiety. What she called the *secure base effect* enables children to move away from attachment figures and to explore the environment. Inanimate objects, such as a teddy bear and a blanket (called the transitional object by Donald Winnicott), also serve as a secure base, one that often accompanies them as they investigate the world.

STRANGE SITUATION. Ainsworth developed the strange situation, the research protocol for assessing the quality and security of an infant's attachment. In this procedure, the infant is exposed to escalating amounts of stress; for example, the infant and the parent enter an unfamiliar room, an unfamiliar adult then enters the room, and the parent leaves the room. The protocol has seven steps (Table 34-4). According to Ainsworth's studies, about 65 percent of infants are securely attached by 24 months.

Anxiety

Bowlby's theory of anxiety holds that a child's sense of distress during separation is perceived and experienced as anxiety and is the prototype of anxiety. Any stimuli that alarm children and cause fear (e.g., loud noises, falling, and cold blasts of air) mobilize signal indicators (e.g., crying) that cause the mother to respond in a caring way by cuddling and reassuring the child. The mother's ability to relieve the infant's anxiety or fear is fundamental to the growth of attachment in the infant. When the mother is close to the child, and the child experiences no fear, the child gains a sense of security, the opposite of anxiety. When the mother is unavailable to the infant because of physical absence (e.g., if the mother is in prison) or because of psychological impairment (e.g., severe depression), anxiety develops in the infant.

Separation anxiety is the response of a child who is isolated or separated from its mother or caretaker. It is most common at 10 to 18 months of age and generally disappears by the end of the third year. It is usually expressed with tearfulness or irritability. Somewhat earlier (at about 8 months), stranger anxiety is an anxiety response to someone other than the caregiver appears.

Signal Indicators. Signal indicators are infants' signs of distress that prompt or elicit a behavioral response in the mother. The primary signal is crying. The three types of signal indicators are hunger (the most common), anger, and pain. Some mothers can distinguish between them, but most mothers generalize the hunger cry to represent distress from pain, frustration, or anger. Other signal indicators that reinforce attachment are smiling, cooing, and looking. The sound of an adult human voice can prompt these indicators.

Losing Attachments. Persons' reactions to the death of a parent or a spouse can be traced to the nature of their past and present attachment to the lost figure. An absence of demonstrable grief may be owing to real experiences of rejection and the lack of closeness in the relationship. The person may even consciously offer an idealized picture of the deceased. Persons who show no grief usually try to present themselves as independent and disinterested in closeness and attachment.

Sometimes, however, the severing of attachments is traumatic. The death of a parent or a spouse can precipitate a depressive disorder, and even

suicide, in some persons. The death of a spouse increases the chance that the surviving spouse will experience a physical or mental disorder during the next year. The onset of depression and other dysphoric states often involves rejection by a significant figure in a person's life.

Disorders of Attachment

Attachment disorders are characterized by biopsychosocial pathology that results from maternal deprivation, a lack of care by, and interaction with, the mother or caregiver. Failure-to-thrive syndromes, psychosocial dwarfism, separation anxiety disorder, avoidant personality disorder, depressive disorders, delinquency, academic problems, and borderline intelligence have been traced to negative attachment experiences. When maternal care is deficient because (1) a mother is mentally ill, (2) a child is institutionalized for a long time, or (3) the primary object of attachment dies, children sustain emotional damage. Bowlby initially thought that the damage was permanent and invariable. However, he revised his theories to consider the time at which the separation occurred, the type and degree of separation, and the level of security that the child experienced before the separation.

Bowlby described a predictable set and sequence of behavior patterns in children who are separated from their mothers for extended periods (more than 3 months): protest, in which the child protests the separation by crying, calling out, and searching for the lost person; despair, in which the child appears to lose hope that the mother will return; and detachment, in which the child emotionally separates him- or herself from the mother. Bowlby believed that this sequence involves ambivalent feelings toward the mother; the child both wants her and is angry with her for her desertion.

Children in the detachment stage respond indifferently when the mother returns; the mother has not been forgotten, but the child is angry at her for having gone away in the first place and fears that she will go away again. Some children have affectionless personalities characterized by emotional withdrawal, little or no feeling, and a limited ability to form affectionate relationships.

Anaclitic Depression. Anaclitic depression, also known as hospitalism, was first described by René Spitz in infants who had made normal

attachments but were suddenly separated from their mothers for varying times and placed in institutions or hospitals. The children became depressed, withdrawn, nonresponsive, and vulnerable to physical illness, but they recovered when their mothers returned, or surrogate mothering was available.

Child Maltreatment

Abused children often maintain their attachments to abusive parents. Studies of dogs have shown that severe punishment and maltreatment increase attachment behavior. When children are hungry, sick, or in pain, they too show clinging attachment behavior. Similarly, when children are rejected by their parents or are afraid of them, their attachment may increase; some children want to remain with an abusive parent. Nevertheless, when a choice must be made between a punishing and a nonpunishing figure, the nonpunishing person is the preferable choice, especially if they are sensitive to the child's needs.

Psychiatric Applications

The applications of attachment theory in psychotherapy are numerous. When a patient can attach to a therapist, a secure base effect is seen. The patient may then be able to take risks, mask anxiety, and practice new patterns of behavior that otherwise might not have been attempted. Patients whose impairments can be traced to never having made an attachment in early life may do so for the first time in therapy, with salutary effects.

Patients whose pathology stems from exaggerated early attachments may attempt to replicate them in therapy. Therapists must enable such patients to recognize the ways their early experiences have interfered with their ability to achieve independence.

For patients who are children and whose attachment difficulties may be more apparent than those of adults, therapists represent consistent and trusted figures who can engender a sense of warmth and self-esteem in children, often for the first time.

Relationship Disorders. A person's psychological health and sense of well-being depend significantly on the quality of his or her relationships and attachment to others, and a core issue in all close personal relationships is

establishing and regulating that connection. In a typical attachment interaction, one person seeks more proximity and affection, and the other either reciprocates, rejects, or disqualifies the request. A pattern is shaped through repeated exchanges. Distinct attachment styles have been observed. Adults with an anxious-ambivalent attachment style tend to be obsessed with romantic partners, suffer from extreme jealousy, and have a high divorce rate. Persons with an avoidant attachment style are relatively uninvested in close relationships, although they often feel lonely. They seem afraid of intimacy and tend to withdraw when there is stress or conflict in the relationship. Break-up rates are high. Persons with a secure attachment style are highly invested in relationships and tend to behave without much possessiveness or fear of rejection.

LEARNING THEORY

Learning is defined as a change in behavior resulting from repeated practice. The principles of learning are always operating and always influencing human activity. Learning principles are often deeply involved in the etiology and maintenance of psychiatric disorders because so much of human behavior (including overt behavior, thought patterns, and emotion) is acquired through learning. Learning processes also strongly influence psychotherapy because human behavior changes. Thus, learning principles can influence the effectiveness of therapy. No method of therapy can be said to be immune to the effects of learning. Even the simple prescription of medication can bring learning processes into play because the patient will have opportunities to learn about the drug's effects and side effects, will need to learn to adhere to the instructions and directions for taking it, and will need to learn to overcome any resistance to adherence.

Basic Concepts and Considerations

A great deal of modern research on learning still focuses on Pavlovian (classical) and operant learning. Pavlovian conditioning, developed by Ivan Petrovich Pavlov (1849–1936), occurs when neutral stimuli are associated with a psychologically significant event. The main result is that the stimuli come to evoke a set of responses or emotions that may contribute to many clinical disorders, including (but not limited to) anxiety disorders and drug

dependence. The events in Pavlov's experiment are often described using terms designed to make the experiment applicable to any situation. The food is the unconditional stimulus (*US*) because it unconditionally elicits salivation before the experiment begins. The bell is the conditional stimulus (*CS*) because it only elicits the salivary response conditional on the bell–food pairings. The new response to the bell is correspondingly called the conditional response (*CR*), and the natural response to the food itself is the unconditional response (*UR*). Modern laboratory studies of conditioning use an extensive range of CSs and USs and measure a wide range of conditioned responses.

Operant conditioning, developed by B.F. Skinner (1904–1990), occurs when a behavior (instead of a stimulus) is associated with a psychologically significant event. In the laboratory, the most famous experimental arrangement is when a rat presses a lever to earn food pellets. In this case, as opposed to Pavlov's, the behavior is an operant because it operates on the environment. The food pellet is a reinforcer—an event that increases the strength of the behavior of which it is made a consequence. A central idea behind this method is that the rat's behavior is "voluntary" in the sense that the animal is not compelled to make the response (it can perform it whenever it "wants" to). In this sense, it is similar to the thousands of operant behaviors that humans choose to commit—freely—in any day. Of course, the even larger idea is that even though the rat's behavior appears as though it is voluntary, it is lawfully controlled by its consequences: if the experimenter were to stop delivering the food pellet, the rat would stop pressing the lever, and if the experimenter were to allow the lever press to produce larger pellets, or perhaps pellets at a higher probability or rate, then the rate of the behavior might increase. The point of operant conditioning experiments, then, is mostly to understand the relation of behavior to its payoff.

Pavlovian and operant conditioning differ in several ways. One of the most fundamental differences is that the responses observed in Pavlov's experiment are *elicited* and thus controlled by presenting an antecedent stimulus. In contrast, the "response" observed in Skinner's experiment is not elicited or compelled by an antecedent stimulus in any obvious way—its consequences instead control it. This distinction between *operants* and *respondents* is essential in clinical settings. If a young patient is referred to the clinic for acting out in the classroom, an initial goal of the clinician will

be to determine whether the behavior is a respondent or an operant. Then the clinician will go about changing either its antecedents or its consequences, respectively, to reduce its probability of occurrence.

Despite the academic separation of operant and respondent conditioning, they have an important common function: both learning processes allow organisms to adapt to the environment. The idea is illustrated by considering the *law of effect* (Fig. 34-2), which says that whether an operant behavior increases or decreases in strength depends on the effect it has on the environment. When the action leads to a positive outcome, the action is strengthened; conversely, when the action leads to a negative outcome, we have *punishment*, and the action is weakened. Similarly, when an action decreases the probability of a positive event, behavior also declines. (Such a procedure is now widely known as a *time-out* from reinforcement.) When an action terminates or prevents the occurrence of a negative event, the behavior will strengthen. By enabling the organism to maximize its interaction with positive events and minimize its interaction with negative ones, operant conditioning allows the organism to optimize its interaction with the environment. Reward learning also provides a framework for understanding the development of somewhat maladaptive behaviors like overeating (in which behavior is reinforced by food) and drug-taking (in which the pharmacologic effects of drugs reinforce behaviors)—cases in which reward principles lead to psychopathology.

A parallel to Figure 34-2 exists in Pavlovian conditioning, in which one can likewise think of whether the CS is associated with positive or negative events (Fig. 34-3). Although such learning can lead to a vast constellation or system of behaviors, in a very general way, it also leads to behavioral tendencies of approach or withdrawal. Thus, when a CS signals a positive US, the CS will evoke approach behaviors—called *sign tracking*. For example, an organism will approach a signal for food. Analogously, when a CS signals a negative US, it will evoke behaviors that tend to move the organism away from the CS.

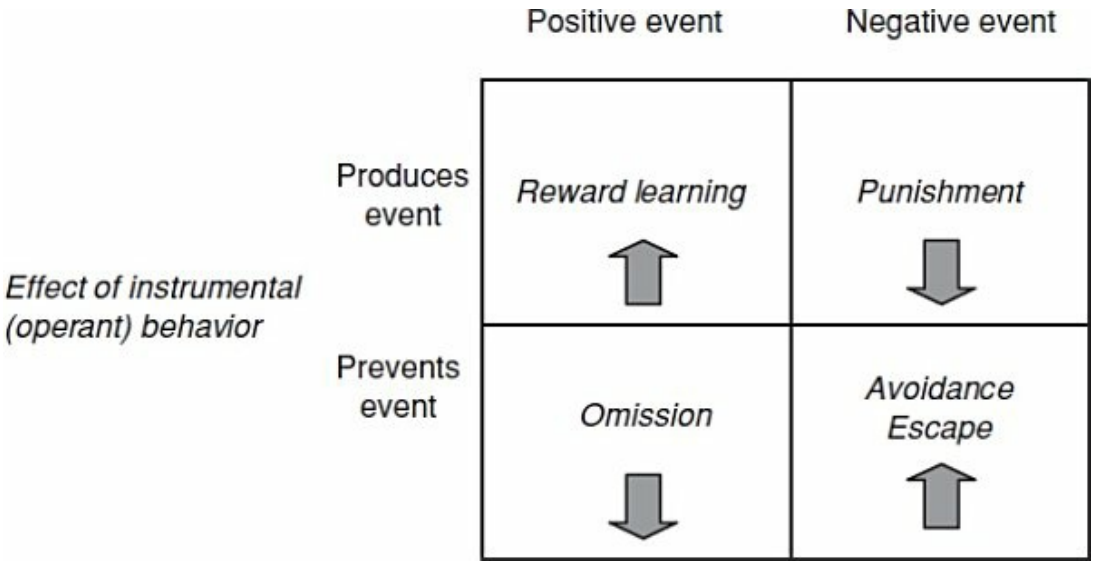

FIGURE 34-2
The law of effect in instrumental/operant learning. Actions either produce or prevent good or bad events, and the strength of the action changes accordingly (*arrow*). "Reinforcement" refers to a strengthening of behavior. *Positive reinforcement* occurs when an action produces a positive event, whereas *negative reinforcement* occurs when an action prevents or eliminates a negative event. (Courtesy of Mark E. Bouton, PhD.)

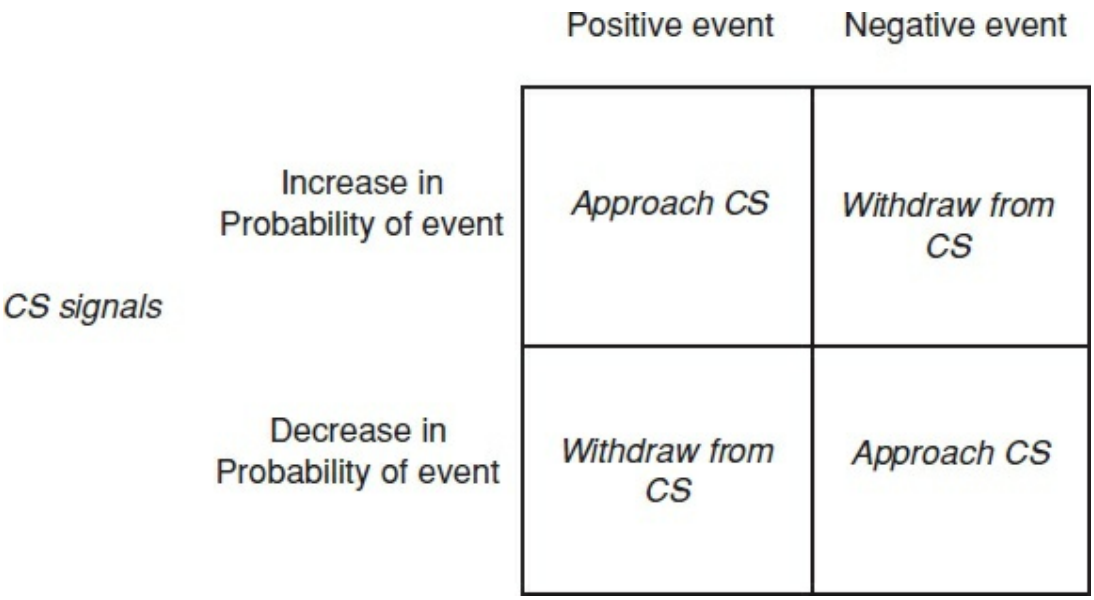

FIGURE 34-3
Sign tracking in Pavlovian learning. Conditional stimuli (CSs) signal either an increase or a decrease in the probability of good or bad events, and the CS generally engages approach or withdrawal behaviors accordingly. (Courtesy of Mark E. Bouton, PhD.)

Conversely, CSs associated with a decrease in the probability of a good

thing will elicit withdrawal behaviors, whereas CSs associated with the decrease in the probability of a bad thing can elicit an approach. An example of the latter case might be a stimulus that signals safety or decreases the probability of an aversive event, which evokes an approach in a frightened organism. In the end, these fundamental behavioral effects of both operant (see Fig. 34-2) and Pavlovian (see Fig. 34-3) learning serve to maximize the organism's contact with good things and minimize contact with bad things.

Perhaps because they have such similar functions, Pavlovian learning and operant learning are influenced by similar variables. For example, in either case, the behavior is especially strong if the magnitude of the US or reinforcer is large, or if the US or reinforcer occurs relatively close to the CS or operant response in time. In either case, the learned behavior decreases if the US or reinforcer that was once paired with the CS or the response is eliminated from the situation. This phenomenon, called *extinction*, provides a means of eliminating unwanted behaviors learned through either form of conditioning and has led to several very effective cognitive-behavioral therapies.

Pavlovian Conditioning

Effects of Conditioning on Behavior. Many laypeople have the mistaken impression that Pavlovian learning is a rigid affair in which a fixed stimulus comes to elicit a fixed response. Conditioning is considerably more complex and dynamic than that. For example, signals for food may evoke a broad set of responses that function to prepare the organism to digest food: they can elicit the secretion of gastric acid, pancreatic enzymes, and insulin along with Pavlov's famous salivary response. The CS can also elicit approach behavior (as described earlier), an increase in body temperature, and a state of arousal and excitement. When a signal for food is presented to a satiated animal or human, they may eat more food. Some of these effects may be motivational; for example, an additional effect of presenting a CS for food is that it can invigorate ongoing operant behaviors that have been reinforced with food. CSs thus have powerful behavioral potential. Signals for food evoke a whole *behavior system* that is functionally organized to find, procure, and consume food.

Pavlovian conditioning is also involved in other aspects of eating. Through

conditioning, humans and other animals may learn to like or dislike certain foods. In animals like rats, flavors associated with nutrients (sugars, starches, calories, proteins, or fats) come to be preferred. Flavors associated with sweet tastes are also preferred, whereas flavors associated with bitter tastes are avoided. At least as necessary, flavors associated with illness become disliked, as illustrated by the person who gets sick drinking an alcoholic beverage and consequently learns to hate the flavor. The fact that flavor CSs can be associated with such a range of biologic consequences (USs) is essential for omnivorous animals to learn about new foods. It also has some clinical implications. For example, chemotherapy can make cancer patients sick, causing the conditioning of an aversion to a recently eaten food (or to the clinic itself). Other evidence suggests that animals may learn to dislike food that is associated with becoming sick with cancer. On the flip side, conditioning can enable external cues to trigger food consumption and craving, potentially influencing overeating and obesity.

Pavlovian conditioning also occurs when organisms ingest drugs. Whenever a drug is taken, in addition to reinforcing the behaviors that lead to its ingestion, the drug constitutes a US and may be associated with potential CSs that are present at the time (e.g., rooms, odors, injection paraphernalia). CSs that are associated with drug USs can sometimes have an interesting property: they often elicit a conditioned response that seems opposite to the unconditional effect of the drug. For example, although morphine causes a rat to feel less pain, a CS associated with morphine elicits an opposite increase, not a decrease in pain sensitivity. Similarly, although alcohol can cause a drop in body temperature, a conditioned response to a CS associated with alcohol is typically increased in body temperature. In these cases, the conditioned response is said to be *compensatory* because it counteracts the drug effect. Compensatory responses are another example of how classical (Pavlovian) conditioning helps organisms prepare for a significant US.

Compensatory conditioned responses have implications for drug abuse. First, they can cause drug tolerance, in which repeated administration of a drug reduces its effectiveness. As a drug and a CS are repeatedly paired, the compensatory response to the CS becomes stronger and more effective at counteracting the effect of the drug. The drug, therefore, has less impact. One implication is that tolerance will be lost if the drug is taken without being signaled by the usual CS. Consistent with this idea, administering a drug in a

new environment can cause a loss of drug tolerance and make drug overdose more likely. A second implication stems from the fact that compensatory responses may be unpleasant or aversive. A CS associated with an opiate may elicit several compensatory responses—it may cause the drug user to be more sensitive to pain, change body temperature, and perhaps become hyperactive (the opposite of another unconditional opiate effect). The unpleasantness of these responses may motivate the user to retake the drug to get rid of them, an example of escape learning, or negative reinforcement, and a classic example of how Pavlovian and operant learning processes might readily interact. The idea is that the urge to take drugs may be strongest in the presence of CSs that have been associated with the drug. The hypothesis is consistent with self-reports of abusers, who, after a period of abstinence, are tempted to retake the drug when they are reexposed to drug-associated cues.

Pavlovian learning may potentially be involved in anxiety disorders. CSs associated with frightening USs can elicit a whole system of conditioned fear responses, broadly designed to help the organism cope. In animals, cues associated with frightening events (such as a brief foot shock) elicit changes in respiration, heart rate, and blood pressure, and even a (compensatory) decrease in sensitivity to pain. Brief CSs that occur close to the US in time can also elicit adaptively timed protective reflexes. For example, the rabbit blinks in response to a brief signal that predicts a mild electric shock near the eye. The same CS, when lengthened in duration and paired with the same US, elicits mainly fear responses, and fear elicited by a CS may potentiate the conditioned eyeblink response elicited by another CS or a startle response to a sudden noise. Once again, CSs do not merely elicit a simple reflex, but also evoke a complex and interactive set of responses.

Classical fear conditioning can contribute to phobias (in which specific objects may be associated with a traumatic US), as well as other anxiety disorders, such as panic disorder and posttraumatic stress disorder (PTSD). In panic disorder, people who have unexpected panic attacks can become anxious about having another one. In this case, the panic attack (the US or UR) may condition anxiety to the external situation in which it occurs (e.g., a crowded bus) and also internal (“interoceptive”) CSs created by early symptoms of the attack (e.g., dizziness or a sudden pounding of the heart). These CSs may then evoke anxiety or panic responses. Panic disorder may begin because external cues associated with panic can arouse anxiety, which

may exacerbate the next unconditional panic attack or panic response elicited by an interoceptive CS. Emotional reactions elicited by CSs may not require conscious awareness for their occurrence or development. Indeed, fear conditioning may be independent of conscious awareness.

In addition to eliciting conditioned responses, CSs also motivate ongoing operant behavior. For example, presenting a CS that elicits anxiety can increase the vigor of operant behaviors learned to avoid or escape the frightening US. Thus, an individual with an anxiety disorder will be more likely to express avoidance in the presence of anxiety or fear cues. Similar effects may occur with CSs that predict other USs (such as drugs or food)—as already mentioned. A drug-associated CS may motivate the drug abuser to take more drugs. The motivating effects of CSs may stem from the fact that CSs may be associated with both the sensory and emotional properties of USs. For example, the survivor of a traumatic train derailment might associate stimuli that occur immediately before derailment (such as the blue flash that occurs when the train separates from its overhead power supply) with both the emotional and the sensory aspects of the crash. Consequently, when the survivor later encounters another flashing blue light (e.g., the lights on a police car), the CS might evoke both emotional responses (mediated by association with the trauma's emotional qualities) and sensory associations (mediated by association with the trauma's sensory qualities). Both might play a role in the nightmares and "reexperiencing" phenomena that are characteristic of PTSD.

The Nature of the Learning Process. Research beginning in the late 1960s began to uncover some critical details about the learning process behind Pavlovian conditioning. Several findings proved especially influential. For example, it was shown that conditioning is not an inevitable consequence of pairing a CS with a US. Such pairings will not cause conditioning if there is a second CS present that already predicts the US. This finding (known as *blocking*) suggests that a CS must provide new information about the US if learning occurs. The importance of the CS's information value is also suggested by the fact that a CS will not be treated as a signal for the US if the US occurs equally often (or is equally probable) in the presence and the absence of the CS. Instead, the organism treats the CS as a signal for the US if the probability of the US is more significant in the presence of the CS than

in its absence. Also, the organism will treat the CS as a signal for “no US” if the probability of the US is less in the presence of the CS than in its absence. In the latter case, the signal is called a *conditioned inhibitor* because it will inhibit other CSs. The conditioned inhibition phenomenon is clinically relevant because inhibitory CSs may hold pathologic CRs like fear or anxiety at bay. A loss of the inhibition would allow the anxiety response to emerge.

There are also essential variants of classical conditioning. In *sensory preconditioning*, two stimuli (A and B) are first paired, and then one of them (A) is later paired with the US. Stimulus A evokes conditioned responding, of course, but so does stimulus B—indirectly, through its association with A. One implication is that exposure to a potent US like a panic attack may influence reactions to stimuli that have never been paired with the US directly; the sudden anxiety to stimulus B might seem spontaneous and mysterious. A related finding is *second-order conditioning.* Here, A is paired with a US first and then subsequently paired with stimulus B. Once again, both A and B will evoke responding. Sensory preconditioning and second-order conditioning increase the range of stimuli that can control the conditioned response. A third variant worth mentioning occurs, as indicated previously, when the onset of a stimulus becomes associated with the rest of that stimulus, as when a sudden increase in heart rate caused by the onset of a panic attack comes to predict the rest of the panic or feeling, or when the onset of a drug may predict the rest of the drug effect. Such intraevent associations may play a role in many of the body’s regulatory functions, such that an initial change in some variable (e.g., blood pressure or blood glucose level) may come to signal a further increase in that variable and therefore initiate a conditioned compensatory response.

Emotional responses can also be conditioned through observation. For example, a monkey that merely observes another monkey being frightened by a snake can learn to be afraid of the snake. The observer learns to associate the snake (CS) with its emotional reaction (US/UR) to the other monkey being afraid. Although monkeys readily learn to fear snakes, they are less likely to associate other salient cues (such as colorful flowers) with fear in the same way. This is an example of *preparedness* in classical conditioning—some stimuli are especially useful signals for some USs. Another example is that tastes are easily associated with illness but not a shock, whereas auditory and visual cues are easily associated with shock but not an illness.

Preparedness may explain why human phobias tend to be for particular objects (snakes or spiders) and not others (knives or electric sockets) that may as often be paired with pain or trauma.

Erasing Pavlovian Learning. If Pavlovian learning plays a role in the etiology of behavioral and emotional disorders, a natural question concerns how to eliminate it or undo it. Pavlov studied *extinction:* conditioned responding decreases if the CS is presented repeatedly without the US after conditioning. Extinction is based on behavioral or cognitive-behavioral therapies designed to reduce pathologic conditioned responding through repeated exposure to the CS (exposure therapy). It is presumably a consequence of any form of therapy in the course of which the patient learns that previous harmful cues are no longer harmful. Another elimination procedure is *counterconditioning,* in which the CS is paired with a very different US/UR.

Counterconditioning was the inspiration for *systematic desensitization,* a behavior therapy technique in which frightening CSs are deliberately associated with relaxation during therapy.

Although extinction and counterconditioning reduce unwanted conditioned responses, they do not destroy the original learning, which remains in the brain, ready to return to behavior under the right circumstances. For example, conditioned responses that have been eliminated by extinction or counterconditioning can recover if time passes before the CS presents again (spontaneous recovery). Conditioned responses can also return if the patient returns to the context of conditioning after extinction in another context, or if the CS is encountered in a context that differs from the one in which extinction has occurred (all are examples of the renewal effect). The renewal effect is significant because it illustrates the principle that extinction performance depends on the organism being in the context in which extinction was learned. If the CS is encountered in a different context, the extinguished behavior may relapse or return. Recovery and relapse can also occur if the current context is associated again with the US (“reinstatement”) or if the CS is paired with the US again (“rapid reacquisition”). One theoretical approach assumes that extinction and counterconditioning do not destroy the original learning but instead entail new learning that gives the CS a second meaning (e.g., “the CS is safe” in addition to “the CS is

dangerous"). As with an ambiguous word, which has more than one meaning, responding evoked by an extinguished or counterconditioned CS depends fundamentally on the current context.

Research on context effects in animal and human learning and memory suggests that a wide variety of stimuli can play context (Table 34-5). Drugs, for example, can be very salient in this regard. When rats are given fear extinction while under the influence of a benzodiazepine tranquilizer or alcohol, fear is renewed when the CS is tested in the absence of the context provided by the drug. This is an example of *state-dependent learning*, in which the retention of information is best when tested in the same state in which it was initially learned. State-dependent fear extinction has apparent implications for combining therapy with drugs. It also has implications for the administration of drugs more generally. For example, if a person were to take a drug to reduce anxiety, the anxiety reduction would reinforce drug-taking. State-dependent extinction might further preserve any anxiety that might otherwise be extinguished during natural exposure to the anxiety-eliciting cues. Thus, drug use could paradoxically preserve the original anxiety, creating a self-perpetuating cycle that could provide a possible explanation for the link between anxiety disorders and substance abuse. One point of this discussion is that drugs can play multiple roles in learning: they can be USs or reinforcers on the one hand, and CSs or contexts on the other. The possible complex behavioral effects of drugs are worth bearing in mind.

Table 34-5
Effective Contextual Stimuli Studied in Animal and Human Research Laboratories

Exteroceptive context:

Interoceptive context:
Drug state
Hormonal state
Mood state
Deprivation state
Recent events
Expectation of events

Passage of time

From Sadock BJ, Sadock VA, Ruiz P. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2009:652.

Another general message is that contemporary theory emphasizes that extinction (and other processes, such as counterconditioning) entails new learning rather than a destruction of the old. Recent psychopharmacological research has built on this idea: if extinction and therapy constitute new learning, drugs that might facilitate new learning might also facilitate the therapy process. For example, there has been considerable recent interest in D-cycloserine, a partial agonist of the *N*-methyl-D-aspartate (NMDA) glutamate receptor. The NMDA receptor is involved in long-term potentiation, a synaptic facilitation phenomenon that has been implicated in several examples of learning. Of interest, there is evidence that the administration of D-cycloserine can facilitate extinction learning in rats and possibly in humans undergoing exposure therapy for anxiety disorders. In the studies supporting this conclusion, the administration of the drug increased the amount of extinction that was apparent after a small (and incomplete) number of extinction trials. Although such findings are promising, it is essential to remember that the context-dependence of extinction, and thus the possibility of relapse with a change of context, may easily remain. Consistent with this possibility, although D-cycloserine allows fear extinction to be learned in fewer trials, it does not appear to prevent or reduce the strength of the renewal effect. Such results further underscore the importance of behavioral research—and behavioral theory—in understanding the effects of drugs on therapy. Nonetheless, the search for drugs that might enhance the *learning* that occurs in therapy situations will continue to be an essential area of research.

Another process that might theoretically modify or erase memory is illustrated by a phenomenon called *reconsolidation.* Newly learned memories are temporarily labile and easy to disrupt before they are consolidated into a more stable form in the brain. The consolidation of memory requires the synthesis of new proteins and can be blocked by administering protein synthesis inhibitors (e.g., anisomycin). Animal research suggests that consolidated memories that have recently been reactivated might also return briefly to a similarly vulnerable state; protein synthesis inhibitors can

likewise block their "reconsolidation." For example, several studies have shown that the reactivation of conditioned fear by one or two presentations of the CS after a brief fear conditioning experience can allow it to be disrupted by anisomycin. When the CS is tested later, there is little evidence of fear—as if reactivation and then drug administration diminished the strength of the original memory. However, like the effects of extinction, these fear-diminishing effects do not necessarily mean that the original learning has been destroyed or erased. There is some evidence that fear of the CS that has been diminished in this way can still return over time (i.e., spontaneously recover) or with reminder treatments. This sort of result suggests that the effect of the drug is somehow able to interfere with retrieval or access to the memory rather than to be an actual "reconsolidation."

Generally speaking, eliminating a behavior after therapy should not be interpreted as the erasure of the underlying knowledge. For the time being, it may be safest to assume that, after any treatment, a part of the original learning may remain in the brain, ready to produce relapse if retrieved. Instead of trying to find treatments that destroy the original memory, another therapeutic strategy might be to accept the possible retention of the original learning and build therapies that allow the organism to prevent or cope with its retrieval. One possibility is to conduct extinction exposure in the contexts in which relapse might be most problematic to the patient and to encourage retrieval strategies (such as the use of retrieval cues like reminder cards) that might help to remind the patient of the therapy experience.

Operant/Instrumental Learning

The Relation Between Behavior and Payoff. Operant learning has many parallels with Pavlovian learning. As one example, extinction also occurs in operant learning if the reinforcer is omitted following training. Although extinction is once again a useful technique for eliminating unwanted behaviors, just as we saw with Pavlovian learning, it does not destroy the original learning—spontaneous recovery, renewal, reinstatement, and rapid reacquisition effects still obtain. Although early accounts of instrumental learning, beginning with Edward Thorndike, emphasized the role of the reinforcer as "stamping in" the instrumental action, more-modern approaches tend to view the reinforcer as a sort of guide or motivator of

behavior. A modern, “synthetic” view of operant conditioning (see later discussion) holds that the organism associates the action with the outcome in much the way that stimulus–outcome learning is believed to be involved in Pavlovian learning.

Human behavior is influenced by a wide variety of reinforcers, including social ones. For example, simple attention from teachers or hospital staff members has been shown to reinforce disruptive or problematic behavior in students or patients. In either case, when the attention is withdrawn and redirected toward other activities, the problematic behaviors can decrease (i.e., undergo extinction). Human behavior is also influenced by verbal reinforcers, like praise, and, more generally, by *conditioned reinforcers,* such as money, that have no intrinsic value except for the value derived through association with more basic, “primary” rewards. Conditioned reinforcers have been used in schools and institutional settings in the so-called *token economies* in which positive behaviors are reinforced with tokens that can be used to purchase valued items. In more natural settings, reinforcers are always delivered in social relationships, in which their effects are dynamic and reciprocal. For example, the relationship between a parent and a child is full of interacting and reciprocating operant contingencies in which the delivery (and withholding) of reinforcers and punishers shapes the behavior of each. Like Pavlovian learning, operant learning is always operating and always influencing behavior.

Research on operant conditioning in the laboratory has offered many insights into how action relates to its payoff. In the natural world, few actions are reinforced every time they are performed; instead, most actions are reinforced only intermittently. In a *ratio reinforcement schedule,* the reinforcer is directly related to the amount of work or responding that the organism emits. That is, there is some work requirement that determines when the next reinforcer will be presented. In a “fixed ratio schedule,” every *x*th action is reinforced; in a “variable ratio schedule,” there is an average ratio requirement, but the number of responses required for each successive reinforcer varies. Ratio schedules, especially variable ratio schedules, can generate high rates of behavior, as seen in the behavior directed at a casino slot machine. In an *interval reinforcement schedule,* the presentation of each reinforcer depends on the organism emitting the response after some time has also elapsed. In a “fixed interval schedule,” the first response after *x* seconds

have elapsed is reinforced. In a "variable interval schedule," there is an interval requirement for each reinforcer, but the length of that interval varies. A person checking e-mail throughout the day is being reinforced on a variable interval schedule—a new message is not present to reinforce each checking response, but the presence of a new message becomes available after variable time points throughout the day. Of interest, on interval schedules, the response rate can vary substantially without influencing the overall rate of reinforcement. (On ratio schedules, there is a more direct relationship between behavior rate and reinforcement rate.) In part because of this, interval schedules tend to generate slower response rates than ratio schedules.

Classic research on operant behavior underscores the fact that the performance of any action always involves *choice.* That is, whenever the individual performs a particular behavior, he or she chooses to engage in that action over many other possible alternatives. When a choice has been studied by allowing the organism to perform either of two different operant behaviors (paying off with their separate schedules of reinforcement), the rate of operant behavior depends not only on the behavior's rate of reinforcement but also on the rate of reinforcement of all other behaviors in the situation. Put most generally, the strength of Behavior 1 (e.g., the rate at which Behavior 1 is performed) is given by

$$B_1 = K^*R_1/(R_1 + R_O)$$

where B_1 can be seen as the strength of Behavior 1, R_1 is the rate at which B_1 has been reinforced, and R_O is the rate at which all alternative (or "other") behaviors in the environment have been reinforced; K is a constant that corresponds to all behavior in the situation and may have a different value for different individuals. This principle, known as the *quantitative law of effect,* captures several ideas that are relevant to psychiatrists and clinical psychologists. It indicates that an action can be strengthened either by increasing its rate of reinforcement (R_1) or decreasing the rate of reinforcement for alternative behaviors (R_O). Conversely, an action can be weakened either by reducing its rate of reinforcement (R_1) or increasing reinforcement for alternative behaviors (R_O). The latter point has an

especially important implication: in principle, one can slow the strengthening of new, undesirable behavior by providing an environment that is otherwise rich in reinforcement (high R_O). Thus, an adolescent who experiments with drugs or alcohol would be less likely to engage in this behavior at a high rate (high B_1) if their environment were otherwise rich with reinforcers (e.g., provided by extracurricular activities or outside interests).

The choice among actions is also influenced by the size of their corresponding reinforcers and how soon the reinforcers will occur. For example, individuals sometimes have to choose between an action that yields a small but immediate reward (e.g., taking a hit of a drug) versus another that yields a larger but delayed reward (e.g., going to a class and earning credit toward a general educational development certificate). Individuals who choose the more immediate reward are often said to be "impulsive," whereas those who choose the delayed reward are said to exercise "self-control." Of interest, organisms often choose immediate small rewards over delayed larger ones, even though it may be maladaptive to do so in the long run. Such "impulsive" choices are especially difficult to resist when the reward is imminent. Choice is believed to be determined by the relative value of the two rewards, with that value being influenced by both the reinforcer's size and its delay. The bigger the reinforcer, the better is the value, and the more immediate the reinforcer, the better, too: when a reward is delayed, its value decreases or is "discounted" over time. When offered a choice, the organism will always choose the action that leads to the reward whose value is currently higher.

Theories of Reinforcement. It is possible to use the preceding principles of operant conditioning without knowing in advance what kind of event or stimulus will be reinforcing for the individual patient. None of the reinforcement rules say much about what sorts of events in an organism's world will play a reinforcer. Skinner defined a reinforcer empirically, by considering the effect it had on operant behavior. A reinforcer was defined as any event that could be shown to increase the strength of an operant if it was made a consequence of the operant. This empirical (some would say "atheoretical") view can be valuable because it allows idiosyncratic reinforcers for idiosyncratic individuals. For instance, if a therapist works

with a child who is injuring himself, the approach advises the therapist merely to search for the consequences of the behavior and then manipulate them to bring the behavior under control. So, if, for example, the child's self-injurious behavior decreases when the parent stops scolding the child for doing it, then the scold is the reinforcer, which might seem counterintuitive to everyone (including the parent who thinks that the scold should function as a punisher). On the other hand, it would also be useful to know what kind of event will reinforce an individual before the therapist has to try everything.

Several approaches allow for predictions ahead of time. Perhaps the most useful is the *Premack principle* (named for researcher David Premack), which claims that, for any individual, reinforcers can be identified by giving the individual a preference test in which he or she is free to engage in any number of activities. The individual might spend the most time engaging in activity A, the second-most time engaged in activity B, and the third-most time engaged in activity C. Behavior A can thus be said to be preferred to B and C, and B is preferred to C. The Premack principle asserts that access to a preferred action will reinforce any action that is less preferred. In the present example, if doing activity C allowed access to doing A or B, activity C will be reinforced—it will increase in strength or probability.

Similarly, activity B will be reinforced by activity A (but not C). The principle accepts large individual differences. For example, in an early study, some children given a choice spent more time eating candy than playing pinball, whereas others spent more time playing pinball then eating candy. Candy eating reinforced pinball playing in the former group. In contrast, pinball playing reinforced candy eating in the latter group. There is nothing particularly special about food (eating) or any particular kind of activity as a possible reinforcer. Any behavior that is preferred to a second behavior will theoretically reinforce the second behavior.

The principle has been refined over the years. It is now recognized that even a less-preferred behavior can reinforce a more-preferred behavior if the organism has been deprived of doing the low-preferred behavior below its ordinary level. In the preceding example, even the low-preference activity C could reinforce A or B if it were suppressed for a while below its baseline level of preference. However, the main implication is that in the long run, a person's reinforcers can be discovered by looking at how they allocate their activities when access to them is free and unconstrained.

Motivational Factors. Instrumental action is often said to be goal-oriented. As Edward Tolman illustrated in many experiments conducted in the 1930s and 1940s, organisms may flexibly perform several actions to achieve a goal; instrumental learning thus provides a variable means to a fixed end. Tolman's perspective on the effects of reinforcers has returned to favor. He argued that reinforcers are not necessary for learning, but instead are essential for motivating instrumental behavior. The classic illustration of this point is the *latent learning* experiment. Rats received several trials in a complex maze in which they were removed from the maze without reward once they got to a particular goal location. When arriving at the goal was suddenly rewarded, the rats suddenly began working through the maze with very few errors. Thus, they had learned about the maze without the benefit of the food reinforcer, but the reinforcer was nonetheless crucial for motivating them to get through the maze efficiently. The reinforcer was unnecessary for learning, but it gave the organism a reason to translate its knowledge into action.

Subsequent research has identified many motivating effects of reward. For example, organisms with experience receiving a small reward may show *positive contrast* when they are suddenly reinforced with a larger reward. That is, their instrumental behavior may become more vigorous than that in control subjects who have received the larger reward all along. Conversely, organisms show *negative contrast* when they are switched from a high reward to a lower reward—their behavior becomes weaker than control subjects who have received the same smaller reward all along. Negative contrast involves frustration and emotionality. Both types of contrast are consistent with the idea that the current effectiveness depends on what the organism has learned to expect; an increase from expectation causes elation, whereas a decrease from expectation causes frustration. There is a sense in which receiving a reward that is smaller than expected might seem punishing.

Negative contrast is an example of a *paradoxical reward effect*—a set of behavioral phenomena given the name because they show that reward can sometimes weaken behavior and that nonreward can sometimes strengthen it. The best known is the *partial reinforcement extinction effect*, in which actions that have been intermittently (or "partially") reinforced persist longer when reinforcers are completely withdrawn than actions that have been continuously reinforced. The finding is considered paradoxical because an

action that has been reinforced (say) half as often as another action may be more persistent. One explanation is that the action that has been partially reinforced has been reinforced in the presence of some frustration—and is thus persistent in new adversity or sources of frustration. Other evidence suggests that effortfulness is a dimension of behavior that can be reinforced. That is, human and animal participants that have been reinforced for performing effortful responses learn a sort of "industriousness" that transfers to new behaviors. One implication is that new behaviors learned in therapy will be more persistent over time if a high effort has been deliberately reinforced.

The organism's current motivational state also influences the effectiveness of a reinforcer. For example, food is more reinforcing for a hungry organism, and water is more reinforcing for a thirsty one. Such results are consistent with many theories of reinforcement (e.g., the Premack principle) because the presence of hunger or thirst would undoubtedly increase the organism's preference ranking for food or water. However, recent research indicates that the effects of motivational states on instrumental actions are not this automatic. Specifically, if a motivational state is going to influence an instrumental action, the individual needs first to learn how the action's reinforcer will influence the motivational state. The process of learning about the effects the reinforcer has on the motivational state is called *incentive learning.*

An experimental example best illustrates incentive learning. In 1992, Bernard Balleine reported a study that taught trained rats that were not hungry to lever press to earn a novel food pellet. The animals were then food-deprived and tested for their lever pressing under conditions in which the lever press no longer produced the pellet. The hunger state did not affect the lever-press rate; that is, hungry rats did not lever press any more than rats that were not food-deprived. On the other hand, if the rat had been given separate experience eating the pellets while it was food-deprived, during the test, it lever pressed at a high rate. Thus, hunger invigorated the instrumental action only if the animal had previously experienced the reinforcer in that state, allowing it to learn that the specific substance influenced the state (incentive learning). The interpretation of this result, and others like it, will be developed further later in this section. The main idea is that individuals will perform an instrumental action when they know that it produces an outcome

that is desirable in the current motivational state. The clinical implications are underexplored but could be significant. For example, persons who abuse drugs will need to learn that the drug makes them feel better in the withdrawal state before the withdrawal will motivate drug-seeking. Persons with anxiety might not be motivated to take a beneficial medication while anxious until they have had the opportunity to learn how the medication makes them feel when they are in the anxious state, and a person with depression may need to learn what natural reinforcers make them feel better while they are depressed. According to theory, direct experience with a reinforcer's effect on depressed mood might be necessary before the person will be interested in performing actions that help to ameliorate the depressed state.

Pavlovian and Operant Learning Together

Avoidance Learning. Theories of the motivating effects of reinforcers have usually emphasized that Pavlovian CSs in the background are also associated with the reinforcer. The expectancy of the reinforcer (or conditioned motivational state) the CSs arouse increases the vigor of the operant response. This is *two-factor* or *two-process theory:* Pavlovian learning co-occurs and motivates behavior during operant learning.

The interaction of Pavlovian and instrumental factors is especially important in understanding avoidance learning (see Fig. 34-2). In avoidance situations, organisms learn to perform actions that prevent the delivery or presentation of an aversive event. The explanation of avoidance learning is subtle because it is difficult to identify an obvious reinforcer. Although preventing the occurrence of the aversive event is essential, how can the nonoccurrence of that event reinforce? The answer is that cues in the environment (Pavlovian CSs) come to predict the occurrence of the aversive event, and consequently, they arouse anxiety or fear. The avoidance response can, therefore, be reinforced if it escapes from or reduces that fear. Pavlovian and operant factors are thus both important: Pavlovian fear conditioning motivates and allows reinforcement of an instrumental action through its reduction. Escape from fear or anxiety is believed to play a significant role in many human behavior disorders, including anxiety disorders. Thus, the obsessive-compulsive patient checks or washes his or her hands repeatedly to

reduce anxiety, the agoraphobic stays home to escape the fear of places associated with panic attacks, and the bulimic learn to vomit after a meal to reduce the learned anxiety evoked by eating the meal.

Although the two-factor theory remains an essential view of avoidance learning, excellent avoidance can be obtained in the laboratory without reinforcement: for example, if an animal is required to perform an action that resembles one of its natural and prepared fear responses—so-called *species-specific defensive reactions* (*SSDRs*). Rats will readily learn to freeze (remain motionless) or flee (run to another environment) to avoid shock, two behaviors that have evolved to escape or avoid predation. Freezing and fleeing are also respondents rather than operants; they are controlled by their antecedents (Pavlovian CSs that predict shock) rather than reinforced by their consequences (escape from fear). Thus, when the rat can use an SSDR for avoidance, the only necessary learning is Pavlovian—the rat learns about environmental cues associated with danger, and these arouse fear and evoke natural defensive behaviors including withdrawal (negative sign tracking; Fig. 34-3). To learn to perform an action that is not similar to a natural SSDR requires more feedback or reinforcement through fear reduction.

A good example is lever pressing, which is easy for the rat to learn when the reinforcer is a food pellet but challenging to learn when the same action avoids shock. More recent work with avoidance in humans suggests an essential role for CS-aversive event and response–no aversive event expectancies. The larger point is that Pavlovian learning is vital in avoidance learning; when the animal can avoid with an SSDR, it is the only learning necessary; when the required action is not an SSDR, Pavlovian learning permits the expectation of something bad.

A cognitive perspective on aversive learning is also encouraged by studies of *learned helplessness*. In this phenomenon, organisms exposed to either controllable or uncontrollable aversive events differ in their reactivity to later aversive events. For example, the typical finding is that a subject exposed to inescapable shock in one phase of an experiment is less successful at learning to escape shock with altogether new behavior in a second phase, whereas subjects exposed to escapable shock are normal. Both types of a subject are exposed to the same shock, but its psychological dimension (its controllability) creates a difference, perhaps because subjects exposed to inescapable shock learn the independence of their actions and the outcome.

Although this finding (and interpretation) was once seen as a model of depression, the current view is that the controllability of stressors mainly modulates their stressfulness and negative impact. At a theoretical level, the result also implies that organisms receiving instrumental contingencies in which their actions lead to outcomes might learn something about the controllability of those outcomes.

One of the main conclusions of aversive learning is that there are biologic and cognitive dimensions to instrumental learning. The possibility that Pavlovian contingencies can control much instrumental learning is also consistent with research in which animals have learned to respond to positive reinforcers. For example, pigeons have been widely used in operant learning experiments since the 1940s. In the typical experiment, the bird learns to peck at a plastic disk on a wall of the chamber (a response "key") to earn food. Although pecking seems to be an operant response, it turns out that the pigeon's peck can be entrained by merely illuminating the key for a few seconds before presenting the reinforcer on several trials. Although there is no requirement for the bird to peck the key, the bird will begin to peck at the illuminated key—a Pavlovian predictor of food—anyway. Its consequences only weakly control the pecking response; if the experimenter arranges things so that pecks prevent the delivery of food (which is otherwise delivered on trials without pecks), the birds will continue to peck almost indefinitely on many trials. (Although the peck has a negative correlation with food, key illumination remains a weakly positive predictor of food.) Thus, this classic "operant" behavior is at least partly a Pavlovian one. Pavlovian contingencies cannot be ignored. When rats are punished with mild foot shock for pressing a lever that otherwise produces food, they stop lever pressing at least partly (and perhaps predominantly) because they learn that the lever now predicts shock, and they withdraw from it. A child might likewise learn to stay away from the parent who delivers punishment rather than refrain from performing the punished behavior. A great deal of behavior in operant learning settings may be controlled by Pavlovian learning and sign tracking rather than authentic operant learning.

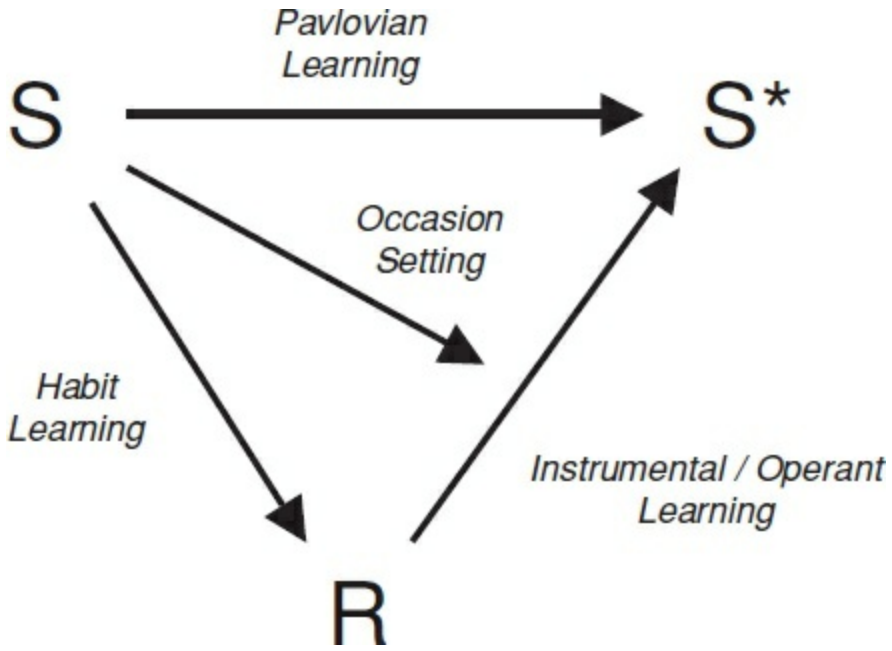

FIGURE 34-4
Any instrumental/operant learning situation permits a number of types of learning, which are always occurring all the time. R, operant behavior or instrumental action; S, stimulus in the background; S*, biologically significant event (e.g., reinforcer, US). (Courtesy of Mark E. Bouton, PhD.)

A Synthetic View of Instrumental Action. Then, the idea is that several hypothetical associations control behavior in any instrumental learning situation, as illustrated in Figure 34-4. Much behavior in an instrumental learning arrangement can be controlled by a Pavlovian factor in which the organism associates background cues (CSs) with the reinforcer (S*, denoting a biologically significant event). As discussed earlier, this type of learning can allow the CS to evoke a variety of behaviors and emotional reactions (and motivational states) that can additionally motivate instrumental action.

In modern terms, the instrumental factor is represented by the organism learning a direct, and similar, association between the instrumental action (R) and the reinforcer (S*). Evidence for this sort of learning comes from experiments on *reinforcer devaluation* (Fig. 34-5). In such experiments, the organism can first be trained to perform two instrumental actions (e.g., pressing a lever and pulling a chain), each paired with a different reinforcer (e.g., food pellet versus a liquid sucrose solution). In a separate second phase, one of the reinforcers (e.g., pellet) is paired with illness, which creates the conditioning of a powerful taste aversion to the reinforcer. In a final test, the

organism is returned to the instrumental situation and can perform either instrumental action. No reinforcers are presented during the test. The result is that the organism no longer performs the action that produced the reinforcer that is now aversive. The organism must have (1) learned which action produced which reinforcer and (2) combined it with the knowledge that it no longer likes or values that reinforcer. The result cannot be explained by the simpler, more traditional view that reinforcers merely stamp in or strengthen instrumental actions.

Organisms also need to learn how reinforcers influence a particular motivational state called “incentive learning.” Incentive learning is crucially involved in instrumental learning as a process through which the animal learns the value of the reinforcer. Thus, in the reinforcer devaluation experiment shown in Figure 34-5, an important thing that occurs in the second phase is that the organism must contact the reinforcer and learn that it does not like it. As described earlier, incentive learning is probably always involved in making outcomes (and the associated actions that produce them) more or less desirable.

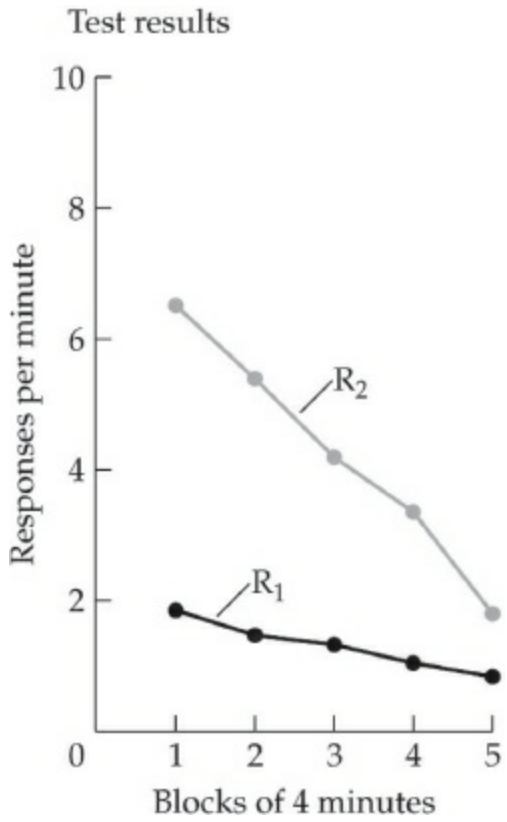

FIGURE 34-5

The reinforcer devaluation effect. Results of the test session. The result indicates the importance of the response–reinforcer association in operant learning. For the organism to perform in the way that it does during testing, it must learn which action leads to which reinforcer and then choose to perform the action that leads to the outcome it currently liked or valued. R1, R2, operant behaviors or instrumental actions. (Data from Colwill and Rescorla [1986]. From Bouton ME. *Learning and Behavior: A Contemporary Synthesis*. Sunderland, MA: Sinauer; 2007.)

Other experiments have illustrated the other associations to the stimulus that are represented in Figure 34-4. In addition to being directly associated with the reinforcer, a stimulus can signal a relation between an action and an outcome. This is called *occasion setting:* instead of eliciting a response directly, stimuli in operant situations can set the occasion for the operant response. There is good evidence that they do so by signaling a specific response–reinforcer relationship. For example, in one experiment, rats learned to lever press and chain pull in background noise and background light. When the noise was present, lever pressing yielded a pellet reinforcer, and chain pulling yielded sucrose.

In contrast, when the light was present, the relations were reversed: Lever pressing yielded sucrose, and chain pulling yielded pellet. There was evidence that the rats learned corresponding relationships. In a second phase, pellets were associated with illness, so the rat no longer valued the pellet. In a final test, rats were allowed to lever press or chain pull in extinction in noise or light present during separate tests. In the presence of the noise, the animal's chain pulled rather than lever pressed. When the light was present, the animal's lever pressed rather than chain pulled. Thus, the noise informed the rat that the lever press yielded a pellet, and the light informed the rat that the chain pull did. This is the occasion-setting function illustrated in Figure 34-4.

It is worth noting that other stimuli besides lights and noises set the occasion for operant behavior. Modern research on learning in animals has underscored the importance of other stimuli, such as temporal and spatial cues, and particular perception and memory processes. A particularly interesting example of research on the *stimulus control* of operant behavior is categorization. Pigeons can be shown images of cars, chairs, flowers, and cats on a computer screen positioned on the wall of a Skinner box. Pecking one of four keys in the presence of these images is reinforced in any picture

containing a car, a chair, a flower, or a cat. Of interest, as the number of exemplars in each category increases, the pigeon makes more errors as it learns the discrimination. However, more exemplars create better learning in the sense that it is more ready to transfer to new test images—after many examples of each category, the pigeon is more accurate at categorizing (and responding accurately to) new stimuli. One implication is that training new behaviors in various settings or ways will enhance generalization to new situations.

The final association in Figure 34-4 is simple *habit learning* or a direct association between the stimulus and the response. Through this association, the background may elicit the instrumental action directly, without the intervening cognition of R–S* and the valuation of S*. Although S–R learning was once believed to dominate learning, the current view sees it as developing only after extensive and consistent instrumental training. In effect, actions that have been performed repeatedly (and repeatedly associated with the reinforcer) become automatic and routine. One source of evidence is the fact that the reinforcer devaluation effect—which implies a kind of cognitive mediation of operant behavior—no longer occurs after extensive instrumental training as if the animal reflexively engages in the response without remembering the actual outcome it produces. It seems reasonable to expect that many pathologic behaviors that come into the clinic might also be automatic and blind through repetition. Of interest, the evidence suggests that the eventual dominance of the S-R habit in behavior does not replace or destroy more cognitive mediation by learned S–S*, R–S*, or S–(R–S*) relations. Under some conditions, even a habitual response might be brought back under the control of the action–reinforcer association. The conversion of actions to habits and the relation of habit to cognition are active areas of research.

BIOLOGY OF MEMORY

The topic of memory is fundamental to the discipline of psychiatry. Memory is the glue that binds our mental life, the scaffolding for our personal history. In part, personality is an accumulation of habits that have been acquired, many very early in life, which creates dispositions and influences how we behave. In the same sense, the neuroses are often products of learning—

anxieties, phobias, and maladaptive behaviors that result from particular experiences. Psychotherapy itself is a process by which new habits and skills are acquired by accumulating new experiences. In this sense, memory is at the theoretical heart of psychiatry's concern with personality, the consequences of early experience, and the possibility of growth and change.

Memory is also of clinical interest because disorders of memory and complaints about memory are common in neurologic and psychiatric illness. Memory impairment is also a side effect of specific treatments, such as electroconvulsive therapy (ECT). Accordingly, the effective clinician needs to understand something of the biology of memory, the varieties of memory dysfunction, and how memory can be evaluated.

From Synapses to Memory

Memory is a particular case of the general biologic phenomenon of *neural plasticity*. Neurons can show history-dependent activity by responding differently as a function of prior input, and this plasticity of nerve cells and synapses is the basis of memory. In the last decade of the 19th century, researchers proposed that the persistence of memory could be accounted for by nerve cell growth. This idea has been restated many times, and current understanding of the synapse as the critical site of change is founded on extensive experimental studies in animals with simple nervous systems. Experience can lead to structural change at the synapse, including alterations in the strength of existing synapses and alterations in the number of synaptic contacts along specific pathways.

Plasticity. Neurobiologic evidence supports two necessary conclusions: first, short-lasting plasticity, which may last for seconds or minutes depending on specific synaptic events, including an increase in neurotransmitter release; and second, long-lasting memory, which depends on new protein synthesis, the physical growth of neural processes, and an increase in the number of synaptic connections.

A significant source of information about memory has come from the extended study of the marine mollusk *Aplysia californica.* Individual neurons and connections between neurons have been identified, and the wiring diagram of some simple behaviors has been described. *Aplysia* is capable of

associative learning (including classic conditioning and operant conditioning) and nonassociative learning (habituation and sensitization). *Sensitization* had been studied using the gill-withdrawal reflex, a defensive reaction in which tactile stimulation causes the gill and siphon to retract. When tactile stimulation is preceded by sensory stimulation to the head or tail, gill withdrawal is facilitated. The cellular changes underlying this sensitization begin when a sensory neuron activates a modulatory interneuron, enhancing the strength of synapses within the circuitry responsible for the reflex. This modulation depends on a second-messenger system in which intracellular molecules (including cyclic adenosine monophosphate [cAMP] and cAMP-dependent protein kinase) lead to enhanced transmitter release that lasts for minutes in the reflex pathway. Both short- and long-lasting plasticity within this circuitry are based on enhanced transmitter release. The long-lasting change uniquely requires the expression of genes and the synthesis of new proteins. Synaptic tagging mechanisms allow gene products delivered throughout a neuron to increase synaptic strength selectively at recently active synapses. Also, the long-term change, but not the short-term change, is accompanied by the growth of neural processes of neurons within the reflex circuit.

In vertebrates, memory cannot be studied as directly as in the simple nervous system of *Aplysia*. Nevertheless, it is known that behavioral manipulations can also result in measurable changes in the brain's architecture. For example, rats reared in enriched as opposed to ordinary environments show an increase in the number of synapses ending on individual neurons in the neocortex. These changes are accompanied by small increases in cortical thickness, the diameter of neuronal cell bodies, and the number and length of dendritic branches. The behavioral experience thus exerts powerful effects on the wiring of the brain.

Many of these same structural changes have been found in adult rats exposed to an enriched environment and adult rats given extensive maze training. In maze training, vision was restricted to one eye, and the corpus callosum was transected to prevent information received by one hemisphere from reaching the other hemisphere. The result was that structural changes in neuronal shape and connectivity were observed only in the trained hemisphere. This finding rules out several nonspecific influences, including motor activity, indirect effects of hormones, and overall level of arousal.

Long-term memory in vertebrates is believed to be based on morphologic growth and change, including increases in synaptic strength along particular pathways.

Long-Term Potentiation. The phenomenon of *long-term potentiation* (LTP) is a candidate mechanism for mammalian long-term memory. LTP is observed when a postsynaptic neuron is persistently depolarized after a high-frequency burst of presynaptic neural firing. LTP has several properties that make it suitable as a physiologic substrate of memory. It is established quickly and then lasts for a long time. It is associative, in that it depends on the co-occurrence of presynaptic activity and postsynaptic depolarization. It occurs only at potentiated synapses, not all synapses terminating on the postsynaptic cell. Finally, LTP occurs prominently in the hippocampus, a structure that is important for memory.

The induction of LTP is known to be mediated postsynaptically and to involve activation of the NMDA receptor, which permits the influx of calcium into the postsynaptic cell. LTP is maintained by an increase in the number of α-amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA; non-NMDA) receptors postsynaptic cell and also possibly by increased transmitter release.

A promising method for elucidating molecular mechanisms of memory relies on introducing specific mutations into the genome. By deleting a single gene, one can produce mice with specific receptors or cell signaling molecules inactivated or altered. For example, in mice with a selective deletion of NMDA receptors in the CA1 field of the hippocampus, many aspects of CA1 physiology remain intact, but the CA1 neurons do not exhibit LTP, and memory impairment is observed in behavioral tasks. Genetic manipulations introduced reversibly in the adult are particularly advantageous, in that specific molecular changes can be induced in developmentally normal animals.

Associative Learning. The study of *classical conditioning* has provided many insights into the biology of memory. Classical conditioning has been especially well studied in rabbits, using a tone as the conditioned stimulus and an air puff to the eye (which automatically elicits a blink response) as the unconditioned stimulus. Repeated pairings of the tone and the air puff lead to

a conditioned response, in that the tone alone elicits an eye blink. Reversible lesions of the deep nuclei of the cerebellum eliminate the conditioned response without affecting the unconditioned response. These lesions also prevent initial learning from occurring, and, when the lesion is reversed, rabbits usually learn. Thus, the cerebellum contains essential circuitry for the learned association. The relevant plasticity appears to be distributed between the cerebellar cortex and the deep nuclei.

An analogous pattern of cerebellar plasticity is believed to underlie motor learning in the vestibuloocular reflex and, perhaps, associative learning of motor responses in general. Based on the idea that learned motor responses depend on the coordinated control of changes in timing and strength of the response, it has been suggested that synaptic changes in the cerebellar cortex are critical for learned timing. In contrast, synaptic changes in the deep nuclei are critical for forming an association between a conditioned stimulus and an unconditioned stimulus.

Fear conditioning and fear-potentiated startle are types of learning that serve as useful models for anxiety disorders and related psychiatric conditions. For example, mice exhibit freezing behavior when returned to the same context in which aversive shock was delivered on an earlier occasion. This type of learning depends on the encoding of contextual features of the learning environment. Acquiring and expressing this type of learning requires neural circuits that include both the amygdala and the hippocampus. The amygdala may be important for associating negative affect with new stimuli. The hippocampus may be important for representing the context. With extinction training, when the context is no longer associated with an aversive stimulus, the conditioned fear response fades. The frontal cortex is believed to play a critical role in extinction.

Cortical Organization of Memory

One fundamental question concerns the locus of memory storage in the brain. In the 1920s, Karl Lashley searched for the site of memory storage by studying the behavior of rats after removing different amounts of their cerebral cortex. He recorded the number of trials needed to relearn a maze problem that rats learned before surgery, and he found that the deficit was proportional to the amount of cortex removed. The deficit did not seem to

depend on the particular location of cortical damage. Lashley concluded that the memory resulting from maze learning was not localized in any one part of the brain but instead was distributed equivalently over the entire cortex.

Subsequent research has led to reinterpretations of these results. Maze learning in rats depends on different types of information, including visual, tactile, spatial, and olfactory information. Neurons that process these various types of information are segregated into different areas of the rat cerebral cortex, and memory storage is segregated in a parallel manner. Thus, the correlation between maze-learning abilities and lesion size that Lashley observed results from progressive encroachment of larger lesions on specialized cortical areas serving the many components of information processing relevant for maze learning.

The functional organization of the mammalian cerebral cortex has been revealed through neuropsychological analyses of deficits following brain damage and physiologic studies of intact brains. The cortical areas responsible for processing and storing visual information have been studied most extensively in nonhuman primates. Nearly one-half of the primate neocortex is specialized for visual functions.

The cortical pathways for visual information processing begin in the primary visual cortex (V1) and proceed from parallel pathways or streams. One stream projects ventrally to the inferotemporal cortex and is specialized for processing information concerning the identification of visual objects. Another stream projects dorsally to the parietal cortex and is specialized for processing information about spatial location.

Specific visual processing areas in the dorsal and ventral streams, together with areas in the prefrontal cortex, register the immediate experience of perceptual processing. The results of perceptual processing are first available as *immediate memory*. Immediate memory refers to the amount of information that can be held in mind (like a telephone number) to be available for immediate use. Immediate memory can be extended in time by rehearsing or otherwise manipulating the information, in which case what is stored is said to be in *working memory*.

Regions of the visual cortex in forward portions of the dorsal and ventral streams serve as the ultimate repositories of visual memories. The inferotemporal cortex, for example, lies at the end of the ventral stream, and inferotemporal lesions lead to selective impairments in both visual object

perception and visual memory. Nonetheless, such lesions do not disrupt elementary visual functions, such as acuity. Electrophysiologic studies in the monkey show that neurons in area TE, which is one part of the inferotemporal cortex, register specific and complex features of visual stimuli, such as shape, and respond selectively to patterns and objects. The inferotemporal cortex can thus be thought of as both a higher-order visual processing system and a storehouse of the visual memories that result from that processing.

In sum, memory is distributed and localized in the cerebral cortex. Memory is distributed in the sense that, as Lashley concluded, there is no cortical center dedicated solely to the storage of memories. Nonetheless, memory is localized in the sense that different aspects or dimensions of events are stored at specific cortical sites—namely, in the same regions that are specialized to analyze and process what is to be stored.

Memory and Amnesia

The principle that the functional specialization of cortical regions determines both the locus of information processing and the locus of information storage does not provide a complete account of memory in the brain. If it did, then brain injury would always include difficulty in memory for a restricted type of information and a loss of ability to process information of that same type. This kind of impairment occurs, for example, in the aphasias and the agnosias. However, there is another kind of impairment that can occur as well, called amnesia.

The hallmark of amnesia is a loss of new learning ability that extends across all sensory modalities and stimulus domains. This *anterograde amnesia* can be explained by understanding the role of brain structures critical for acquiring information about facts and events. Typically, anterograde amnesia occurs together with *retrograde amnesia,* a loss of knowledge acquired before the onset of amnesia. Retrograde deficits often have a temporal gradient, following a principle known as Ribot’s law; deficits are most severe for information that was most recently learned.

A patient with a presentation of amnesia exhibits severe memory deficits in the context of the preservation of other cognitive functions, including language comprehension and production, reasoning, attention, immediate

memory, personality, and social skills. The selectivity of the memory deficit in these cases implies that intellectual and perceptual functions of the brain are separated from the capacity to lay down in memory the records that ordinarily result from engaging in intellectual and perceptual work.

Specialized Memory Function. Amnesia can result from damage to the medial portion of the temporal lobe or damage to regions of the midline diencephalon. Studies of a severely amnesic patient known as HM stimulated intensive investigation of the role of the medial temporal lobe in memory.

HM became amnesic in 1953, at 27 years of age, when he sustained a bilateral resection of the medial temporal lobe to relieve severe epilepsy. The removal included approximately one-half of the hippocampus, the amygdala, and most neighboring entorhinal and perirhinal cortices (Fig. 34-6). After the surgery, HM's seizure condition was much improved, but he experienced profound forgetfulness. His intellectual functions were generally preserved. For example, HM exhibited normal immediate memory, and he could maintain his attention during conversations. After an interruption, however, HM could not remember what had recently occurred. HM's dense amnesia was permanent and debilitating. In HM's words, he felt as if he were waking from a dream because he had no recollection of what had just happened.

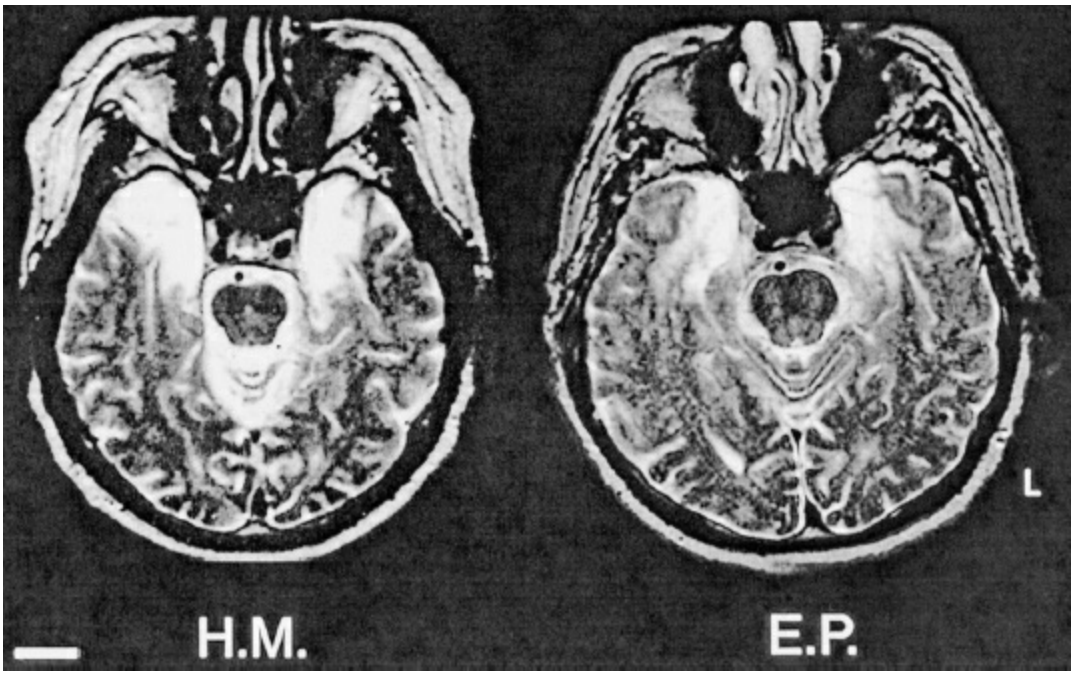

FIGURE 34-6
Structural magnetic resonance images of the brains of patients HM and EP through the level of the temporal lobe. Damaged tissue is indicated by bright signal in these T2-weighted axial images. Both patients sustained extensive damage to medial temporal structures, as the result of surgery for epilepsy in HM, and as the result of viral encephalitis in EP. Scale bar: 2 cm. L, left side of the brain. (Reprinted from Corkin S, Amaral EG, González RG, Johnson KA, Hyman BT. H. M.'s medial temporal lobe lesion: Findings from magnetic resonance imaging. *J Neurosci*. 1997;17(10):3964–3979 and Stefanacci L, Buffalo EA, Schmolck H, Squire LR. Profound amnesia after damage to the medial temporal lobe: A neuroanatomical and neuropsychological profile of patient E.P. *J Neurosci*. 2000;20(18):7024–7036, with permission.)

In monkeys, many parallels to human amnesia have been demonstrated after surgical damage to anatomical components of the medial temporal lobe. Cumulative study of the resulting memory impairment eventually identified the medial temporal structures and connections crucial for memory. These include the hippocampus, including the dentate gyrus, hippocampal fields CA1, CA2, CA3, and the subiculum—and the adjacent cortical regions, including the entorhinal, perirhinal, and parahippocampal cortices.

Another important medial temporal lobe structure is the amygdala. The amygdala is involved in the regulation of much of emotional behavior. In particular, the storage of emotional events engages the amygdala. Modulatory effects of projections from the amygdala to the neocortex are responsible for producing enhanced memory for emotional or arousing events compared to

neutral events.

A detailed study of amnesic patients offers unique insights into the nature of memory and its organization in the brain. An extensive series of informative studies, for example, described the memory impairment of patient EP.

EP was diagnosed with herpes simplex encephalitis at 72 years of age. Damage to the medial temporal lobe region (see Fig. 34-6) produced persistent and profound amnesia. During testing sessions, EP was cordial and talked freely about his life experiences, but he relied exclusively on stories from his childhood and early adulthood. He would repeat the same story many times. Strikingly, his performance on tests of recognition memory was no better than would result from guessing (Fig. 34-7A). Tests involving facts about his life and autobiographical experiences revealed poor memory for the time leading up to his illness but normal memory for his childhood (Fig. 34-7B). EP also has good spatial knowledge about the town in which he lived as a child, but he was unable to learn the layout of the neighborhood where he moved to after he became amnesic (Fig. 34-7C).

Given the severity of the memory problems experienced by EP and other amnesic patients, it is noteworthy that these patients nonetheless perform typically on certain kinds of memory tests. The impairment selectively concerns memory for factual knowledge and autobiographical events, collectively termed *declarative memory.* Amnesia presents as a global deficit, in that it involves memory for information presented in any sensory modality, but the deficit is limited, in that it covers only memory for facts and events.

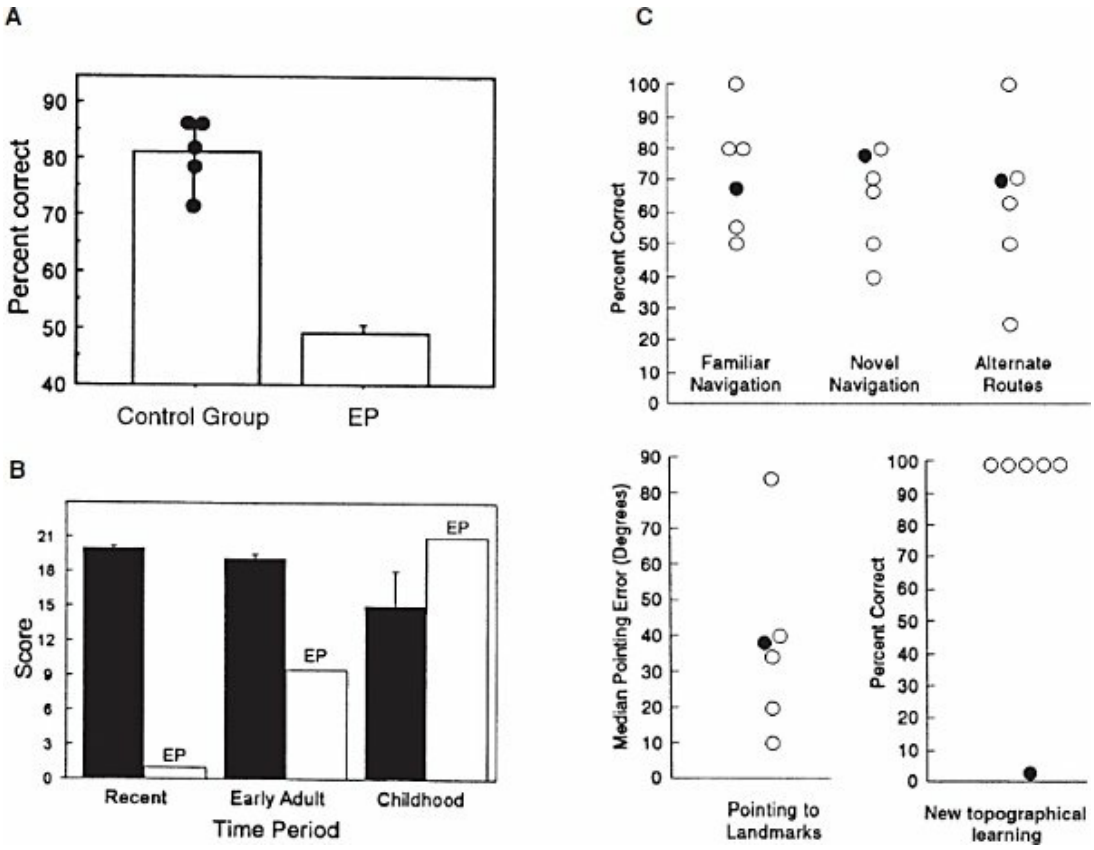

FIGURE 34-7

Formal test results for patient EP, showing severe anterograde and retrograde deficits, with intact remote memory. **A:** Scores were combined from 42 different tests of recognition memory for words given to patient EP and a group of five healthy control subjects. The testing format was either two-alternative forced choice or yes–no recognition. Brackets for EP indicate the standard error of the mean. Data points for the control group indicate each participant's mean score across all 42 recognition memory tests. EP's average performance (49.3 percent correct) was not different from chance and was approximately five standard deviations (SDs) below the average performance of control subjects (81.1 percent correct; SD, 6.3). **B:** Autobiographical remembering was quantified by using a structured interview known as the Autobiographical Memory Interview. Items assessed personal semantic knowledge (maximum score 21 for each time period). Performance for the recent time period reflects poor memory for information that could have been acquired only subsequent to the onset of his amnesia. For EP, performance for the early adult period reflects retrograde memory deficits. Performance for the childhood period reflects good remote memory. Similar results for semantic and episodic remembering were obtained from these time periods. (Data from Kopelman MD, Wilson BA, Baddeley AD. The autobiographical memory interview: A new assessment of autobiographical and personal semantic memory in amnesic patients. *J Clin Exp Neuropsychol.* 1989;5:724; and Reed JM, Squire LR. Retrograde amnesia for facts and events: Findings from four new cases. *J Neurosci.* 1998;18:3943). **C:** Assessments of spatial memory demonstrated EP's good memory for spatial knowledge from his childhood, along with extremely poor new learning of spatial information.

Performance was compared to that of five individuals (*open circles*) who attended EP's high school at the same time as he did, lived in the region over approximately the same time period, and, like EP (*filled circles*), moved away as young adults. Normal performance was found for navigating from home to different locations in the area (familiar navigation), between different locations in the area (novel navigation), and between these same locations when a main street was blocked (alternative routes). Subjects were also asked to point to particular locations while imagining themselves in a particular location (pointing to landmarks), or they were asked about locations in the neighborhoods in which they currently lived (new topographical learning). EP showed difficulty only in this last test, because he moved to his current residence after he became amnesic. (Data from Teng E, Squire LR. Memory for places learned long ago is intact after hippocampal damage. *Nature.* 1999;400:675.) (Adapted from Stefanacci L, Buffalo EA, Schmolck H, Squire LR. Profound amnesia after damage to the medial temporal lobe: A neuroanatomical and neuropsychological profile of patient E. P. *J Neurosci*. 2000;20(18):7024–7036. Printed with permission.)

Hippocampal pathology in patients with amnesia can also be revealed using high-resolution magnetic resonance imaging (MRI). Such studies indicate that damage limited to the hippocampus results in clinically significant memory impairment. In addition to the hippocampus, other medial temporal lobe regions also make critical contributions to memory. Thus, a moderately severe memory impairment results from CA1 damage, whereas a more profound and disabling amnesia results from medial temporal lobe damage that includes the hippocampus and adjacent cortex. Memory impairment due to medial temporal lobe damage is also typical in patients with early Alzheimer disease or amnestic mild cognitive impairment. As Alzheimer disease progresses, the pathology affects many cortical regions and produces substantial cognitive deficits and memory dysfunction.

Amnesia can also result from damage to structures of the medial diencephalon. The critical regions damaged in diencephalic amnesia include the mammillary nuclei in the hypothalamus, the dorsomedial nucleus of the thalamus, the anterior nucleus, the internal medullary lamina, and the mammillothalamic tract. However, uncertainty remains regarding which specific lesions are required to produce diencephalic amnesia. *Alcoholic Korsakoff syndrome* is the most prevalent and best-studied example of diencephalic amnesia, and in these cases, the damage is found in brain regions that may be especially sensitive to prolonged bouts of thiamine deficiency and alcohol abuse. Patients with alcoholic Korsakoff syndrome typically exhibit memory impairment due to a combination of diencephalic

damage and frontal lobe pathology. Frontal damage alone produces characteristic cognitive deficits and specific memory problems (e.g., in effortful retrieval and evaluation); in Korsakoff syndrome, the pattern of deficits thus extends beyond what is commonly found in other amnesia cases (see Table 34-6).

Table 34-6
Memory and Cognitive Deficits Associated with Frontal Damage

Test	Amnesia	Korsakoff Syndrome	Frontal Lobe Damage
Delayed recall	+	+	−
Dementia Rating Scale: Memory index	+	+	−
Dementia Rating Scale: Initiation and perseveration index	−	+	+
Wisconsin Card Sorting Test	−	+	+
Temporal order memory	+	++	++
Metamemory	−	+	+
Release from proactive interference	−	+	−

+, deficit; −, no deficit; ++, disproportionate impairment relative to item memory.

From Squire LR, Zola-Morgan S, Cave CB, Haist F, Musen G, Suzuki WA. *Memory, organization of brain systems and cognition Cold Spring Harb Symp Quant Biol*. 1990;55:1007.

The ability to remember factual and autobiographical events depends on the integrity of both the cortical regions responsible for representing the information in question and several brain regions responsible for memory formation. Thus, medial temporal and diencephalic brain areas work in concert with widespread areas of neocortex to form and to store declarative

memories (Fig. 34-8).

Retrograde Amnesia

Memory loss in amnesia typically affects recent memories more than remote memories (Fig. 34-9). Temporally graded amnesia has been demonstrated retrospectively in studies of amnesic patients and prospectively in studies of monkeys, rats, mice, and rabbits. These findings have important implications for understanding the nature of the memory storage process. Memories are dynamic, not static. As time passes after learning, some memories are forgotten, whereas others become stronger due to a process of *consolidation* that depends on cortical, medial temporal, and diencephalic structures.

The study of retrograde amnesia has been important for understanding how memory changes over time. The dynamic nature of memory storage can be conceptualized as follows. An event is experienced and encoded by a collection of cortical regions involved in representing a combination of different event features. At the same time, the hippocampus and adjacent cortex receive pertinent high-level information from all sensory modalities. Later, when the original event is recalled, the same set of cortical regions is activated. If a subset of the cortical regions is activated, the hippocampus and related structures can facilitate recall by facilitating the remaining cortical regions (i.e., pattern completion). When the original event is retrieved and newly associated with other information, hippocampal–cortical networks can be modified. In this way, a gradual consolidation process occurs that changes memory storage (see Fig. 34-8). The neocortical components representing some events can become so effectively linked together that ultimately a memory can be retrieved without any contribution from the medial temporal lobe. As a result, amnesic patients can exhibit normal retrieval of remote facts and events and autobiographical memories. Distributed neocortical regions are the permanent repositories of these enduring memories.

In contrast to what is observed after damage restricted to the hippocampus, extensive retrograde impairments for facts and events from the distant past can also occur. Damage to the frontal lobes, for example, can lead to difficulty in organizing memory retrieval. Accurate retrieval often begins with activation of lifetime periods and proceeds to identify general classes of events and then more specific events, but this process becomes difficult

following frontal damage. Damage to other cortical regions can also impair memory storage. Networks in the anterolateral temporal cortex, for example, are critical for retrieving stored information because these areas are essential for long-term storage itself. Patients with *focal retrograde amnesia* exhibit substantial retrograde memory impairments together with only moderately impaired new learning ability. Some capacity for new learning remains, presumably, because medial temporal lobe structures can communicate with other areas of the cortex that remain undamaged.

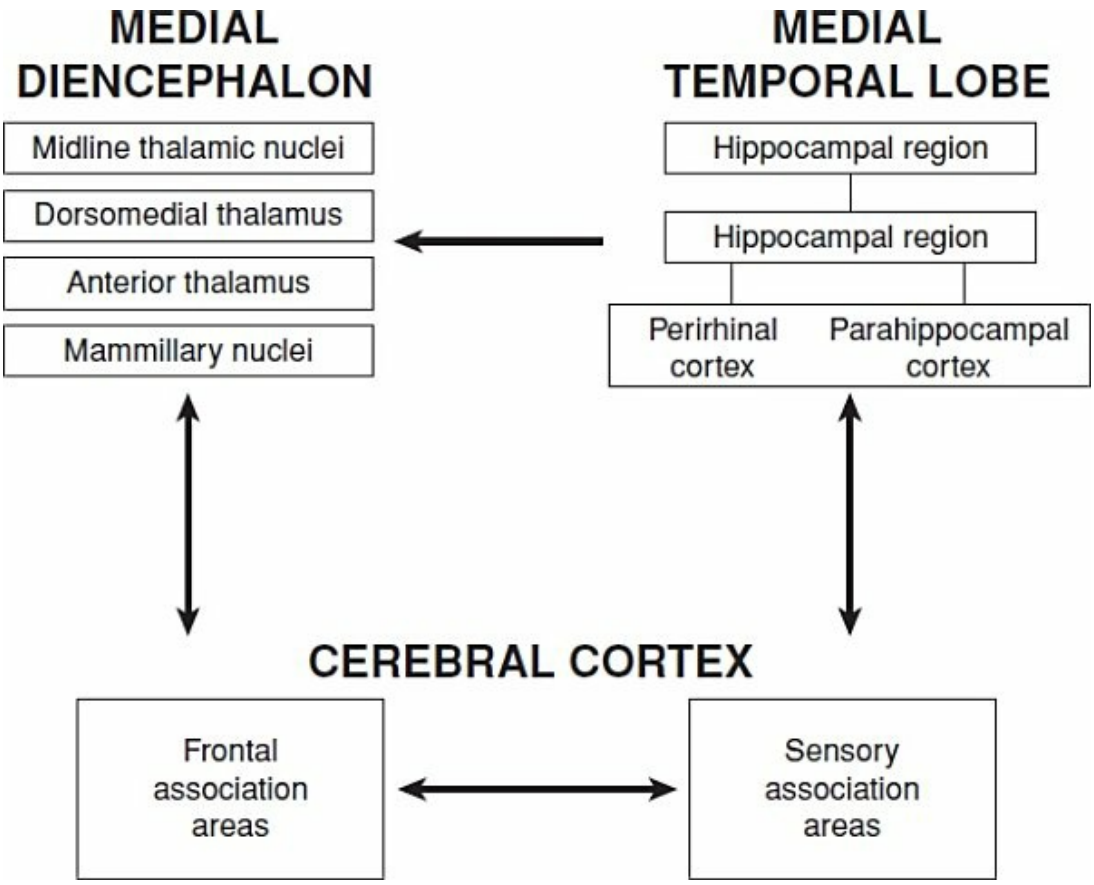

FIGURE 34-8
Brain regions believed to be critical for the formation and storage of declarative memory. Medial diencephalon and medial temporal regions are critical for declarative memory storage. The entorhinal cortex is the major source of projections for the neocortex to the hippocampus, and nearly two-thirds of the cortical input to the entorhinal cortex originates in the perirhinal and parahippocampal cortex. The entorhinal cortex also receives direct connections from the cingulate, insula, orbitofrontal, and superior temporal cortices. (Adapted from Paller KA. Neurocognitive foundations of human memory. In: Medin DL, ed.: *The Psychology of Learning and Motivation*. Vol. 40. San Diego, CA: Academic Press; 2008:121 and Gluck MA, Mercado E, Myers CE. *Learning and Memory: From Brain to Behavior*. New York: Worth; 2008:109, Fig. 3-16.)

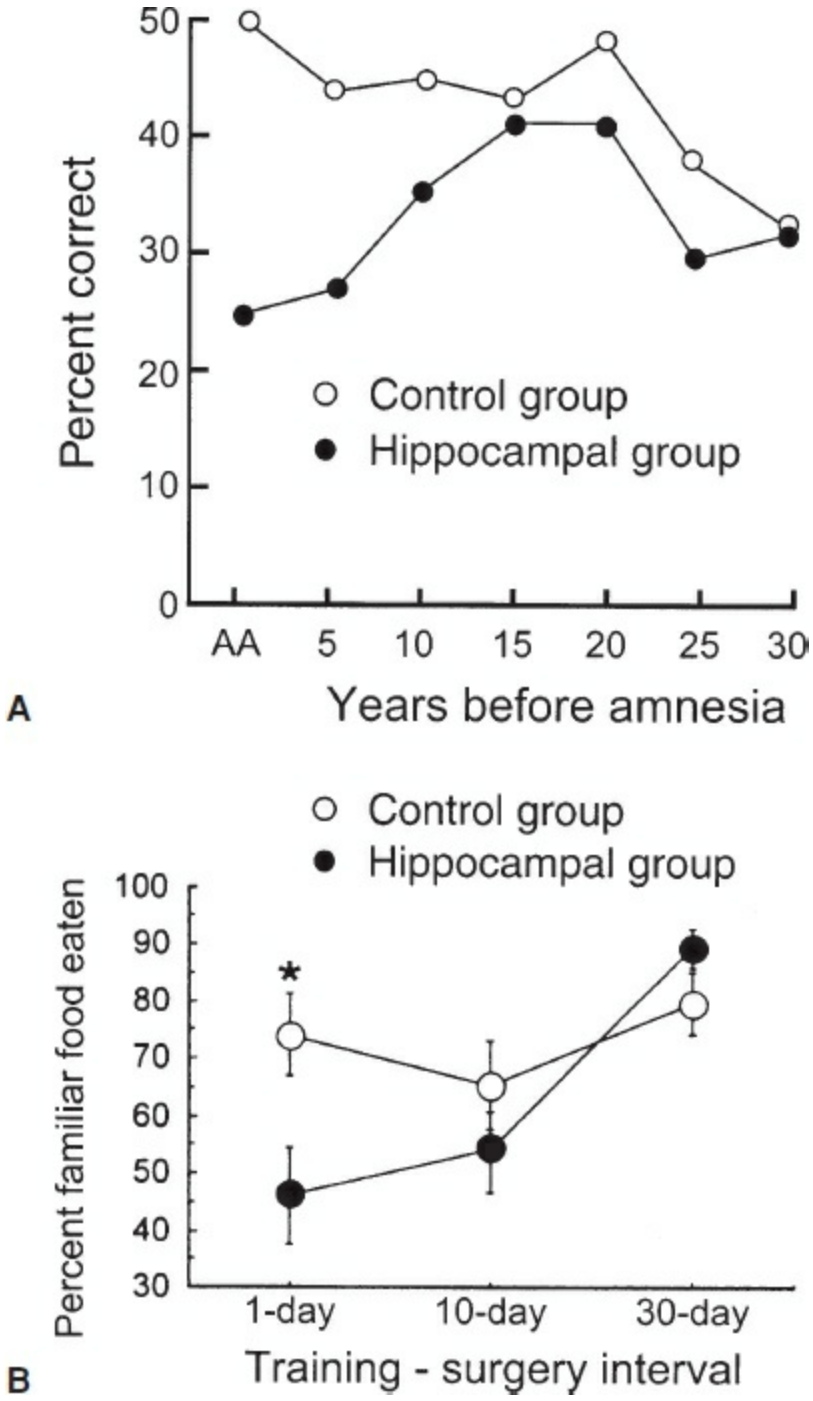

FIGURE 34-9

A: Temporally limited retrograde amnesia for free recall of 251 news events. Scores were aligned relative to the onset of amnesia in patients (*N* = 6) and to a corresponding time point in age-matched and education-matched healthy individuals (*N* = 12). The time period after the onset of amnesia is labeled AA (anterograde amnesia) to designate that this time point assessed memory for events that occurred after the onset of amnesia. Standard errors ranged from 2 to 10 percent. Brain damage in the patient group was limited primarily to the hippocampal region. **B:** Temporally limited retrograde amnesia in rats with lesions

of the hippocampus and subiculum. Rats learned to prefer an odorous food as the result of an encounter with another rat with that odor on its breath. Percent preference for the familiar food was observed for three training-surgery intervals. At 1 day after learning, the control group performed significantly better than the rats with lesions ($p < 0.05$). At 30 days, the two groups performed similarly, and both groups performed well above chance. *Error bars* show standard errors of the mean. (Adapted from Manns JR, Hopkins RO, Squire LR. Semantic memory and the human hippocampus. *Neuron*. 2003;38(1):127–133 and Clark RE, Broadbent NJ, Zola SM, Squire LR. Anterograde amnesia and temporally graded retrograde amnesia for a nonspatial memory task after lesions of hippocampus and subiculum. *J Neurosci*. 2002;22(11):4663–4669, with permission.)

MULTIPLE TYPES OF MEMORY

Memory is not a single faculty of the mind but consists of various subtypes. Amnesia affects only one kind of memory, *declarative memory*. Declarative memory is what is ordinarily meant by the term *memory* in everyday language. Declarative memory supports the conscious recollection of facts and events. The classic impairment in amnesia thus concerns memory for routes, lists, faces, melodies, objects, and other verbal and nonverbal material, regardless of the sensory modality in which the material is presented.

Amnesic patients can display a broad impairment in these components of declarative memory, while several other memory abilities are preserved. The heterogeneous set of preserved abilities is collectively termed *nondeclarative memory*. Nondeclarative memory includes skill learning, habit learning, simple forms of conditioning, and priming (see next section). For these kinds of learning and memory, amnesic patients can perform normally.

In controlled laboratory settings, the acquisition of a variety of perceptual, perceptual-motor, and cognitive skills can be tested in isolation, and amnesic patients are found to acquire these skills at rates equivalent to the rates at which healthy individuals acquire the skills. For example, amnesic patients can learn to read mirror-reversed text normally, they exhibit the typical facilitation in reading speed with successive readings of ordinary prose, and they improve as rapidly as healthy individuals at a speeded reading of repeating nonwords. Also, amnesic patients can, after seeing strings of letters generated by a finite-state rule system, classify novel strings of letters as rule-based or not rule-based. Classification performance is normal even though amnesic patients are impaired at remembering the events of training or the

specific items they have studied.

Priming

Priming refers to the facilitation of the ability to detect or to identify a particular stimulus based on a specific recent experience. Many tests have been used to measure priming in amnesia and show that it is intact. For example, words might be presented in a study phase and then again, after a delay, in a test phase, when a priming measure such as reading speed is obtained. Patients are instructed to read words as quickly as possible in such a test, and they are not informed that memory is being assessed.

In one priming test, patients named pictures of previously presented objects reliably faster than they named pictures of new objects, even after a delay of 1 week. This facilitation occurred at normal levels, even though the patients were markedly impaired at recognizing which pictures had been presented previously. Particularly striking examples of preserved priming come from studies of patient EP (Fig. 34-10), who exhibited intact priming for words but performed at chance levels when asked to recognize which words had been presented. This form of memory, termed *perceptual priming,* is thus a distinct class of memory independent of the medial temporal lobe regions typically damaged in amnesia.

Another form of priming reflects improved access to meaning rather than percepts. For example, subjects study a list of words, including *tent* and *belt,* and then are asked to free-associate them. Thus, they are given words such as *canvas* and *strap* and asked to produce the first word that comes to mind. The result is that subjects are more likely to produce *tent* in response to *canvas* and to produce *belt* in response to *strap* than if the words *tent* and *belt* had not been presented recently. This effect, called *conceptual priming,* is also preserved in amnesic patients, even though they fail to recognize the same words on a conventional memory test (Fig. 34-11).

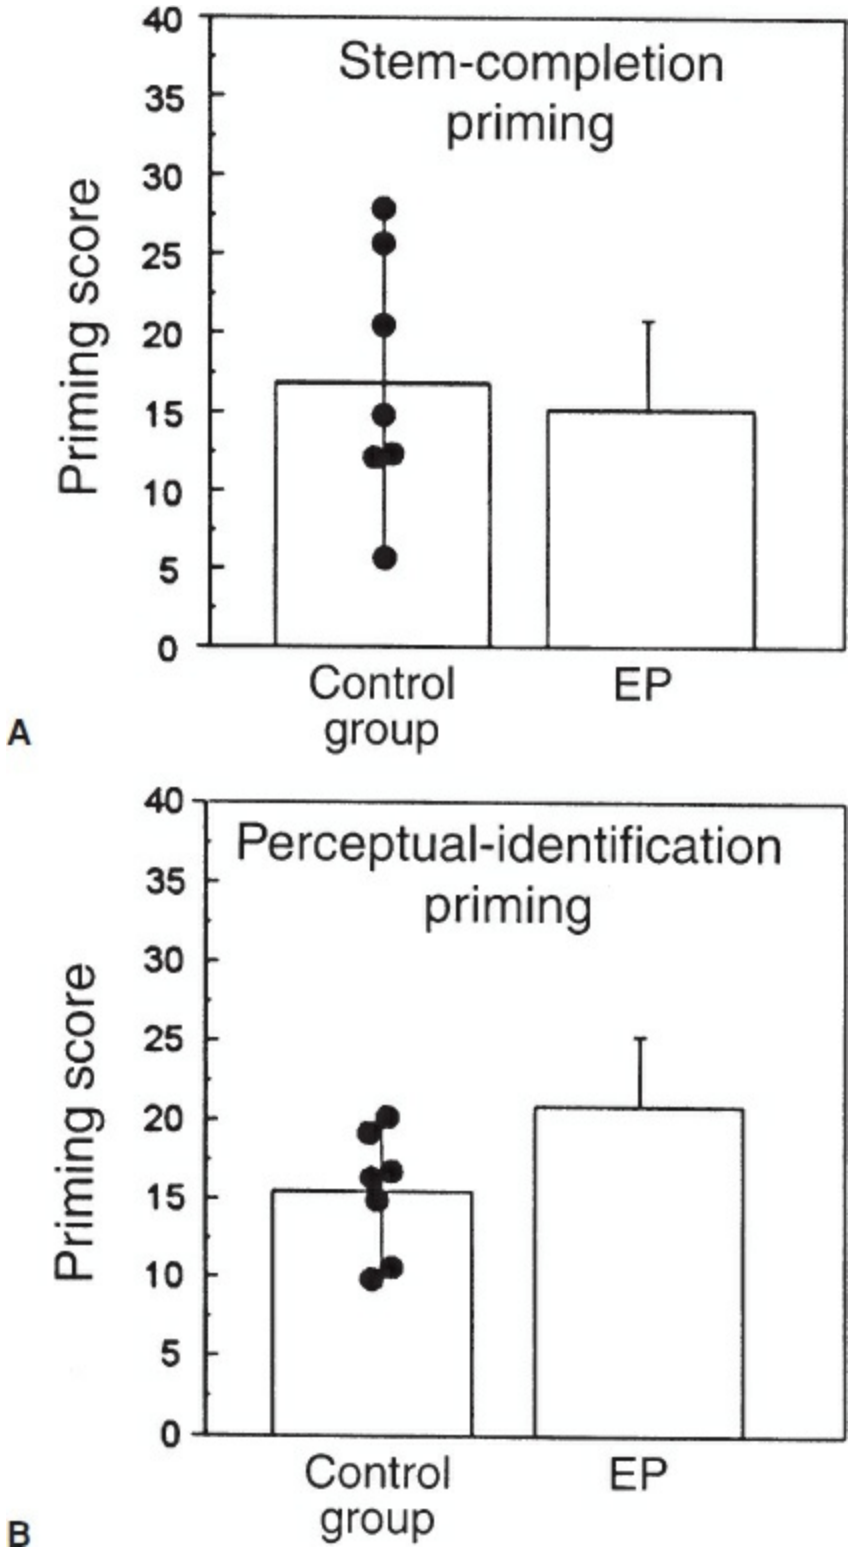

FIGURE 34-10

Preserved priming in patient EP relative to seven control subjects. **A:** Stem-completion priming on six separate tests. Priming reflected a tendency for subjects to complete three-letter stems with previously encountered words when they were instructed to produce the first word to come to mind (e.g., MOT___

completed to form MOTEL). Priming scores were calculated as percentage correct for studied words minus percentage correct for baseline words (guessing). **B:** Perceptual-identification priming on 12 separate tests. Subjects attempted to read 48 words that were visually degraded. Priming scores were calculated as percentage correct identification of previously studied words minus percentage correct identification of nonstudied words. Brackets indicate standard error of the mean. (Data from Hamann SB, Squire LR. Intact perceptual memory in the absence of conscious memory. *Behav Neurosci*. 1997;111:850.) (Reprinted from Stefanacci L, Buffalo EA, Schmolck H, Squire LR. Profound amnesia after damage to the medial temporal lobe: A neuroanatomical and neuropsychological profile of patient E. P. *J Neurosci*. 2000;20(18):7024–7036, with permission.)

Not all types of priming are preserved in amnesia. Some priming tests have been designed to examine the formation of new associations. When priming tests are based not on preexisting knowledge but the acquisition of new associative knowledge, priming tends to be impaired. In other words, priming in certain complex situations can require the same type of linkage among multiple cortical regions critical for declarative memory.

Memory Systems

Table 34-7 depicts one scheme for conceptualizing multiple types of memory. Declarative memory depends on medial temporal and midline diencephalic structures along with large portions of the neocortex. This system provides for the rapid learning of facts (*semantic memory*) and events (*episodic memory*). Nondeclarative memory depends on several different brain systems. Habits depend on the neocortex and the neostriatum, and the cerebellum is essential for the conditioning of skeletal musculature, the amygdala for emotional learning, and the neocortex for priming.

Declarative memory and nondeclarative memory differ in significant ways. Declarative memory is phylogenetically more recent than nondeclarative memory. Also, declarative memories are available to conscious recollection. The flexibility of declarative memory permits the retrieved information to be available to multiple response systems. Nondeclarative memory is inaccessible to awareness and is expressed only by engaging specific processing systems. Nondeclarative memories are stored as changes within these processing systems—changes encapsulated such that the stored information has limited access to other processing systems.

Semantic memory, which concerns general knowledge of the world, has

often been categorized as a separate form of memory. Facts committed to memory typically become independent of the original episodes in which the facts were learned. Amnesic patients can sometimes acquire information that would ordinarily be learned as facts, but the patients learn it by relying on a different brain system than the system that supports declarative memory.

Consider a test requiring the concurrent learning of eight object pairs. Healthy individuals can rapidly learn which the correct object in each pair is, whereas severely amnesic patients like EP learn only gradually over many weeks, and at the start of each session, they cannot describe the task, the instructions, or the objects. In patients who do not have severe amnesia, factual information is typically acquired as conscious declarative knowledge. In these cases, the brain structures that remain intact within the medial temporal lobe presumably support learning. In contrast, when factual information is acquired as nondeclarative knowledge, as in the case of EP's learning of pairs of objects, learning likely occurs directly as a habit, perhaps supported by the neostriatum. Humans thus appear to have a robust capacity for habit learning that operates outside of awareness and independent of the medial temporal lobe structures that are damaged in amnesia.

Frontal Contributions to Memory

Although amnesia does not occur after limited frontal damage, the frontal lobes are fundamentally crucial for declarative memory. Patients with frontal lesions have a poor memory for the context in which information was acquired, they have difficulty in unaided recall, and they may even have some mild difficulty on tests of item recognition. More generally, patients with frontal lesions have difficulty implementing memory retrieval strategies and evaluating and monitoring their memory performance.

NEUROIMAGING AND MEMORY

The understanding of memory derived from studies of amnesia has been extended through studies using various methods for monitoring brain activity in healthy individuals. For example, activation of posterior prefrontal regions with positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) have shown that these regions are involved in strategic processing during retrieval and working memory. Anterior frontal regions

near the frontal poles have been linked with functions such as evaluating the products of retrieval. Frontal connections with posterior neocortical regions support the organization of retrieval and the manipulation of information in working memory. Consistent with the evidence from patients with frontal lesions, frontal–posterior networks can be viewed as instrumental in the retrieval of declarative memories and the online processing of new information.

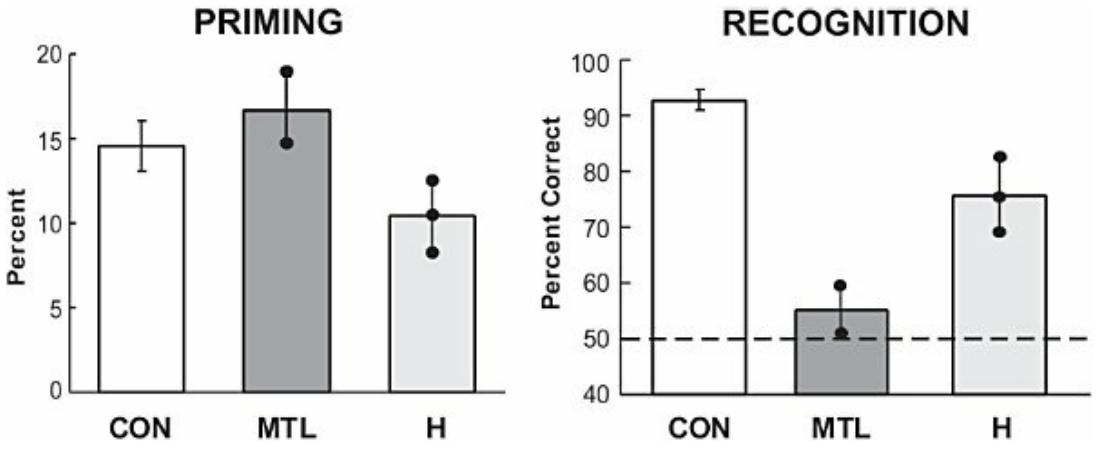

FIGURE 34-11

Preserved conceptual priming in amnesia. In the free association test, subjects studied a set of words (e.g., *lemon*) and 5 minutes later viewed cue words that included associates of the studied words (e.g., *orange*). Subjects were asked to produce the first word that came to mind in response to each cue word. Results are shown separately for the control group (CON; *n* = 12), amnesic patients with large medial temporal lobe lesions (MTL; *n* = 2), and amnesic patients with lesions believed to be limited to the hippocampal region (H; *n* = 3). The **left panel** shows conceptual priming scores computed as the percentage of studied words produced in the free association test minus a baseline measure of the likelihood of producing those words by chance. All of the groups performed similarly in the conceptual priming test. The **right panel** shows results from a yes–no recognition memory test using comparable words. Both patient groups were impaired relative to the control group. The *dashed line* indicates chance performance. The data points for the MTL and H groups show the scores of individual patients averaged across four separate tests. *Brackets* show standard errors of the mean for the control group. (Reprinted from Levy DA, Stark CEL, Squire LR. Intact conceptual priming in the absence of declarative memory. *Psychol Sci*. 2004;15(10):680–686, with permission.)

Neuroimaging has also identified contributions to memory made by the parietal cortex. Multiple parietal regions (including inferior and superior parietal lobules, precuneus, posterior cingulate, and retrosplenial cortex) are activated in conjunction with remembering recent experiences. Although

many functions have been hypothesized to explain this parietal activity, a single consensus position has not yet been reached, and it may be the case that several different functions are relevant.

Neuroimaging studies have also illuminated priming phenomena and how they differ from declarative memory. Perceptual priming appears to reflect changes in the early stages of the cortical pathways engaged during perceptual processing. For example, in the case of stem-completion priming, in which subjects study a list of words (e.g., MOTEL) and then are tested with a list of stems (e.g., MOT___) and with instructions to complete each stem with the first word to come to mind, neuroimaging and divided visual-field studies have implicated visual processing systems in extrastriate cortex, especially in the right hemisphere. In contrast, the conscious recollection of remembered words engages brain areas at later stages of processing. Neural mechanisms supporting priming and declarative memory retrieval have also been distinguished in brain electrical activity recorded from the scalp (Fig. 34-12). In sum, priming differs from declarative memory in that it is signaled by brain activity that occurs earlier, and that originates in different brain regions.

Table 34-7
Types of Memory

   3. Simple classical conditioning
   4. Nonassociative learning

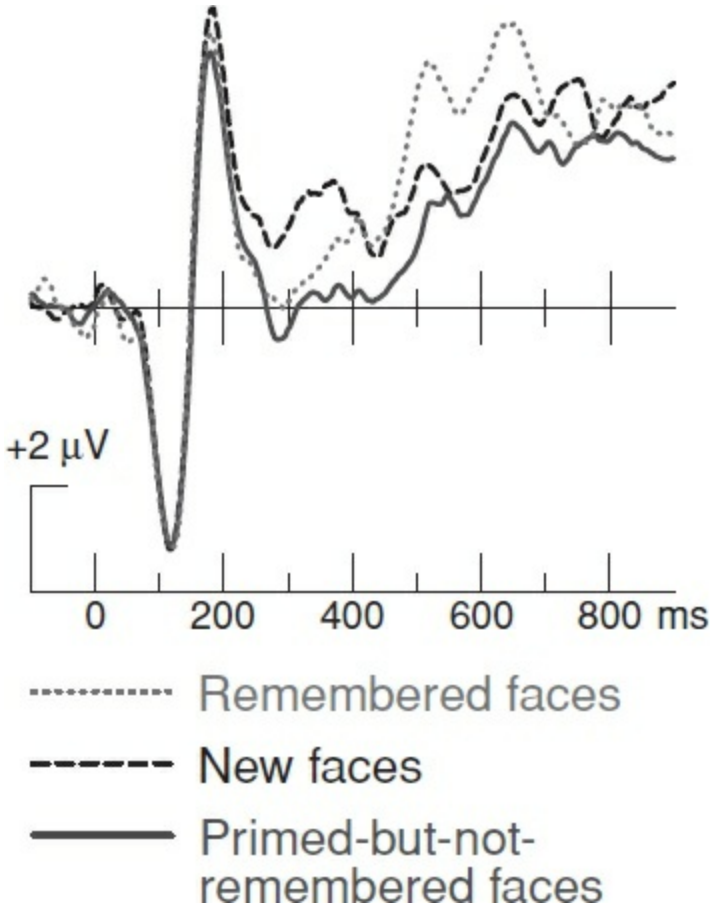

FIGURE 34-12
Brain potentials associated with perceptual priming versus declarative memory retrieval. Paller et al. (2003) studied 16 volunteers, who took a memory test involving three sorts of faces: new faces, faces they had seen recently and remembered well, and faces they had seen but did not remember because the faces had been presented too briefly to process effectively. In a companion experiment with a priming test, speeded responses were found, indicative of priming. Frontal recordings of brain waves elicited by the primed faces included negative potentials from 200 to 400 ms after face presentation that differed from the brain waves elicited by new faces. These differences were particularly robust for trials with the fastest responses (data shown were from trials with responses faster than the median reaction time). Remembered faces uniquely elicited positive brain waves that began about 400 ms after face presentation. Brain potential correlates of face recollection occurred later than those for perceptual priming and were larger over posterior brain regions. (Adapted from Paller KA, Hutson CA, Miller BB, Boehm SG. Neural manifestations of memory with and without awareness. *Neuron*. 2003;38(3):507–516, with permission.)

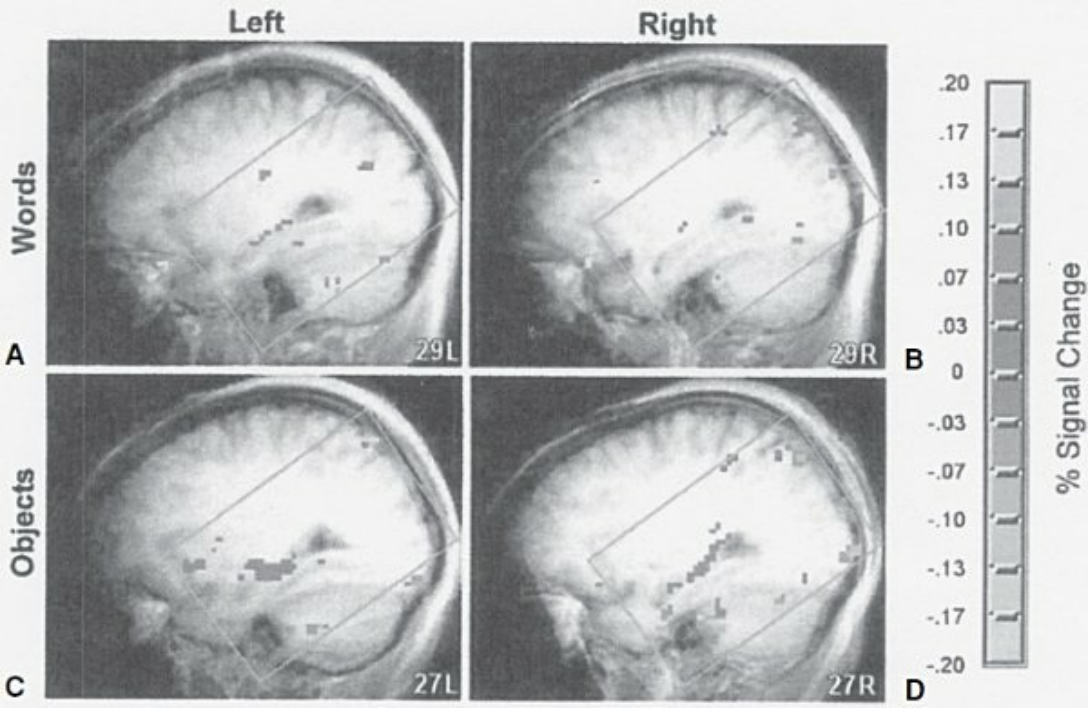

FIGURE 34-13
Activity in the left and right hippocampal regions measured with functional magnetic resonance imaging (fMRI) during declarative memory retrieval. Data were collected from 11 participants who saw words at study and test and from 11 different participants who saw pictures of namable objects at study and test. Recognition memory accuracy was 80.2 percent correct for words and 89.9 percent correct for objects. Areas of significant fMRI signal change (targets vs. foils) are typically shown in sagittal sections as color overlays on averaged structural images. The *box* indicates the area in which reliable data were available for all subjects. With words, retrieval-related activity was observed in the hippocampus on the left side (**A**) but not on the right side (**B**). With namable objects, retrieval-related activity was observed in the hippocampus on both the left side (**C**) and the right side (**D**). (Reprinted from Stark CE, Squire LR. Functional magnetic resonance imaging (fMRI) activity in the hippocampal region during recognition memory. *J Neurosci*. 2000;20(20):7776–7781, with permission.)

Hippocampal activity associated with the formation and retrieval of declarative memories has also been investigated with neuroimaging. In keeping with the neuropsychological evidence, the hippocampus appears to be involved in the recollection of recent events (Fig. 34-13). The retrieval-related hippocampal activity has been observed in memory tests with many different types of stimuli. The hippocampus is also active during the initial storage of information. Whereas the left inferior prefrontal cortex is engaged as a result of attempts to encode a word, hippocampal activity at encoding is more closely associated with whether encoding leads to a stable memory that

can later be retrieved (Fig. 34-14). These findings confirm and extend the idea that medial temporal and frontal regions are essential for memory storage and make different contributions.

SLEEP AND MEMORY

The speculation that memories are processed during sleep has a long history. Freud noted that dreams could reveal fragments of recent experiences in the form of day residues. Although many questions about how and why memories may be processed during sleep remain unresolved, recent experiments have provided new empirical support to bolster the idea that memory processing during sleep serves an adaptive function. It is now clear that memory performance can be facilitated when sleep occurs after initial learning, and that sleep-related facilitation can be observed for many different types of memory.

Memory storage appears to be aided explicitly by processing during deep sleep within a few hours after learning, especially in stages 3 and 4 (slow-wave sleep). Some results indicate that slow-wave sleep facilitates the storage of declarative memories but not nondeclarative memories. Direct evidence for this proposal has been obtained using stimulation with olfactory stimuli (Fig. 34-15), stimulation with direct current electrical input at the approximate frequency of electroencephalographic slow waves, and other methods. Furthermore, neuronal recordings in animals have revealed a phenomenon of hippocampal replay, in which activity patterns expressed during the day are later observed during sleep. In summary, declarative memories acquired during waking can be processed again during sleep, and this processing can influence the likelihood of subsequent memory retrieval when the individual is awake. The facilitation of declarative memory is typically manifest as a reduction in the amount of forgetting that occurs, not as an improvement in memory.

ASSESSMENT OF MEMORY FUNCTIONS

A variety of quantitative methods are available to assess memory functions in neurologic and psychiatric patients. Quantitative methods are useful for evaluating and following patients longitudinally and carrying out a one-time

examination to determine the status of memory function. It is desirable to obtain information about the severity of memory dysfunction, as well as to determine whether a memory is selectively affected or whether memory problems are occurring, as they often do, against a background of additional intellectual deficits. Although some widely available tests, such as the Wechsler Memory Scale, provide useful measures of memory, most single tests assess memory rather narrowly. Even general-purpose neuropsychological batteries provide for only limited testing of memory functions. A complete assessment of memory usually involves several specialized tests that sample intellectual functions, new learning capacity, remote memory, and memory self-report.

The assessment of general intellectual functions is central to any neuropsychological examination. In the case of memory testing, information about intellectual functions provides information about a patient's general test-taking ability and a way to assess the selectivity of memory impairment. Useful tests include the Wechsler Adult Intelligence Scale; a test of object naming, such as the Boston Naming Test; a rating scale to assess the possibility of global dementia; a test of word fluency; and specialized tests of frontal lobe function.

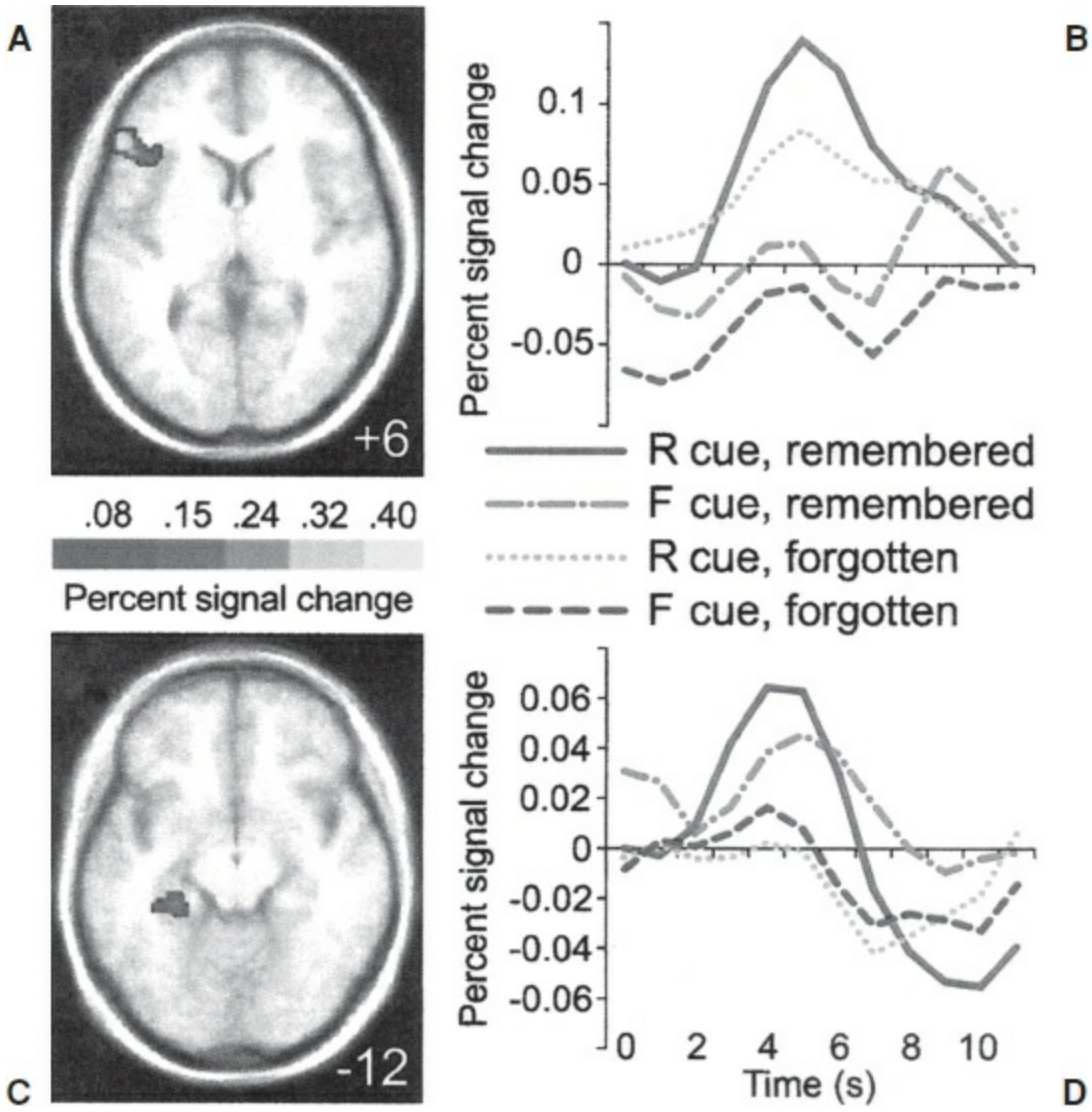

FIGURE 34-14

Functional activations of prefrontal and medial temporal regions that were predictive of later memory performance. Single words were presented visually, each followed by an instruction to remember (R cue) or to forget (F cue). Trials were sorted based on the remember or forget instruction and on subsequent recognition performance. Activity in the left inferior prefrontal cortex and left hippocampus was predictive of subsequent recognition but for different reasons. Left inferior prefrontal activation (**A**) was associated with the encoding attempt, in that responses were largest for trials with a cue to remember, whether or not the word was actually recognized later. The time course of activity in this region (**B**) was computed based on responses that were time locked to word onset (time 0). Left inferior prefrontal activity increased for words that were later remembered, but there was a stronger association with encoding attempt, because responses were larger for words followed by an R cue that were later forgotten than for words followed by an F cue that were later remembered. In contrast, left parahippocampal and posterior hippocampal activation (**C**) was associated with encoding success. As shown by the time course of activity in this region (**D**), responses were largest for words that were subsequently remembered, whether

the cue was to remember or to forget. (Reprinted from Reber PJ, Siwiec RM, Gitelman DR, Parrish TB, Mesulam MM, Paller KA. Neural correlates of successful encoding identified using functional magnetic resonance imaging. *J Neurosci*. 2002;22(21):9541–9548, with permission.)

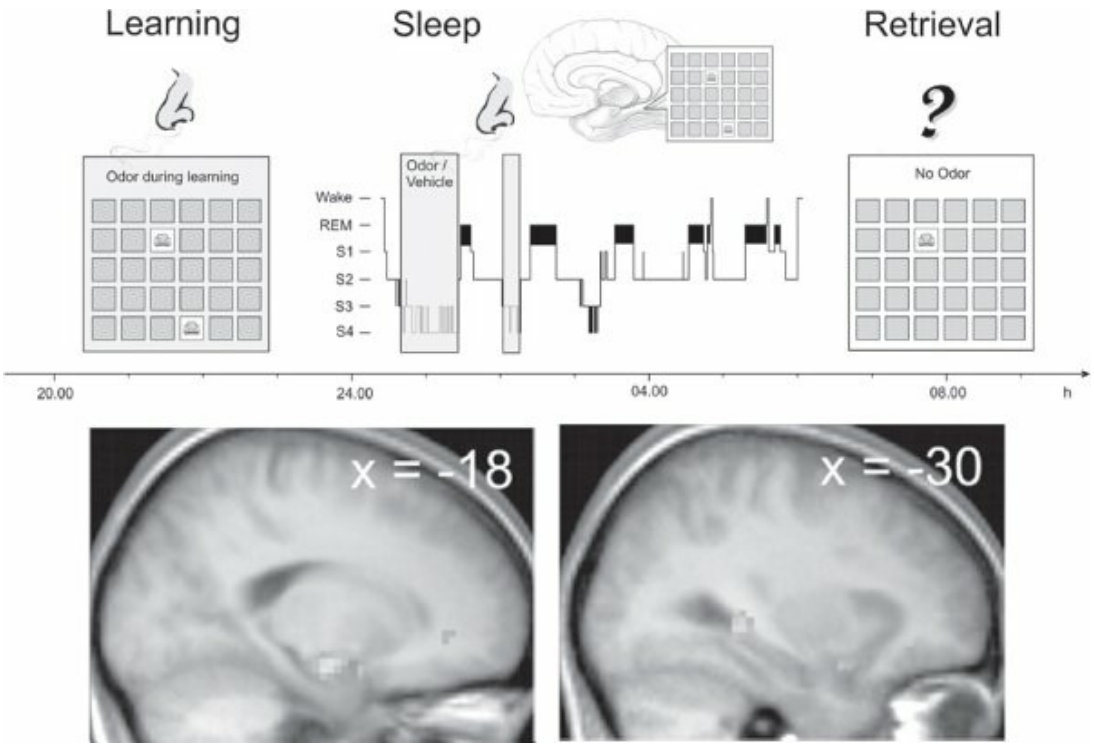

FIGURE 34-15
Evidence for memory processing during sleep. Subjects first learned object–location associations when a rose odor was present. Following learning, subjects slept wearing a device for delivering odors to the nose, and the rose odor was administered during the first two slow-wave sleep periods of the night (in 30-second periods to prevent habituation). Memory facilitation was observed when object–location associations were tested the following morning in the absence of odor stimulation. Facilitated memory was not found when stimulation occurred during slow-wave sleep but not during learning, when stimulation occurred during learning and then during rapid-eye-movement (REM) sleep, or when subjects were kept awake. Moreover, odor stimulation during slow-wave sleep was found to produce anterior and posterior hippocampal activation (**lower panels**). (Reprinted from Rasch B, Büchel C, Gais S, Born J. Odor cues during slow-wave sleep prompt declarative memory consolidation. *Science*. 2007;315(5817):1426–1429, with permission.)

New Learning Capacity

Memory tests are sensitive to impaired new learning ability when they adhere to either of two critical principles. First, tests are sensitive to memory impairment when more information is presented than can be held in

immediate memory. For example, one might ask patients to memorize a list of 10 faces, words, sentences, or digits, given that 10 items are more than can be held in mind. The paired-associate learning task is an especially sensitive test of this kind. In the paired-associate task, the examiner asks the patient to learn a list of unrelated pairs of words (e.g., queen–garden, office–river) and then to respond to the first word in each pair by recalling the second word.

Second, tests are sensitive to memory impairment when a delay, filled with distraction, is interposed between the learning phase and the test phase. In that case, examiners typically ask patients to learn a small amount of information and then distract them for several minutes by conversation to prevent rehearsal. Recollection is then assessed for the previously presented material. Memory can be tested by the unaided recall of previously studied material (free recall), presenting a cue for the material to be remembered (cued recall), or by testing recognition memory. In multiple-choice tests of recognition memory, the patient tries to select previously studied items from a group of studied and unstudied items. In yes–no recognition tests, patients see studied and unstudied items one at a time and are asked to say “yes” if the item was presented previously and “no” if it was not. These methods for assessing recently learned material vary in their sensitivity for detecting memory impairment, with free recall being most sensitive, cued recall intermediate, and recognition least sensitive.

The specialization of function of the two cerebral hemispheres in humans means that left and right unilateral damage is associated with different kinds of memory problems. Accordingly, different kinds of memory tests must be used when unilateral damage is a possibility. In general, damage to medial temporal or diencephalic structures in the left cerebral hemisphere causes difficulty remembering verbal material, such as word lists and stories. Damage to medial temporal or diencephalic structures in the right cerebral hemisphere impairs memory for faces, spatial layouts, and other nonverbal material that is typically encoded without verbal labels. Left medial temporal damage can lead to impaired memory for spoken and written text. Right medial temporal damage can lead to impaired learning of spatial arrays, whether the layouts are examined by vision or touch. A useful way to test for nonverbal memory is to ask a patient to copy a complex geometric figure, and then, after a delay of several minutes, without forewarning, ask the patient to reproduce it.

Remote Memory

Evaluations of retrograde memory loss should attempt to determine the severity of any memory loss and the period that it covers. Most quantitative tests of remote memory are composed of material in the public domain that can be corroborated. For example, tests have been used that concern news event, photographs of famous persons, or former one-season television programs. An advantage of these methods is that one can sample large numbers of events and often target particular periods. A disadvantage is that these tests are not so useful for detecting memory loss for information learned during the weeks or months immediately before the onset of amnesia. Most remote memory tests sample periods rather coarsely and cannot detect a retrograde memory impairment covering only a few months.

In contrast, autobiographical memory tests can potentially provide fine-grained information about a patient's retrograde memory. In the word-probe task, first used by Francis Galton in 1879, patients are asked to recollect specific episodes from their past in response to single word cues (e.g., bird and ticket) and date the episodes. The number of episodes recalled tends to be systematically related to the time the episode is taken. Most memories naturally come from recent periods (the last 1 to 2 months). In contrast, patients with amnesia often exhibit temporally graded retrograde amnesia, drawing relatively few episodic memories from the recent past but producing as many remote autobiographical memories as normal subjects (see Fig. 34-9).

Memory Self-Reports

Patients can often supply descriptions of their memory problems that are extremely useful for understanding the nature of their impairment. Tests of the ability to judge one's memory abilities are called tests of *metamemory.* Self-rating scales are available that yield quantitative and qualitative information about memory impairment. As a result, it is possible to distinguish memory complaints associated with depression from memory complaints associated with amnesia. Depressed patients tend to rate their memory as poor in a relatively undifferentiated way, endorsing equally all of the items on a self-rating form. By contrast, amnesic patients tend to endorse

some items more than others; that is, there is a pattern to their memory complaints. Amnesic patients do not report difficulty in remembering very remote events or in following what is being said to them, but they do report having difficulty remembering an event a few minutes after it happens. Indeed, self-reports can match rather closely the description of memory dysfunction that emerges from objective tests. Specifically, new-learning capacity is affected, immediate memory is intact, and very remote memory is intact. Some amnesic patients, however, tend to underestimate their memory impairment markedly. In patients with Korsakoff syndrome, for example, their poor metamemory stems from frontal lobe dysfunction. In any case, querying patients in some detail about their sense of impairment and administering self-rating scales are valuable and informative adjuncts to more formal memory testing.

Psychogenic Amnesia

Patients sometimes exhibit memory impairment that differs markedly from the typical patterns of memory loss that follow brain damage. For example, some cases of amnesia present with a sudden onset of retrograde amnesia, a loss of personal identity, and minimal anterograde amnesia. These patients may even be unable to recall their name. Given the psychological forces that prompt the onset of amnesia in these cases, they are commonly termed *psychogenic amnesia,* or sometimes *hysterical amnesia, functional amnesia,* or *dissociative amnesia.*

Differentiating psychogenic amnesia from a memory disorder that results from frank neurologic injury or disease is often straightforward. Psychogenic amnesias typically do not affect new-learning capacity. Patients enter the hospital able to record a continuing procession of daily events. By contrast, new-learning problems tend to be at the core of neurologic amnesia. The main positive symptom in psychogenic amnesia is extensive and severe retrograde amnesia. Patients may be unable to recollect pertinent information from childhood or some part of their past. Formal neuropsychological testing has shown that the pattern of memory deficits varies widely from patient to patient. This variability may reflect a patient’s commonsense concepts of memory, even when symptoms are not the result of conscious attempts to simulate amnesia. Some patients may perform poorly only when asked to

remember past autobiographical events. Other patients also may fail at remembering past news events. Some patients perform well when memory tests appear to assess general knowledge, such as remembering the names of celebrities or cities. Learning new material is usually intact, perhaps because such tests appear to concern the present moment, not traveling into the past. Occasionally, patients with psychogenic amnesia exhibit broad memory deficits such that they cannot perform previously familiar skills or identify everyday objects or common vocabulary words.

By contrast, patients with neurologic amnesia never forget their name, and remote memory for the events of childhood and adolescence is typically normal unless there is damage to the lateral temporal or frontal lobes. Patients with psychogenic amnesia sometimes have evidence of head trauma or brain injury, but the pattern of deficits cannot be taken as a straightforward result of neurologic insult. The clinician's challenge is not to distinguish psychogenic amnesia from neurologic amnesia, but to distinguish psychogenic amnesia from malingering. Indeed, the diagnosis of psychogenic amnesia can be difficult to substantiate and may be met with skepticism by hospital staff. Some features that argue in favor of a genuine psychogenic disorder include (1) memory test scores that are not as low as possible, and never worse than chance levels; (2) memory access that is improved by hypnosis or amobarbital (Amytal) interview; and (3) a significant premorbid psychiatric history. In some cases, psychogenic amnesia has been observed to clear after days, but in many cases, it has persisted as a potentially permanent feature of the personality.

IMPLICATIONS

Memory Distortion

Current understanding of the biology of memory has significant implications for several fundamental issues in psychiatry. Given the selective and constructive nature of autobiographical remembering and the imperfect nature of memory retrieval more generally, it is surprising that memory is so often accurate. How much can we trust our memories? Subjective feelings of confidence are not perfect indicators of retrieval accuracy. Moreover, memory distortion can lead to unfortunate consequences, such as when

mistaken eyewitness testimony harms an innocent individual.

It is possible to remember with confidence events that never happened. For example, it is possible to confuse an event that was only imagined or dreamed about with a real-life event. One factor contributing to memory distortion is that similar brain regions are essential both for visual imagery and for the long-term storage of visual memories (Fig. 34-16). Another factor contributing to memory distortion is that memory functions best in remembering the gist of an event, not the particulars from which the gist is derived. In a noted demonstration, people listen to a list of words: *Candy, sour, sugar, tooth, heart, taste, dessert, salt, snack, syrup, eat,* and *flavor.* Subsequently, when asked to write down the words they heard, 40 percent wrote down the word *sweet,* even though it did not appear on the list. Thus, many people in this demonstration failed to discriminate between the words presented and a word strongly associated with all the words but had not itself been presented. The word *sweet* can be thought of as a gist word, a word that represents the other words, which captures the meaning of the whole list. Presumably, the words in the study list evoked a thought of the word *sweet,* either at the time of learning or during the memory test, and people then tended to confuse merely thinking of the word with actually hearing it.

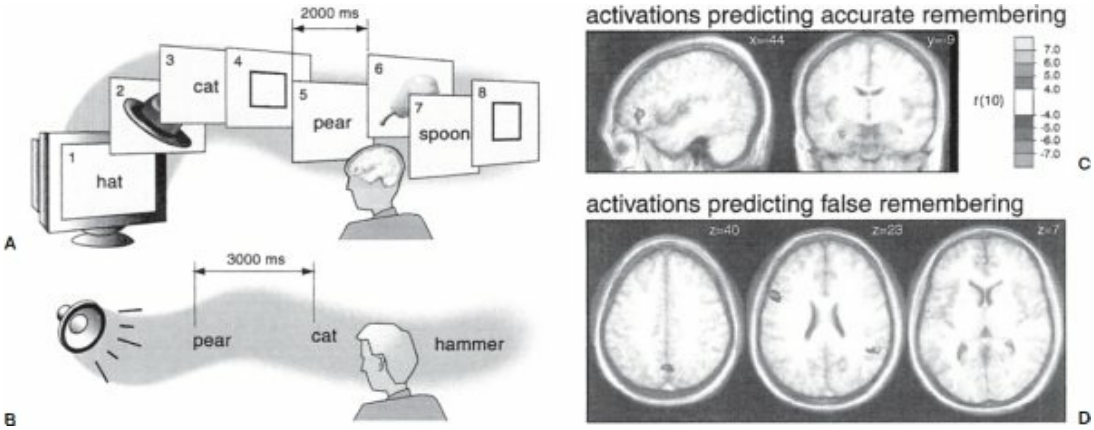

FIGURE 34-16

Neural substrates of false memories. **A:** Functional magnetic resonance imaging data were acquired in a learning phase, when subjects read names of objects and visualized the referents. One-half of the names were followed 2 seconds later by a picture of the object. **B:** In a surprise memory test given outside of the scanner, subjects listened to object names and decided whether they had seen a picture of the corresponding object. On some trials, subjects claimed to have seen a picture of an object that they had only imagined. **C:** Results showed that the left inferior prefrontal cortex and the left anterior hippocampus were more active during learning in response to pictures later remembered compared to pictures later

forgotten. **D:** Several different brain areas showed a greater response to words in the learning phase that were later falsely remembered as pictures compared to words not misremembered. Activations that predicted false remembering were found in a brain network important for the generation of visual imagery in response to object names (precuneus, inferior parietal cortex, and anterior cingulate, shown in the left, middle, and right images, respectively). (Reprinted from Gonsalves B, Reber PJ, Gitelman DR, Parrish TB, Mesulam MM, Paller KA. Neural evidence that vivid imagining can lead to false remembering. *Psychol Sci*. 2004;15(10):655–660, with permission.)

The reconstructive nature of recollection means that the interpretation of eyewitness testimony is not straightforward. Whole episodes are not available in the neocortex, but rather must be pieced together based on fragmentary components and in the context of potentially misleading influences present at the time of retrieval. Studies in adults and children have documented that illusory memories can be created. Children are particularly susceptible to these effects, especially when subjected to leading questions and false suggestions.

Given these features of memory, when memory for childhood abuse is remembered after many years, it is prudent to ask whether the memory is accurate. Genuine examples of memory recovery have been documented, whereby an individual produces a veridical memory for a past traumatic event after not recalling the event for extended periods. Numerous examples of apparent memory recovery have also been subsequently discovered to be instances of false memory. Unfortunately, there is no perfect method, in the absence of independent corroboration, for determining whether a recollective experience is based on a real event.

Infantile Amnesia

The biology of memory has also provided insights relevant to the phenomenon of infantile amnesia—the apparent absence of conscious memory for experiences from approximately the first 3 years of life. Traditional views of infantile amnesia have emphasized repression (psychoanalytic theory) and retrieval failure (developmental psychology). A common assumption has been that adults retain memories of early events but cannot bring them into consciousness. However, it now appears that the capacity for declarative memory does not become fully available until approximately the third year of life, whereas nondeclarative memory emerges

early in infancy (e.g., classical conditioning and skill learning). Thus, infantile amnesia results not from the adult's failure to retrieve early memories, but from the child's failure to store them adequately in the first place.

Nevertheless, studies in young infants show that a rudimentary capacity for declarative memory is present even at a few months of age. As a child develops, memories can be retained across increasingly long intervals, and what is represented becomes correspondingly richer and more full of detail. Medial temporal and diencephalic regions seem to be sufficiently developed during these early months and years. What limits the capacity for declarative memory appears to be the gradual development and differentiation of the neocortex.

As the neocortex develops, the memories represented there become more complex, language abilities allow for more elaborate verbal descriptions of events, and a developing sense of self supports autobiographical knowledge. As new strategies emerge for organizing incoming information, declarative memories become more persistent, more richly encoded, and better interconnected with other information. It is not the case that fully formed childhood memories are stored but cannot be retrieved. The perspective consistent with the current understanding of the biology of memory is that declarative memories formed very early in life are fragmentary, simple, and tied to the specific context of an infant's understanding of the world. They are unlike typical declarative memories in adults, which are imbued with meaning and a complex understanding of events.

Memories and the Unconscious

The existence of multiple memory systems also has implications for issues central to psychoanalytic theory, including the construct of the *unconscious.* How one believes that experience influences current behavior depends on what view one takes of the nature of memory. By the traditional view, memory is a unitary faculty, and representations in memory vary mainly in strength and accessibility. Unconscious material is below some threshold of accessibility but could potentially be made available to consciousness.

The modern, biologic view begins with the distinction between a kind of memory that can be brought to mind—declarative memory—and other kinds

of memory that are, by their nature, unconscious. Stored nondeclarative memories are expressed through performance without affording any conscious memory content. Nondeclarative memories shape our personalities in the form of numerous habits and conditioned responses. In this view, one's behavior is indeed affected by events from early life, but the effects of early experience persist in a nondeclarative form without necessarily including an explicit, conscious record of the events. Learned behavior can be expressed through altered dispositions, preferences, conditioned responses, habits, and skills, but exhibiting such behavior need not be accompanied by an awareness that behavior is being influenced by experience, nor is there a necessity that any particular experience has been recorded as a complete episode. That is, an influence from early experience does not require memory of any specific episode. One can be afraid of dogs without remembering being knocked down by a dog as a child. In this case, the fear of dogs is not experienced as a memory. It is experienced as a part of the personality. Furthermore, an intense fear of dogs carries with it no implication that the brain retains a specific record of any early experience that subsequently resulted in fear of dogs.

Behavioral change can occur by acquiring new habits that supersede old ones or by becoming sufficiently aware of a habit that one can to some extent isolate it, countermand it, or limit the stimuli that elicit it. However, one need not become aware of any early formative event in the same sense that one knows the content of declarative memory. The unconscious does not become conscious. Various forms of nondeclarative memory simply influence behavior without having the additional capacity for these influences to become accessible to conscious awareness.

34.2 Normality and Mental Health

There has been an implicit assumption that mental health could be defined as the antonym of mental illness. In other words, mental health was the absence of psychopathology and synonymous with *normal.* Achieving mental health by alleviating gross pathologic signs and symptoms of illness is also the definition of the mental health model strongly advocated by third-party

payers. Indeed, viewing mental health as simply the absence of mental illness is at the heart of much of the debate concerning mental health policies. The great epidemiologic studies of the last half-century also focused on who was mentally ill, and not well.

DEFINING MENTAL HEALTH

Several steps are necessary for defining positive mental health. The first step is to note that "average" is not healthy; it always includes mixing in with the healthy the prevalent amount of psychopathology in the population. For example, in the general population, being of "average" weight or eyesight is unhealthy, and if all sources of biopsychosocial pathology were excluded from the population, the average IQ would be significantly greater than 100.

The second step in discussing mental health is to appreciate the caveat that what is healthy sometimes depends on geography, culture, and the historical moment. Sickle cell trait is unhealthy in New York City, but in the tropics, where malaria is endemic, the sickling of red blood cells may be lifesaving.

The third step is to make clear whether one is discussing *trait* or *state.* Who is physically healthier—an Olympic miler disabled by a temporary but straightforward (state) sprained ankle or a person with type 1 diabetes (trait) with temporarily normal blood sugar? In cross-cultural studies, such differences become especially important. Superficially, an Indian mystic in a state of trance may resemble a person with catatonic schizophrenia, but the mystic does not resemble someone in the schizophrenic condition over time.

The fourth and most crucial step is to appreciate the twofold danger of "contamination by values." On the one hand, cultural anthropology teaches us how fallacious any definition of mental health can be. Competitiveness and scrupulous neatness may be healthy in one culture and regarded as personality disorders in another. Furthermore, if mental health is "good," what is it good for? The self or society? For "fitting in" or for creativity? For happiness or survival? Furthermore, who should be the judge?

MODELS OF MENTAL HEALTH

This chapter contrasts six different empirical approaches to mental health. First, mental health can be conceptualized as *above normal* and a mental state

that is objectively desirable, as in Sigmund Freud's definition of mental health, which is the capacity to work and love. Second, from the viewpoint of healthy adult development, mental health can be conceptualized as *maturity.* Third, mental health can be conceptualized in terms of *positive psychology*—as epitomized by the presence of multiple human strengths. Fourth, mental health can be conceptualized as *emotional intelligence* and successful object relations. Fifth, mental health can be conceptualized as *subjective well-being*—a mental state that is subjectively experienced as happy, contented, and desired. Sixth, mental health can be conceptualized as *resilience,* as the capacity for successful adaptation and homeostasis.

Model A: Mental Health as Above Normal

This first perspective differs from the traditional medical approach to health and illness. No manifest psychopathology equals mental health. In this medical model, if one were to put all individuals on a continuum, normality would encompass a significant portion of adults, and abnormality would be the small remainder. This definition of health correlates with the traditional role model of the doctor who attempts to free his patient from grossly observable signs of illness. In other words, in this context, health refers to a reasonable, rather than an optimal state of functioning. However, as already pointed out, mental health is not normal; it is above average. Some believe that true mental health is the exception, not the rule. Moreover, until recently, some believed that mental health was imaginary.

Model B: Mental Health as Maturity

Unlike other organs of the body that are designed to stay the same, the brain is designed to be plastic. Therefore, just as optimal brain development requires almost a lifetime, so does assessing positive mental health. A 10-year-old's lungs and kidneys are more likely to reflect optimal function than are those of a 60-year-old, but that is not true of a 10-year-old's central nervous system. To some extent, then, adult mental health reflects a continuing process of maturational unfolding. Statistically, physically healthy 70-year-olds are mentally healthier than they were at age 30 years; for example, Laura Carstensen found through prospective studies that individuals are less depressed and show greater emotional modulation at age 70 years

than they did at age 30 years.

However, if prospective studies of adult development reveal that the immature brain functions less well than the mature brain, does that mean that adolescents are mentally healthier than toddlers? Are the middle-aged mentally healthier than adolescents? The answer is both yes and no, but the question illustrates that in order to understand mental health, we must first understand what we mean by maturity.

To confirm the hypothesis that maturity and positive mental health are almost synonymous, it is necessary to study the behavior and emotional states of persons over a lifetime. Although such longitudinal studies have come to fruition only recently, all of them illustrate the association of maturity with increasing mental health. After age 50 years, of course, the association between mental health and maturity is contingent on a healthy central nervous system. The ravages of illnesses like brain trauma, major depression, arteriosclerosis, Alzheimer's, and alcoholism must all be avoided.

The association of mental health to maturity is probably mediated not only by progressive brain myelination into the sixth decade but also by the evolution of emotional and social intelligence through experience. Erik Erikson conceptualized that such development produced a "widening social radius." In such a view, life after age 50 years was no longer a staircase leading downward, as in the Pennsylvania Dutch cartoons of life-span development, but a path leading outward. In Erikson's model, the adult social radius expanded over time through the mastery of specific tasks such as "Identity versus Identity Diffusion," "Intimacy versus Isolation," "Generativity versus Stagnation," and "Integrity versus Despair."

Identity. In such a model, the social radius of each adult developmental task fits inside the next. First, adolescents must achieve an *Identity* that allows them to become separate from their parents, for mental health and adult development cannot evolve through a false self. The task of *Identity* requires mastering the last task of childhood: sustained separation from social, residential, economic, and ideologic dependence on the family of origin. Identity is not just a product of egocentricity, of running away from home, or of marrying to get out of a dysfunctional family. There is a world of difference between the instrumental act of running away from home and the developmental task of knowing where one's family values end and one's

values begin. Such separation derives as much from the identification and internalization of important adolescent friends and nonfamily mentors as it does from simple biologic maturation. For example, our accents become relatively fixed by age 16 years and reflect those of our adolescent peer group rather than the accents of our parents.

Intimacy. Then, young adults should develop *Intimacy*, which permits them to become reciprocally, and not selfishly, involved with a partner. However, living with just one other person in an interdependent, reciprocal, committed, and contented fashion for years and years may seem neither desirable nor possible to a young adult. Once achieved, however, the capacity for intimacy may seem as effortless and desirable as riding a bicycle. Sometimes the relationship is with a person of the same gender; sometimes, it is entirely asexual; and sometimes, as in religious orders, the interdependence is with a community. Superficially, mastery of intimacy may take very different guises in different cultures and epochs, but "mating-for-life" and "marriage-type love" are developmental tasks built into the developmental repertoires of many warm-blooded species, including ours.

Career Consolidation. *Career Consolidation* is a task that is usually mastered together with or that follows the mastery of intimacy. Mastery of this task permits adults to find a career as valuable as they once found play. On a desert island, one can have a hobby but not a career, for careers involve being of value to other people. Four crucial developmental criteria transform a "job" or hobby into a "career:" Contentment, compensation, competence, and commitment. Such a career can be "wife and mother"—or, in more recent times, "husband and father." To the outsider, the process of Career Consolidation often appears "selfish," but without such "selfishness," one becomes "selfless" and has no "self" to give away in the next stage of generativity. Persons with schizophrenia and individuals with a severe personality disorder often manifest a lifelong inability to achieve either intimacy or sustained, gratifying employment.

Generativity. *Generativity* involves the demonstration of a clear capacity to care for and guide the next generation. Research reveals that sometime between ages 35 and 55 years, our need for achievement declines, and our

need for community and affiliation increases. Depending on the opportunities that the society makes available, generativity can mean serving as a consultant, guide, mentor, or coach to young adults in the larger society. Like leadership, generativity means to be in a caring relationship in which one gives up much of the control that parents retain over young children. Good mentors learn "to hold loosely" and to share responsibility. Generativity reflects the capacity to give the self—finally completed through mastery of the first three tasks of adult development—away. Its mastery is strongly correlated with successful adaptation to old age. This is because, in old age, there are inevitable losses, and these may overwhelm us if we have not continued to grow beyond our immediate family.

Integrity. Finally, in old age, it is common to feel that some life exists after death and that one is part of something greater than oneself. Thus, the last life task in Erikson's words is *Integrity,* achieving some sense of peace and unity with respect both to one's life and to the whole world. Erikson described integrity as "an experience which conveys some world order and spiritual sense. No matter how dearly paid for, accepting one's life cycle as something that had to be and that, by necessity, permitted no substitutions."

It must be kept in mind that mastery of one life task is not necessarily healthier than mastery of another, for adult development is neither a foot race nor a moral imperative. Instead, these sequential tasks are offered as a road map to help clinicians make sense of where they are and where their patients might be located. One can be a mature 20-year-old, that is, healthy. One can be an immature 50-year-old, which may be unhealthy. Nevertheless, acquiring a social radius that extends beyond the person by definition allows more flexibility and is usually healthier than self-preoccupation. Generativity by ages 40 to 50 years offers a powerful predictor of a contented old age.

Model C: Mental Health as Positive or "Spiritual" Emotions

This model defines mental and spiritual health as the amalgam of the positive emotions that bind us to other human beings. Love, hope, joy, forgiveness, compassion, faith, awe, and gratitude comprise the essential positive and "moral" emotions included in this model. Of great importance, these selected positive emotions all involve human connection. None of the emotions listed

is just about the self. These positive emotions appear to be a common denominator of all major faiths. Omitted from the list are five other positive emotions—excitement, interest, contentment (happiness), humor, and a sense of mastery, for a person can feel these latter five emotions alone on a desert island.

Negative emotions originating in the hypothalamus, such as fear and anger, are elaborated in the human amygdala (larger in humans than in other mammals). Of tremendous importance to individual survival, the negative emotions are all about "me." In contrast, positive emotions, apparently generated in the limbic system and unique to mammals, can free the self from the self. People feel the emotions of vengeance and forgiveness deeply, but the long-term results of these two emotions are very different. Negative emotions are crucial for survival in the present time. The positive emotions are more expansive and help us to broaden and build. In the future, they widen one's tolerance for strangers, expand one's moral compass, and enhance one's creativity. Whereas negative emotions narrow attention and miss the forest for the trees, positive emotions, especially joy, make thought patterns more flexible, creative, integrative, and efficient.

The effect of positive emotion on the autonomic (visceral) nervous system has much in common with the relaxation response to meditation. In contrast to the metabolic and cardiac arousal that the fight-or-flight response of negative emotion induces in our *sympathetic* autonomic nervous system, positive emotion via our *parasympathetic* nervous system reduces basal metabolism, blood pressure, heart rate, respiratory rate, and muscle tension. fMRI studies of Kundalini yoga practitioners demonstrate that meditation increases the activity of the hippocampus and the right lateral amygdala, which in turn leads to parasympathetic stimulation and the sensation of deep peacefulness.

Positive emotions have a biologic basis, which means that they have evolved through natural selection. The prosocial emotions probably reflect adaptations that permitted the survival of relatively defenseless *Homo sapiens* and their defenseless children in the African savannah 1 to 2 million years ago.

Evidence for Positive Emotions. It has taken recent developments in neuroscience and ethology to make positive emotions a subject fit for

scientific study. For example, infantile autism, a not uncommon genetic disorder of emotional attachment, was not discovered until 1943 by a Johns Hopkins child psychiatrist, Leo Kanner—in his son. Until then, medicine could not articulate a positive emotion as basic, but as cognitively subtle, as attachment. Today, the congenital lack of empathy and difficulties of attachment in childhood autism can be recognized by any competent pediatrician.

To locate positive emotion in the mammalian limbic system has been a slow, arduous process. In 1955, James Olds, an innovative neuropsychologist, observed that 35 of 41 electrode placements within the limbic system of rats, but only 2 of 35 placements outside of the limbic system, proved sufficiently rewarding to lead to self-stimulation. Also in the 1950s, neurobiologist Paul MacLean pointed out that the limbic structures govern our mammalian capacity not only to remember (cognition), but also to play (joy), to cry out at separation (faith/trust), and to take care of our own (love). Except for rudimentary memory, reptiles express none of these qualities.

Studies using fMRI demonstrated that when individuals subjectively experience existential states of fear, sadness, or pleasure, blood flow increases in limbic areas and decreases in many higher brain areas. Various studies have located pleasurable human experiences (tasting chocolate, winning money, admiring pretty faces, enjoying music, and experiencing orgasmic ecstasy) in limbic areas—especially in the orbitofrontal region, anterior cingulate, and insula. These diverse structures are closely integrated and organized to help us to seek and to recognize all that falls under the rubric of mammalian love and human spirituality.

The *anterior cingulate gyrus* links valence and memory to create attachment. Along with the hippocampus, the anterior cingulate is the brain region most responsible for making the past meaningful. In terms of mediating attachment, the anterior cingulate receives one of the richest dopaminergic innervations of any cortical area. Thus, the cingulate gyrus provides motivational salience not only for lovers but also for drug addicts. The anterior cingulate is crucial in directing whom we should approach and whom we should avoid. Maternal touch, body warmth, and odor via the limbic system and primarily via the anterior cingulate regulate a rat pup’s behavior, neurochemistry, endocrine release, and circadian rhythm. Brain

imaging studies reveal that the anterior cingulate gyrus is aroused neither by facial recognition of friends per se nor by sexual arousal per se. Instead, anterior cingulate fMRI images light up when a lover gazes at a picture of a partner's face or when a new mother hears her infant's cry.

Perhaps no area of the brain is more ambiguous in its evolutionary heritage or more crucial to mental health than our *prefrontal cortex.* The prefrontal cortex is in charge of estimating rewards and punishments and plays a critical role in adapting and regulating our emotional response to new situations. Thus, the prefrontal lobes are deeply involved in emotional, "moral," and "spiritual" lives.

From an evolutionary standpoint, the human frontal lobes are not different from chimpanzees in terms of the number of neurons. Instead, it is the frontal lobe white matter (the connectivity between neurons through myelinated fibers) that accounts for larger frontal lobes of humans. This connectivity to the limbic system underscores its "executive" function, which includes the ability to delay gratification, comprehend symbolic language, and, most importantly, to establish temporal sequencing. By being able to connect memory of the past to "memory of the future," the frontal lobes establish for *Homo sapiens* predictable cause and effect.

Surgical or traumatic ablation of the ventromedial prefrontal cortex can turn a conscientious, responsible adult into a moral imbecile without any other evidence of intellectual impairment.

The *insula* is another part of the limbic system that is only beginning to be understood. The insula is a medial cortical gyrus located between the amygdala and the frontal lobe. The brain has no sensation; humans feel emotion only in their bodies. The insula helps to bring these visceral feelings into consciousness: The pain in one's heart of grief, the warmth in one's heart of love, and the tightness in one's gut from fear all make their way into consciousness through the insula.

Both the limbic anterior cingulate and insula appear to be active in the positive emotions of humor, trust, and empathy. The higher apes are set apart from other mammals by a unique neural component called the spindle cell. Humans have 20 times more spindle cells than chimps or gorillas (adult chimpanzees average about 7,000 spindle cells; human newborns have four times more, and human adults have almost 200,000 spindle cells). Monkeys and other mammals, with the possible exception of whales and elephants, are

lacking in these unique cells. These large, cigar-shaped spindle or "von Economo" neurons appear to be central to the governance of social emotions and moral judgment. Spindle cells may have helped the Great Apes and humans integrate their mammalian limbic systems with their expanding neocortices. Spindle cells are concentrated in the anterior cingulate cortex, the prefrontal cortex, and the insula. More recently, scientists have discovered a particular group of "mirror neurons" in the insula and anterior cingulate. These neurons are more highly developed in humans than in primates and appear to mediate empathy—the experience of "feeling" the emotions of another.

Although the practical applications of this newest model of mental health are still many years away, these findings provide further evidence that the brain and mind are one. In several studies, the prosocial biologic activity of the anterior cingulate cortex and insula was highest in individuals with the highest social awareness (based on objectively scored tests). In other words, there are not only individual biologic differences for negative mental health, but also positive mental health.

Model D: Mental Health as Socioemotional Intelligence

High socioemotional intelligence reflects above-average mental health in the same way that a high IQ reflects above-average intellectual aptitude. Such emotional intelligence lies at the heart of positive mental health. In the *Nicomachean Ethics*, Aristotle defined socioemotional intelligence as follows: "Anyone can become angry—that is easy. However, to be angry with the right person, to the right degree, at the right time, for the right purpose, and in the right way—that is not easy."

All emotions exist to assist in basic survival. Although the exact number of primary emotions is arguable, seven emotions are currently distinguished according to characteristic facial expressions connoting anger, fear, excitement, interest, surprise, disgust, and sadness. The capacity to identify these different emotions in ourselves and others plays a vital role in mental health. The benefits of reading feelings from nonverbal cues have been demonstrated in almost a score of countries. These benefits included being better emotionally adjusted, more popular, and more responsive to others. Empathic children do better in school and are more popular than their peers

without being more intelligent. The Head Start Program, a program of the United States Department of Health and Human Services that provides education and other services for low-income children and their families, found that early school success was achieved not by intelligence but by knowing what kind of behavior is expected, knowing how to rein in the impulse to misbehave, being able to wait, and knowing how to get along with other children. At the same time, the child must communicate his or her needs and turn to teachers for help.

Ethologically, emotions are critical to mammalian communication. Because such communications are not always consciously recognized, the more skillful individuals are in identifying their emotions, the more skilled the individual will be in communicating with others, and in empathically recognizing their emotions. Put differently, the more you are skilled in empathy, the more others will value you, and the greater will be your social supports, self-esteem, and intimate relationships.

The following criteria can define social and emotional intelligence:

- Accurate conscious perception and monitoring of one's emotions.
- Modification of emotions so that their expression is appropriate. This involves the capacity to self-soothe personal anxiety and to shake off hopelessness and gloom.
- Accurate recognition of and response to emotions in others.
- Skill in negotiating close relationships with others.
- Capacity for focusing emotions (motivation) toward the desired goal. This involves delayed gratification and adaptively displacing and channeling impulse.

Some behavioral scientists divide emotions into positive and negative as if negative emotions were unhealthy (this point of view was emphasized in Model C). This tendency is an oversimplification. As with pus, fever, and cough, the negative emotions of sadness, fear, and anger are also crucial to healthy self-preservation. On the one hand, positive emotions like joy, love, interest, and excitement are associated with subjective contentment; on the other hand, although negative emotions interfere with contentment, their expression can be equally healthy.

Advances in Studying Emotional Intelligence. Over the last 15 years,

three critical empirical steps have been taken in our understanding of the relationship of socioemotional intelligence to positive mental health.

The first step is that both fMRI studies and neurophysiologic experimentation have led to advances in our understanding of integrating the prefrontal cortex with the limbic system, especially with the amygdala and its connections. As noted in the previous model, these research advances have brought us closer to understanding emotions as neurophysiologic phenomena rather than as Platonic abstractions. The prefrontal cortex is the region of the brain responsible for working memory, and the frontal lobes, through their connections to the amygdala, hippocampus, and other limbic structures, encode emotional learning in a manner quite distinct from both conventional conditioning and declarative memory.

The second step has been the slow but steady progress in conceptualizing and measuring "emotional intelligence." Over the last decade, measures of emotional intelligence have evolved rapidly.

The third advance is the use of videotape to chart emotional interaction. Videos of sustained family interactions reveal that an essential aspect of healthy infant development, of adolescent development, and marital harmony is how partners or parents respond to emotion in others. To ignore, to punish, and to be intimidated or contemptuous of how another feels spells disaster. Children of emotionally attuned parents are better at handling their own emotions and are more effective at soothing themselves when upset. Such children even manifest lower levels of stress hormones and other physiologic indicators of emotional arousal.

There are now many exercises in handling relationships that help couples, business executives, and diplomats to become more skilled at conflict resolution and negotiation. In the last decade, there has also been an increasing effort to teach schoolchildren core emotional and social competencies, sometimes called "emotional literacy." The relevance of these advances in psychology to psychiatry includes teaching emotion recognition and differentiation in eating disorders and teaching anger modulation and finding creative solutions to social predicaments for behavior disorders.

Model E: Mental Health as Subjective Well-Being

Positive mental health does not just involve being a joy to others; one must

also experience subjective well-being. Long before humankind considered definitions of mental health, they pondered criteria for subjective happiness. For example, objective social support accomplishes little if, subjectively, the individual cannot feel loved. Thus, the capacity for subjective well-being becomes a vital model of mental health.

Subjective well-being is never categorical. Healthy blood pressure is the objective absence of hypotension and hypertension, but happiness is less neutral. Subjective well-being is not just the absence of misery, but the presence of positive contentment. Nevertheless, if happiness is an inescapable dimension of mental health, happiness is often regarded with ambivalence. If through the centuries, philosophers have sometimes regarded happiness as the highest good, psychologists and psychiatrists have tended to ignore it.

Subjective happiness can have maladaptive as well as adaptive facets. The search for happiness can appear selfish, narcissistic, superficial, and banal. Pleasures can come quickly and soon be gone. Happiness is often based on illusion or dissociative states. Illusory happiness is seen in the character structure associated with bipolar and dissociative disorders. Maladaptive happiness can bring temporary bliss but has no sticking power. In the Study of Adult Development, scaled measures of "happiness" had little predictive power and, often, insignificant association with other subjective and objective measures of contentment. It is because of such ambiguity of meaning that, throughout this section, the term *subjective well-being* will be substituted for happiness.

Empirical Evidence. The mental health issues involved in subjective well-being are complicated and clouded by historical relativism, value judgment, and illusion. Europeans have always been skeptical of the American concern with happiness. Only in the last decade have investigators pointed out that a primary function of positive emotional states and optimism is that they facilitate self-care. Subjective well-being makes available personal resources that can be directed toward innovation and creativity in thought and action. Thus, subjective well-being, like optimism, becomes an antidote to learned helplessness. Again, controlling for income, education, weight, smoking, drinking, and disease, happy people are only half as likely to die at an early age or become disabled as unhappy people.

A distinction can be made between *pleasure* and *gratification.* Pleasure is

in the moment, is closely allied with happiness, and involves the satisfaction of impulse and biologic needs. Pleasure is highly susceptible to habituation and satiety. If pleasure involves satisfaction of the senses and emotions, gratification involves joy, purpose, and the satisfaction of "being the best you can be" and meeting aesthetic and spiritual needs.

Subjective (unhappy) distress can be healthy. As ethologically minded investigators have long pointed out, subjective negative affects (e.g., fear, anger, and sadness) can be healthy reminders to seek environmental safety and not to wallow in subjective well-being. If positive emotions facilitate optimism and contentment, fear is the first protection against the external threat; sadness protests against loss and summons help and anger signals trespass.

Clarifying Subjective Well-Being. Since the 1970s, investigators have made a serious effort to attend to definitional and causal parameters of subjective well-being and address critical questions. One such question is: Is subjective well-being more a function of environmental good fortune or a function of an inborn, genetically based temperament? Put differently, does subjective well-being reflect trait or state? If subjective well-being reflects a safe environment and the absence of stress, it should fluctuate over time, and those individuals who are happy in one domain or time in their lives might not be happy in another.

A second question, but one related to the first, is what is a cause and what is an effect. Are happy people more likely to achieve enjoyable jobs and good marriages, or do conjugal stability and career contentment lead to subjective well-being? Or are such positive associations the result of still a third factor? For example, the absence of a genetic tendency for alcoholism, for major depression, for trait neuroticism, and even for the presence of a chronic wish to give socially desirable answers (impression management) might facilitate both subjective well-being and reports of a good marriage and career contentment.

As with physiologic homeostasis, evolution has prepared humans to make subjective adjustments to environmental conditions. Thus, one can adapt to good and bad events to not remain in a state of either elation or despair. However, humans have a more challenging time adjusting to their genes. Studies of adopted-away twins have demonstrated that half of the variance in

subjective well-being is due to heritability. The subjective well-being of monozygotic twins raised apart is more similar than the subjective well-being of heterozygous twins raised together. Among the heritable factors making a significant contribution to high subjective well-being are low trait neuroticism, high trait extraversion, absence of alcoholism, and absence of major depression. In contrast to tested intelligence, when heritable variables are controlled, subjective well-being is not affected by environmental factors like income, parental social class, age, and education.

If subjective well-being were mainly due to the meeting of basic needs, then there should be a relatively low correlation between subjective well-being in work and subjective well-being in recreational settings or subjective well-being in social versus subjective well-being in solitary settings. Because women experience more objective clinical depression than men, the fact that gender is not a determining factor in subjective well-being is interesting. One explanation is that women appear to report both positive and negative affects more vividly than men. In one study, gender accounted for only 1 percent of the variance in happiness, but 13 percent of the variance in the intensity of reported emotional experiences.

Other Sources of Well-Being. In some instances, the environment *can* be critical to subjective well-being. Young widows remain subjectively depressed for years. Even though their poverty has been endured for centuries, respondents in impoverished nations, like India and Nigeria, report lower subjective well-being than other, more prosperous nations. The loss of a child never stops aching. Although achieving concrete goals like money and fame does not lead to a sustained increase in subjective well-being, social comparison, such as seeing a neighbor become more prosperous than you, can exert a negative effect on subjective well-being.

The maintenance of self-efficacy, agency, and autonomy make additional environmental contributions to subjective well-being. For example, elders will use their discretionary income to live independently, even though this means living alone rather than with relatives. Subjective well-being is usually higher in democracies than in dictatorships. Assuming responsibility for favorable or unfavorable outcomes (internalization) is another major factor leading to subjective well-being. Placing the blame elsewhere (externalization) significantly reduces subjective well-being. In other words,

the mental mechanisms of paranoia and projection make people feel worse rather than better.

Refined methods of measurement of subjective states of mind have included the Positive and Negative Affect Scale (PANAS), which assesses both positive and negative affect, each with 10 affect items. The *Satisfaction with Life Scale* represents the most recent evolution of a general life satisfaction scale. Most recently, the widely validated Short Form 36 (SF-36) has allowed clinicians to assess the subjective cost/benefits of clinical interventions. Because short-lived environmental variables can distort subjective well-being, a consensus is emerging that naturalistic experience-sampling methods are the most valid way to assess subjective well-being. With such sampling methods, research subjects are contacted at random times during the day for several days or weeks and asked to assess their subjective well-being. Finally, to tease verbal self-report from actual subjective experience, physiologic measures of stress (e.g., measuring galvanic skin response and salivary cortisol and filming facial expression by concealed cameras) have also proven useful.

Model F: Mental Health as Resilience

There are three broad classes of coping mechanisms that humans use to overcome stressful situations. First, there is how an individual elicits help from appropriate others: Namely *consciously seeking social support.* Second, there are *conscious cognitive strategies* that individuals intentionally use to master stress. Third, there are *adaptive involuntary coping mechanisms* (often called "defense mechanisms") that distort our perception of internal and external reality to reduce subjective distress, anxiety, and depression.

Involuntary Coping Mechanisms. Involuntary coping mechanisms reduce conflict and cognitive dissonance during sudden *changes* in internal and external reality. If such changes, in reality, are not "distorted" and "denied," they can result in disabling anxiety or depression, or both. Such homeostatic mental "defenses" shield us from sudden changes in the four lodestars of conflict: impulse (affect and emotion), reality, people (relationships), and social learning (conscience). First, such involuntary mental mechanisms can restore psychological homeostasis by ignoring or

deflecting sudden increases in the lodestar of impulse—affect and emotion. Psychoanalysts call this lodestar "id," religious fundamentalists call it "sin," cognitive psychologists call it "hot cognition," and neuroanatomists point to the hypothalamic and limbic regions of the brain.

Second, such involuntary mental mechanisms can provide a mental time-out to adjust to sudden changes in *reality* and self-image, which cannot be immediately integrated. Individuals who initially responded to the television images of the sudden destruction of New York City's World Trade Center as if it were a movie provide a vivid example of the denial of an external reality that was changing too fast for voluntary adaptation. Sudden good news—the instant transition from student to a physician or winning the lottery—can evoke involuntary mental mechanisms as often as can an unexpected accident or a diagnosis of leukemia.

Third, involuntary mental mechanisms can mitigate sudden unresolvable conflict with important *people,* living or dead. People become a lodestar of conflict when one cannot live with them and cannot live without them. Death is such an example; another is an unexpected proposal of marriage. Internal representations of essential people may continue to cause conflict for decades after they are dead yet continue to evoke an involuntary mental response.

Finally, the fourth source of conflict or anxious depression is social learning or conscience. Psychoanalysts call it "superego," anthropologists call it "taboos," behaviorists call it "conditioning," and neuroanatomists point to the associative cortex and the amygdala. This lodestar is not just the result of admonitions from our parents that we absorb before age 5 years, but it is formed by our whole identification, with culture, and sometimes by irreversible learning resulting from overwhelming trauma.

Healthy Involuntary Mental Mechanisms. Longitudinal studies from both Berkeley's Institute of Human Development and Harvard's Study of Adult Development have illustrated the importance of the mature defenses to mental health.

HUMOR. Humor makes life easier. With humor, one sees all, feels much, but does not act. Humor permits the discharge of emotion without individual discomfort and unpleasant effects upon others. Mature humor allows individuals to look directly at what is painful, whereas dissociation and

slapstick distract them. However, like the other mature defenses, humor requires the same delicacy as building a house of cards—timing is everything.

ALTRUISM. When used to master conflict, altruism involves an individual getting pleasure from giving to others what the individual would have liked to receive. For example, using reaction formation, a former alcohol abuser works to ban alcohol in his town and annoys his social drinking friends. Using altruism, the same former alcoholic serves as an Alcoholics Anonymous sponsor to a new member—achieving a transformative process that may be lifesaving to both the giver and receiver. Many acts of altruism involve a free will, but others involuntarily soothe unmet needs.

SUBLIMATION. The sign of a successful sublimation is neither careful cost accounting nor shrewd compromise, but rather psychic alchemy. By analogy, sublimation permits the oyster to transform an irritating grain of sand into a pearl. In writing his Ninth Symphony, the deaf, angry, and lonely Beethoven transformed his pain into triumph by putting Schiller's "Ode to Joy" to music.

SUPPRESSION. Suppression is a defense that modulates emotional conflict or internal/external stressors through stoicism. Suppression minimizes and postpones but does not ignore gratification. Empirically, this is the defense most highly associated with other facets of mental health. Effective suppression is analogous to a well-trimmed sail; every restriction is precisely calculated to exploit, not hide, the winds of passion. Evidence that suppression is not merely a conscious "cognitive strategy" is provided by the fact that jails would empty if delinquents could learn just to say "No."

ANTICIPATION. If suppression reflects the capacity to keep current impulse in mind and control it, anticipation is the capacity to keep the affective response to an unbearable future event in mind in manageable doses. The defense of anticipation reflects the capacity to perceive future danger affectively and cognitively and by this means to master conflict in small steps. Examples are that moderate amounts of anxiety before surgery promote postsurgical adaptation and that anticipatory mourning facilitates the adaptation of parents

of children with leukemia.

Psychiatry needs to understand how best to facilitate the transmutation of less-adaptive defenses into more-adaptive defenses. One suggestion has been first to increase social supports and interpersonal safety and second, to facilitate the intactness of the central nervous system (e.g., rest, nutrition, and sobriety). The newer forms of integrative psychotherapies using videotape can also catalyze such change by allowing patients actually to see their involuntary coping style.

SOCIOBIOLOGY AND ETHOLOGY

Sociobiology

The term *sociobiology* was coined in 1975 by Edward Osborne Wilson, an American biologist whose book, called *Sociobiology*, emphasized the role of evolution in shaping behavior. Sociobiology is the study of human behavior based on the transmission and modification of genetically influenced behavioral traits. It explores the ultimate question of *why* specific behaviors or other phenotypes came to be.

Evolution. Evolution is described as any change in the genetic makeup of a population. It is the foundational paradigm from which all of biology arises. It unites ethology, population biology, ecology, anthropology, game theory, and genetics. Charles Darwin (1809–1882) posited that natural selection operates via differential reproduction, in a competitive environment, whereby specific individuals are more successful than others. Given that differences among individuals are at least somewhat heritable, any comparative advantage will result in a gradual redistribution of traits in succeeding generations, such that favored characteristics will be represented in a more significant proportion over time. In Darwin's terminology, *fitness* meant reproductive success.

COMPETITION. Animals vie with one another for resources and territory, the area that is defended for the exclusive use of the animal, and that ensures access to food and reproduction. The ability of one animal to defend a disputed territory or resource is called *resource holding potential*, and the more significant this potential, the more successful the animal.

AGGRESSION. Aggression serves both to increase territory and to eliminate

competitors. Defeated animals can emigrate, disperse, or remain in the social group as subordinate animals. A dominance hierarchy in which animals are associated with subtle but well-defined ways is part of every social pattern.

REPRODUCTION. Because behavior is influenced by heredity, those behaviors that promote reproduction and survival are among the most important. Men tend to have a higher variance in reproductive success than do women, thus inclining men to be competitive with other men. Male–male competition can take various forms; for example, sperm can be thought of as competing for access to the ovum. Competition among women, although genuine, typically involves social undermining rather than overt violence. Sexual dimorphism, or different behavioral patterns for males and females, evolves to ensure the maintenance of resources and reproduction.

ALTRUISM. *Sociobiologists define altruism* as behavior that reduces the personal reproductive success of the initiator while increasing that of the recipient. According to the traditional Darwinian theory, altruism should not occur in nature because, by definition, selection acts against any trait whose effect is to decrease its representation in future generations. However, an array of altruistic behaviors occurs among free-living mammals as well as humans. In a sense, altruism is selfishness at the level of the gene rather than at the level of the individual animal. A classic case of altruism is the female worker classes of individual wasps, bees, and ants. These workers are sterile and do not reproduce, but labor altruistically for the reproductive success of the queen.

Another possible mechanism for the evolution of altruism is group selection. If groups containing altruists are more successful than those composed entirely of selfish members, the altruistic groups succeed at the expense of the selfish ones, and altruism evolves. However, within each group, altruists are at a severe disadvantage relative to selfish members; however well the group as a whole does.

IMPLICATIONS FOR PSYCHIATRY. Evolutionary theory provides possible explanations for some disorders. Some may be manifestations of adaptive strategies. For example, cases of anorexia nervosa may be partially understood as a strategy ultimately caused to delay mate selection,

reproduction, and maturation in situations where males are perceived as scarce. Persons who take risks may do so to obtain resources and gain social influence. An erotomanic delusion in a single postmenopausal woman may represent an attempt to compensate for the painful recognition of reproductive failure.

Studies of Identical Twins Reared Apart: Nature versus Nurture. Studies in sociobiology have stimulated one of the oldest debates in psychology. Does human behavior owe more to nature or to nurture? Curiously, humans readily accept that genes determine most of the behaviors of nonhumans, but tend to attribute their behavior almost exclusively to nurture. However, recent data unequivocally identify our genetic endowment as equally important, if not more important, factors.

The best "experiments of nature" permitting an assessment of the relative influences of nature and nurture are cases of genetically identical twins separated in infancy and raised in different social environments. If nurture is the most important determinant of behavior, they should behave differently. On the other hand, if nature dominates, each will closely resemble the other, despite their having never met. Several hundred pairs of twins separated in infancy, raised in separate environments, and then reunited in adulthood have been rigorously analyzed. Nature has emerged as a critical determinant of human behavior.

Laura R and Catherine S were reunited at the age of 35. They were identical twins that had been adopted by two different families in Chicago. Growing up, neither twin was aware of the other's existence. As children, each twin had a cat named Lucy, and both habitually cracked their knuckles. Laura and Catherine each began to have migraine headaches beginning at the age of 14. Both were elected valedictorian of their high school classes and majored in journalism in college. Each sister had married a man named John and had given birth to a daughter in wedlock. Both of their marriages fell apart within 2 years. Each twin maintained a successful rose garden and took morning spin classes at their local fitness center. Upon meeting, each twin discovered that the other had also named her daughter Erin and owned a German Sheppard

named Rufus. They had similar voices, hand gestures, and mannerisms.

Jack Y and Oskar S, identical twins born in Trinidad in 1933 and separated in infancy by their parents' divorce, were first reunited at age 46. His Catholic mother and grandmother raised Oskar in Nazi-occupied Sudetenland, Czechoslovakia. Jack was raised by his Orthodox Jewish father in Trinidad and spent time on an Israeli kibbutz. Each wore aviator glasses and a blue sport shirt with shoulder plackets, had a trim mustache, liked sweet liqueurs, stored rubber bands on his wrists, read books and magazines from back to front, dipped buttered toast in his coffee, flushed the toilet before and after using it, enjoyed sneezing loudly in crowded elevators to frighten other passengers, and routinely fell asleep at night while watching television. Each was impatient, squeamish about germs, and gregarious.

Bessie and Jessie, identical twins, separated at 8 months of age after their mother's death, were first reunited at age 18. Each had had a bout of tuberculosis, and they had similar voices, energy levels, administrative talents, and decision-making styles. Each had had her hair cut short in early adolescence. Jessie had a college-level education, whereas Bessie had had only 4 years of formal education, yet Bessie scored 156 on intelligence quotient testing, and Jessie scored 153. Each read avidly, which may have compensated for Bessie's sparse education; she created an environment compatible with her inherited potential.

Neuropsychological Testing Results. The dominant influence of genetics on behavior has been documented in several sets of identical twins on the Minnesota Multiphasic Personality Inventory (MMPI). Twins reared apart generally showed the same degree of genetic influence across the different scales as twins reared together. For example, despite being reared on different continents, in countries with different political systems and different languages, two particularly fascinating identical twin pairs generated scores more closely correlated across 13 MMPI scales than the already tight correlation noted among all tested identical twin pairs, most of whom had shared similar rearing.

Reared-apart twin studies report a high correlation (r = 0.75) for IQ similarity. In contrast, the IQ correlation for reared-apart nonidentical twin

siblings is 0.38, and for sibling pairs in general, it is in the 0.45 to 0.50 range. Strikingly, IQ similarities are not influenced by similarities in access to dictionaries, telescopes, and original artwork, in parental education and socioeconomic status, or characteristic parenting practices. These data overall suggest that tested intelligence is determined roughly two-thirds by genes and one-third by the environment.

Studies of reared-apart identical twins reveal a genetic influence on alcohol use, substance abuse, childhood antisocial behavior, adult antisocial behavior, risk aversion, and visuomotor skills, as well as on psychophysiological reactions to music, voices, sudden noises, and other stimulation, as revealed by brain wave patterns and skin conductance tests. Moreover, reared-apart identical twins show that genetic influence is pervasive, affecting virtually every measured behavioral trait. For example, many individual preferences previously assumed to be due to nurture (e.g., religious interests, social attitudes, vocational interests, job satisfaction, and work values) are strongly determined by nature.

A selected glossary of some terms used in this section and other ethologic terms is given in Table 34-8.

Table 34-8
Selected Glossary of Ethologic Terms

Action-specific energy	Energy associated with the innate releasing mechanism and specific to a particular behavior pattern, which builds up if the releasing stimulus is not present to activate the behavior pattern; conversely, it is depleted by repetition.
Aggression	Intraspecific conflict manifested by physical attack or social signaling.
Appetitive behavior	Phase of behavior involving the active seeking of sign stimuli and thought to be driven by action-specific energy accumulating through inactivity of the specific behavior pattern.

Consummatory response	Phase of behavior whereby the energy driving the appetitive phase is released. Involves the perception of sign stimuli, the activation of the innate releasing mechanism (IRM), and the performance of the fixed action pattern (FAP).
Critical period	The time during which imprinting must occur, usually shortly after birth or early in life. Also known as “sensitive period.”
Displacement activity	A set of behavior patterns occurring alongside an unrelated set of behavior patterns. Originally, irrelevant movements from one behavioral system occurring in the presence of powerful but thwarted drive from another behavior system.
Ethology	The biologic study of behavior. From the Greek ethos, meaning custom, usage, manner, habit. The modern usage is attributed to Oskar Heinroth, Konrad Lorenz’s teacher.
Fixed action pattern (FAP)	A genetically determined behavior pattern that is initiated by stimuli particular to the pattern and that consists of species-specific, stereotyped movements.
Imprinting	A specialized form of learning occurring early in life and often influencing behavior later in life. The exposure to the stimulus situation must occur during a particular period, the critical period, and the exposure can be of short duration and without obvious reward. The learning is particularly resistant to change.
Innate	Genetically determined behavior patterns; in theory not influenced by experience.
Innate releasing	Sensory mechanism selectively responsive to

mechanism (IRM)	specific external stimuli and responsible for triggering the stereotyped motor response.
Instinct	A developmental process resulting in species-typical behavior.
Redirection activity	The venting of one drive from two or more incompatible, but simultaneously activated, drives on some third animal or object.
Ritualization	Process of a behavior pattern being incorporated through evolution into a primary signaling function, frequently with exaggeration and embellishment of some of the movements.

Ethology

The systematic study of animal behavior is known as ethology. In 1973, the Nobel Prize in psychiatry and medicine was awarded to three ethologists, Karl von Frisch, Konrad Lorenz, and Nikolaas Tinbergen. Those awards highlighted the particular relevance of ethology, not only for medicine but also for psychiatry.

Konrad Lorenz. Born in Austria, Konrad Lorenz (1903–1989) is best known for his studies of imprinting. Imprinting implies that, during a specific short period of development, a young animal is highly sensitive to a specific stimulus that then, but not at other times, provokes a specific behavior pattern. Lorenz described newly hatched goslings programmed to follow a moving object and thereby become imprinted rapidly to follow it and, possibly, similar objects. Typically, the mother is the first moving object the gosling sees, but should it see something else first, the gosling follows it. For instance, a gosling imprinted by Lorenz followed him and refused to follow a goose (Fig. 34-17). Imprinting is an essential concept for psychiatrists to understand to link early developmental experiences with later behaviors.

Lorenz also studied the behaviors that function as sign stimuli—that is, social releasers—in communications between individual animals of the same species. Many signals have the character of fixed motor patterns that appear

automatically; the reaction of other members of the species to the signals is equally automatic.

Lorenz is also well known for his study of aggression. He wrote about the practical function of aggression, such as territorial defense by fish and birds. Aggression among members of the same species is common, but Lorenz pointed out that in normal conditions, it seldom leads to killing or even to serious injury. Although animals attack one another, a certain balance appears between tendencies to fight and flight, with the tendency to fight to be strongest in the center of the territory and the tendency to flight strongest at a distance from the center.

FIGURE 34-17
In a famous experiment, Konrad Lorenz demonstrated that goslings responded to him as if he were the natural mother. (Reprinted from Hess EH. Imprinting, an effect of early experience, imprinting determines later social behavior in animals. *Science*. 1959;130(3368):133–141, with permission.)

In many works, Lorenz tried to draw conclusions from his ethologic studies of animals that could also be applied to human problems. The postulation of a primary need for aggression in humans, cultivated by the

pressure for selecting the best territory, is a primary example. Such a need may have served a practical purpose historically, when humans lived in small groups that had to defend themselves from other groups. Competition with neighboring groups could become an important factor in selection. Lorenz pointed out, however, that this once useful trait may be outliving its survival value, now that we live in an era with weapons that can kill not just individuals but entire populations.

Nikolaas Tinbergen. Born in the Netherlands, Nikolaas Tinbergen (1907–1988), a British zoologist, conducted a series of experiments to analyze various aspects of animal behavior. He was also successful in quantifying behavior and measuring the power or strength of various stimuli in eliciting specific behavior. Tinbergen described displacement activities, which have been studied mainly in birds. For example, in a conflict situation, when the needs for fight and flight are of roughly equal strength, birds sometimes do neither. Instead, they display behavior that appears to be irrelevant to the situation (e.g., a herring gull defending its territory can start to pick grass). Displacement activities of this kind vary according to the situation and the species concerned. Humans can engage in displacement activities when under stress.

Lorenz and Tinbergen described innate releasing mechanisms, animals' responses triggered by releasers, which are specific environmental stimuli. Releasers (including shapes, colors, and sounds) evoke sexual, aggressive, or other responses. For example, big eyes in human infants evoke more caretaking behavior than do small eyes.

In his later work, Tinbergen, along with his wife, studied early childhood autistic disorder. They began by observing the behavior of autistic and typical children when they meet strangers, analogous to the techniques used in observing animal behavior. In particular, they observed in animals the conflict between fear and the need for contact and noted that the conflict could lead to behavior similar to that of autistic children. They hypothesized that, in certain predisposed children, fear can greatly predominate and can also be provoked by stimuli that generally have a positive social value for most children. This innovative approach to studying infantile autistic disorder opened up new avenues of inquiry. Although their conclusions about preventive measures and treatment must be considered tentative, their method

shows how ethology and clinical psychiatry can relate to each other.

Karl von Frisch. Born in Austria, Karl von Frisch (1886–1982) conducted studies on changes of color in fish and demonstrated that fish could learn to distinguish among several colors and that their sense of color was somewhat congruent with that of humans. He later went on to study the color vision and behavior of bees and is most widely known for his analysis of how bees communicate with one another—that is, their language, or what is known as their dances. His description of the exceedingly complex behavior of bees prompted an investigation of communication systems in other animal species, including humans.

Characteristics of Human Communication. Communication is traditionally seen as an interaction in which a minimum of two participants—a sender and a receiver—share the same goal: exchanging accurate information. Although shared interest in accurate communication remains valid in some domains of animal signaling—notably such well-documented cases as the "dance of the bees," whereby foragers inform other workers about the location of food sources—a more selfish and, in the case of social interaction, more accurate model of animal communication has mostly replaced this concept.

Sociobiologic analyses of communication emphasize that because individuals are genetically distinct, their evolutionary interests are similarly distinct, although admittedly with significant fitness overlap, especially among kin, reciprocators, parents and offspring, and mated pairs. Senders are motivated to convey information that induces the receivers to behave in a manner that enhances the senders' fitness. Receivers, similarly, are interested in responding to communication only insofar as such a response enhances their fitness. One crucial way to enhance reliability is to make the signal costly; for example, an animal could honestly indicate its physical fitness, freedom from parasites and other pathogens, and possibly its genetic quality as well by growing elaborate and metabolically expensive secondary sexual characteristics such as the oversized tail of a peacock. Human beings, similarly, can signal their wealth by conspicuous consumption. This approach, known as the *handicap principle,* suggests that effective communication may require that the signaler engages in exceptionally costly

behavior to ensure success.

Subhuman Primate Development

An area of animal research that has relevance to human behavior and psychopathology is the longitudinal study of nonhuman primates. Monkeys have been observed from birth to maturity, not only in their natural habitats and laboratory facsimiles but also in laboratory settings that involve various degrees of social deprivation early in life. Social deprivation has been produced through two predominant conditions: social isolation and separation. Socially isolated monkeys are raised in varying degrees of isolation and are not permitted to develop normal attachment bonds. Monkeys separated from their primary caretakers, thereby experience disruption of an already developed bond. Social isolation techniques illustrate the effects of an infant's early social environment on subsequent development (Figs. 34-18 and 34-19), and separation techniques illustrate the effects of loss of a significant attachment figure. The name most associated with isolation and separation studies is Harry Harlow. A summary of Harlow's work is presented in Table 34-9.

In a series of experiments, Harlow separated rhesus monkeys from their mothers during their first weeks. During this time, the monkey infant depends on its mother for nourishment and protection, and physical warmth and emotional security—*contact comfort,* as Harlow first termed it in 1958. Harlow substituted a surrogate mother made from wire or cloth for the real mother. The infants preferred the cloth-covered surrogate mother, which provided contact comfort, to the wire-covered surrogate, which provided food but no contact comfort (Fig. 34-20).

Treatment of Abnormal Behavior. Stephen Suomi demonstrated that monkey isolates could be rehabilitated if exposed to monkeys that promote physical contact without threatening the isolates with aggression or overly complex play interactions. These monkeys were called therapist monkeys. To fill such a therapeutic role, Suomi chose normal young monkeys that would play gently with the isolates and approach and cling to them. Within 2 weeks, the isolates were reciprocating the social contact, and their incidence of abnormal self-directed behaviors began to decline significantly. By the end of

the 6-month therapy period, the isolates were actively initiating play bouts with both the therapists and each other, and most of their self-directed behaviors had disappeared. The isolates were observed closely for the next 2 years, and their improved behavioral repertoires did not regress over time. The results of this and subsequent monkey-therapist studies underscored the potential reversibility of early cognitive and social deficits at the human level. The studies also served as a model for developing treatments for socially retarded and withdrawn children.

FIGURE 34-18
Social isolate after removal of isolation screen.

Several investigators have argued that social separation manipulations with nonhuman primates provide a compelling basis for animal models of

depression and anxiety. Some monkeys react to separations with behavioral and physiologic symptoms similar to those seen in depressed human patients; both ECT and tricyclic drugs effectively reverse the symptoms in monkeys. Not all separations produce depressive reactions in monkeys, just as separation does not always precipitate depression in humans, young and old.

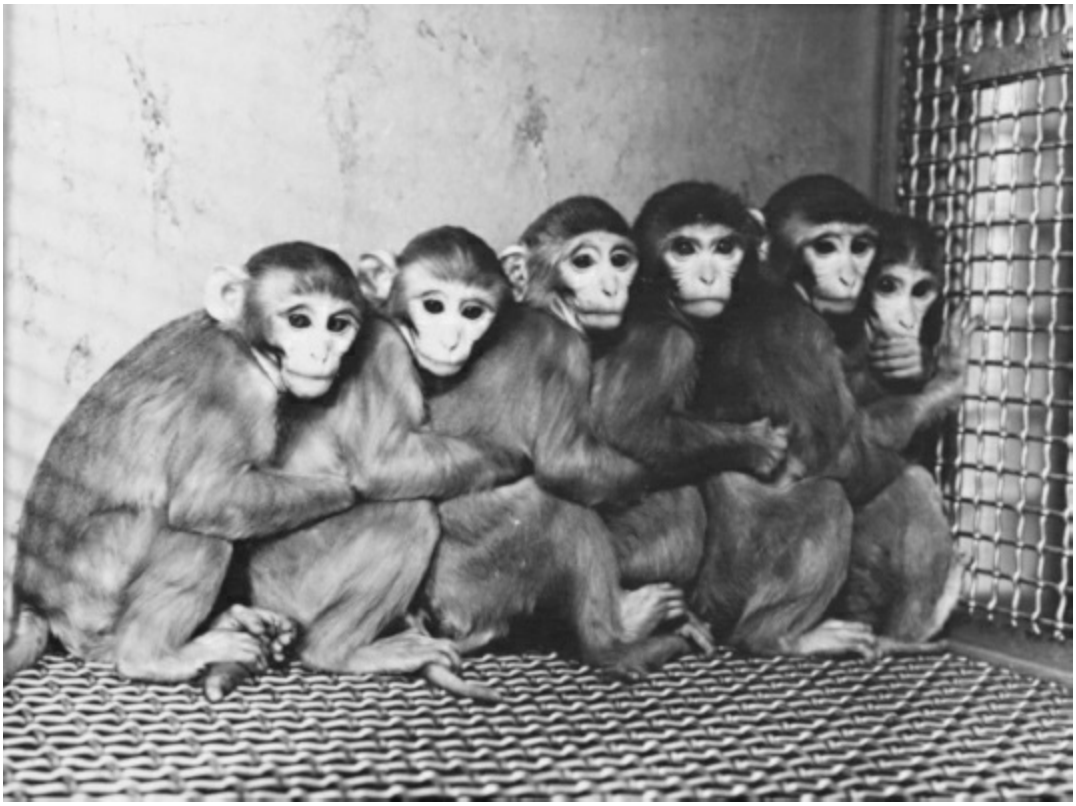

FIGURE 34-19
Choo-choo phenomenon in peer-only-reared infant rhesus monkeys.

Table 34-9
Social Deprivation in Nonhuman Primates

Type of Social Deprivation	Effects
Total isolation (not allowed to develop	Self-orality, self-clasping, very fearful when placed with peers, unable to copulate. If impregnated, female is unable to nurture young (motherless mothers). If isolation goes beyond 6 mo, no

caretaker or peer bond)	recovery is possible.
Mother-only reared	Fails to leave mother and explore. Terrified when finally exposed to peers. Unable to play or to copulate.
Peer-only reared	Engages in self-orality, grasps others in clinging manner, easily frightened, reluctant to explore, timid as adult, play is minimal.
Partial isolation (can see, hear, and smell other monkeys)	Stares vacantly into space, engages in self-mutilation, stereotyped behavior patterns.
Separation (taken from caretaker after bond has developed)	Initial protest stage changing to despair 48 hours after separation; refuses to play. Rapid reattachment when returned to mother.

Adapted from work of Harry Harlow, M.D.

Individual Differences. Recent research has revealed that some rhesus monkey infants consistently display fearfulness and anxiety in situations where similarly reared peers to show normal exploratory behavior and play. These situations generally involve exposure to a novel object or situation. Once the object or situation has become familiar, any behavioral differences between the anxiety-prone, timid infants and their outgoing peers disappear, but the individual differences appear to be stable during development. Infant monkeys at 3 to 6 months of age that are at high risk for fearful or anxious reactions tend to remain at high risk for such reactions, at least until adolescence.

A long-term follow-up study of these monkeys has revealed some behavioral differences between fearful and nonfearful female monkeys when they become adults and have their first infants. Usually, fearful female monkeys who grow up in socially benign and stable environments become fine mothers, but fearful female monkeys who have reacted with depression to frequent social separations during childhood are at high risk for maternal dysfunction; more than 80 percent of these mothers either neglect or abuse their first offspring. However, nonfearful female monkeys that encounter the same number of social separations but do not react to any of these separations with depression turn out to be good mothers.

Experimental Disorders

Stress Syndromes. Several researchers, including Ivan Petrovich Pavlov in Russia and W. Horsley Gantt and Howard Scott Liddell in the United States, studied the effects of stressful environments on animals, such as dogs and sheep. Pavlov produced a phenomenon in dogs, which he labeled *experimental neurosis,* by using a conditioning technique that led to symptoms of extreme and persistent agitation. The technique involved teaching dogs to discriminate between a circle and an ellipse and then progressively diminishing the difference between them. Gantt used the term *behavior disorders* to describe the reactions he elicited from dogs forced into similar conflictual learning situations. Liddell described the stress response he obtained in sheep, goats, and dogs as *experimental neurasthenia,* which was produced in some cases by merely doubling the number of daily test trials in an unscheduled manner.

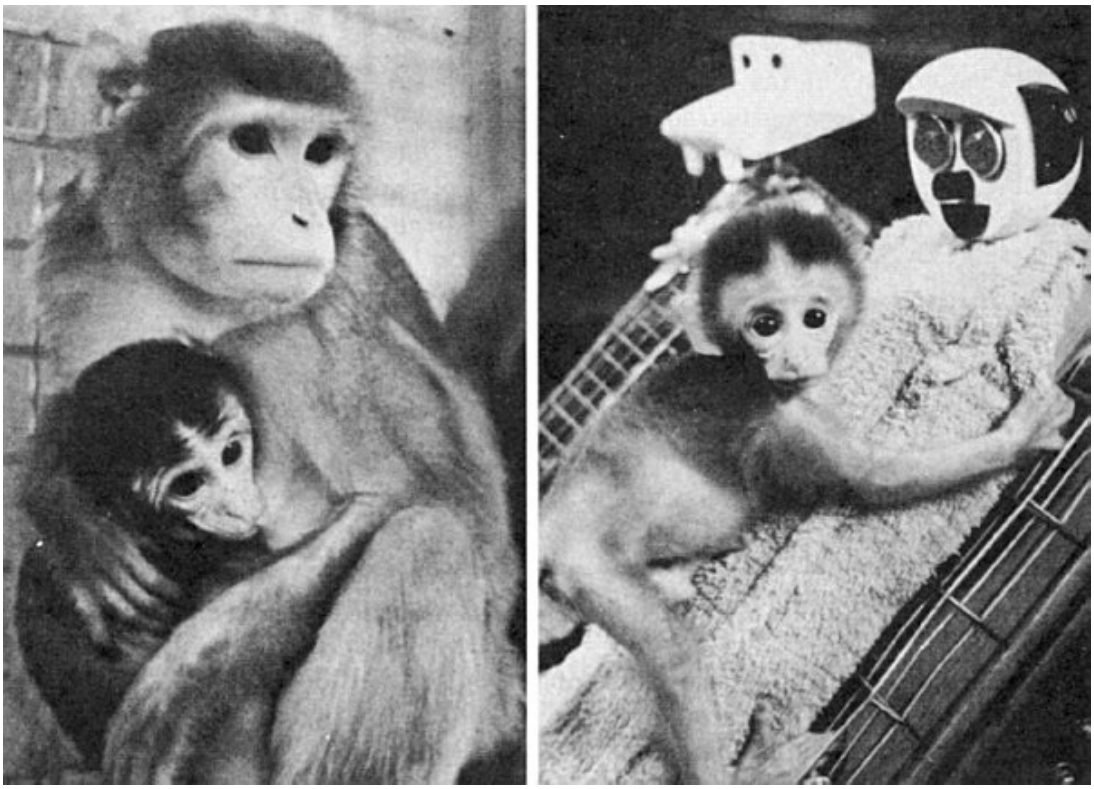

FIGURE 34-20
Monkey infant with mother (**left**) and with cloth-covered surrogate (**right**).

Learned Helplessness. The learned helplessness model of depression, developed by Martin Seligman, is an excellent example of an experimental disorder. Dogs were exposed to electric shocks from which they could not escape. The dogs eventually gave up and did not attempt to escape new shocks. The apparent giving up generalized to other situations, and eventually, the dogs always appeared to be helpless and apathetic. Because the cognitive, motivational, and affective deficits displayed by the dogs resembled symptoms common to human depressive disorders, learned helplessness, although controversial, was proposed as an animal model of human depression. In connection with learned helplessness and the expectation of inescapable punishment, research on subjects has revealed brain release of endogenous opiates, destructive effects on the immune system, and elevation of the pain threshold.

A social application of this concept involves schoolchildren who have learned that they fail in school no matter what they do; they view themselves as helpless losers, and this self-concept causes them to stop trying. Teaching them to persist may reverse the process, with excellent results in self-respect

and school performance.

Unpredictable Stress. Rats subjected to chronic unpredictable stress (crowding, shocks, irregular feeding, and interrupted sleep time) show decreases in movement and exploratory behavior; this finding illustrates the roles of unpredictability and lack of environmental control in producing stress. These behavioral changes can be reversed by antidepressant medication. Animals under experimental stress (Fig. 34-21) become tense, restless, hyperirritable, or inhibited in specific conflict situations.

Dominance. Animals in a dominant position in a hierarchy have certain advantages (e.g., mating and feeding). Being more dominant than peers is associated with elation, and a fall in position in the hierarchy is associated with depression. When persons lose jobs, are replaced in organizations, or otherwise have their dominance or hierarchical status changed, they can experience depression.

Temperament. Temperament mediated by genetics plays a role in behavior. For example, one group of pointer dogs was bred for fearfulness and a lack of friendliness toward persons, and another group was bred for the opposite characteristics. The phobic dogs were extremely timid and fearful and showed decreased exploratory capacity, increased startle response, and cardiac arrhythmias. Benzodiazepines diminished these fearful, anxious responses. Amphetamines and cocaine aggravated the responses of genetically nervous dogs to a greater extent than they did the responses of stable dogs.

Brain Stimulation. Pleasurable sensations have been produced in humans and animals through self-stimulation of specific brain areas, such as the medial forebrain bundle, the septal area, and the lateral hypothalamus. Rats have engaged in repeated self-stimulation (2,000 stimulations per hour) to gain rewards. Catecholamine production increases with self-stimulation of the brain area, and drugs that decrease catecholamines decrease the process. The centers for sexual pleasure and opioid reception are closely related anatomically. Heroin addicts report that the so-called rush after intravenous injection of heroin is akin to an intense sexual orgasm.

Pharmacologic Syndromes. With the emergence of biologic psychiatry, many researchers have used pharmacologic means to produce syndrome analogs in animal subjects. Two classic examples are the reserpine (Serpasil) model of depression and the amphetamine psychosis model of paranoid schizophrenia. In the depression studies, animals given the norepinephrine-depleting drug reserpine exhibited behavioral abnormalities analogous to major depressive disorder in humans. The behavioral abnormalities produced were generally reversed by antidepressant drugs. These studies tended to corroborate the theory that depression in humans is, in part, the result of diminished levels of norepinephrine. Similarly, animals given amphetamines acted in a stereotypical, inappropriately aggressive, and frightened manner that resembled paranoid psychotic symptoms in humans. These models are considered too simplistic in their concepts of cause, but they remain as early paradigms for this type of research.

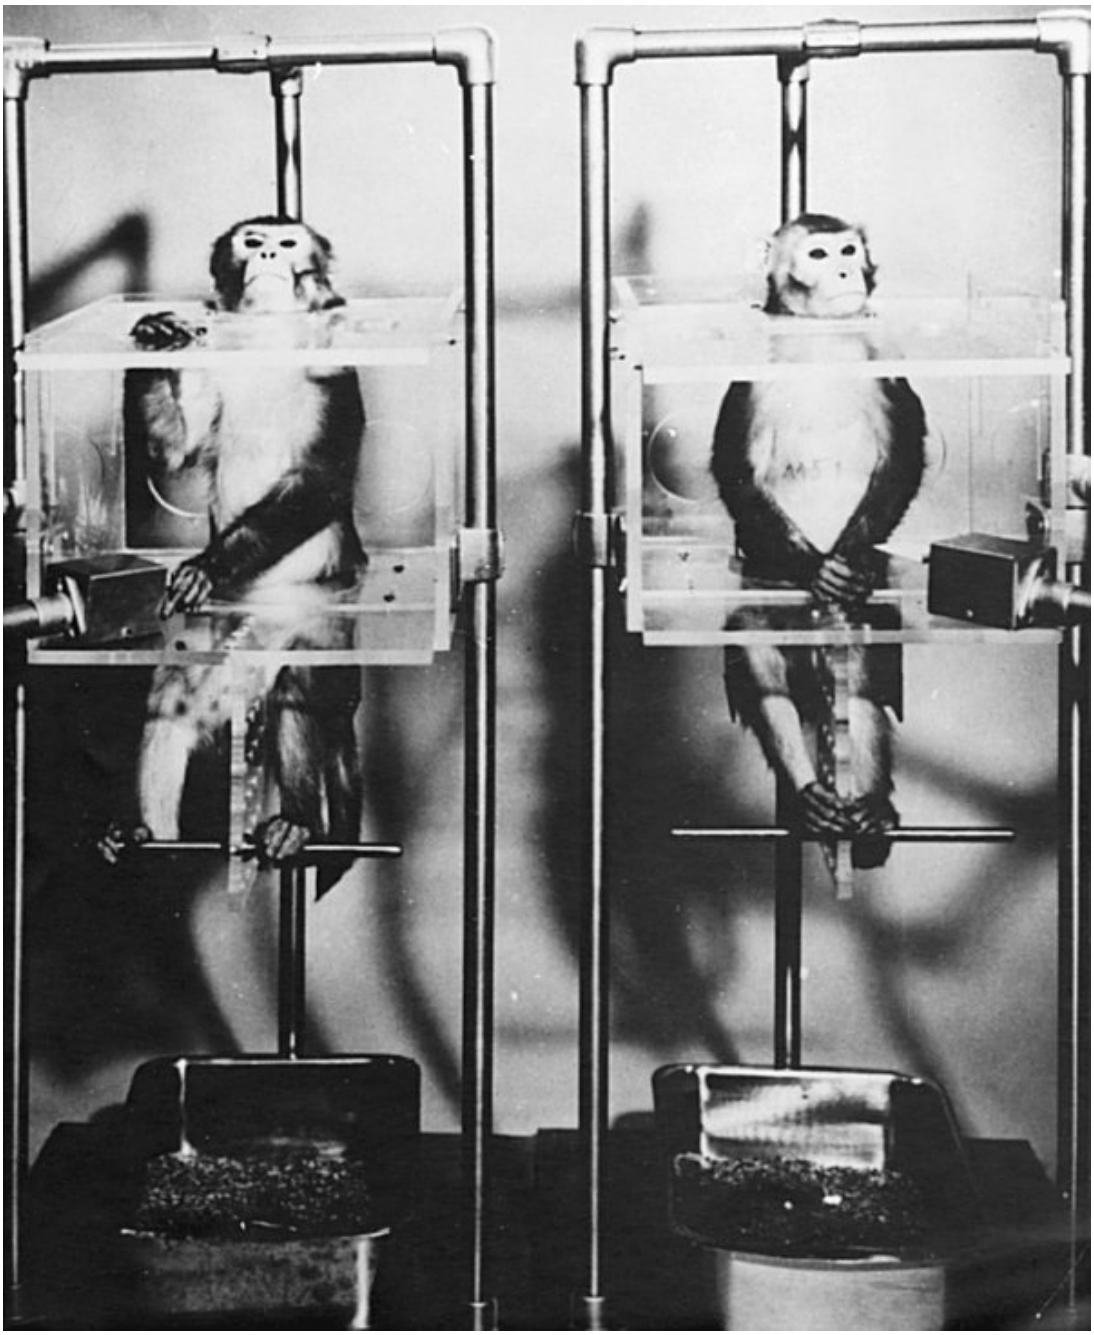

FIGURE 34-21
The monkey on the left, known as the executive monkey, controls whether both will receive an electric shock. The decision-making task produces a state of chronic tension. Note the more relaxed attitude of the monkey on the **right**. (From U.S. Army photographs, with permission.)

Studies have also been done on the effects of catecholamine-depleting drugs on monkeys during separation and reunion periods. These studies showed that catecholamine depletion and social separation could interact in a

highly synergistic fashion and yield depressive symptoms in subjects for whom mere separation or low-dose treatment alone does not suffice to produce depression.

Reserpine has produced a severe depression in humans and, as a result, is rarely used as either an antihypertensive (its original indication) or an antipsychotic. Similarly, amphetamine and its congeners (including cocaine) can induce psychotic behavior in persons who use it in overdose or over long periods.

Sensory Deprivation

The history of sensory deprivation and its potentially deleterious effects evolved from instances of aberrant mental behavior in explorers, shipwrecked sailors, and prisoners in solitary confinement. Toward the end of World War II, startling confessions, induced by the brainwashing prisoners of war, caused a rise of interest in this psychological phenomenon brought about by the deliberate diminution of sensory input.

To test the hypothesis that an essential element in brainwashing is prolonged exposure to sensory isolation, D. O. Hebb and his coworkers brought solitary confinement into the laboratory. They demonstrated that volunteer subjects—under conditions of visual, auditory, and tactile deprivation for periods of up to 7 days—reacted with increased suggestibility. Some subjects also showed characteristic symptoms of the sensory deprivation state: anxiety, tension, inability to concentrate or organize thoughts, increased suggestibility, body illusions, somatic complaints, intense subjective emotional distress, and vivid sensory imagery—usually visual and sometimes reaching the proportions of hallucinations with a delusionary quality.

Psychological Theories. Anticipating psychological explanation, Sigmund Freud wrote: “It is interesting to speculate what could happen to ego function if the excitations or stimuli from the external world were either drastically diminished or repetitive. Would there be an alteration in the unconscious mental processes and an effect upon the conceptualization of time?”

Indeed, under conditions of sensory deprivation, the abrogation of such

ego functions as perceptual contact with reality and logical thinking brings about confusion, irrationality, fantasy formation, hallucinatory activity, and wish-dominated mental reactions. In the sensory-deprivation situation, the subject becomes dependent on the experimenter and must trust the experimenter to satisfy such basic needs as feeding, toileting, and physical safety. A patient undergoing psychoanalysis may be in a kind of sensory deprivation room (e.g., a soundproof room with dim lights and a couch) in which primary-process mental activity is encouraged through free association.

COGNITIVE. Cognitive theories stress that the organism is an information-processing machine, whose purpose is an optimal adaptation to the perceived environment. Without sufficient information, the machine cannot form a cognitive map against which the current experience is matched. Disorganization and maladaptation then result. To monitor their behavior and to attain optimal responsiveness, persons must receive continuous feedback; otherwise, they are forced to project outward idiosyncratic themes that have little relation to reality. This situation is similar to that of many psychotic patients.

Physiologic Theories. The maintenance of optimal conscious awareness and accurate reality testing depends on a necessary state of alertness. This alert state, in turn, depends on a constant stream of changing stimuli from the external world, mediated through the ascending reticular activating system in the brainstem. In the absence or impairment of such a stream, as occurs in sensory deprivation, alertness drops away, direct contact with the outside world diminishes, and impulses from the inner body and the central nervous system may gain prominence. For example, idioretinal phenomena, inner ear noise, and somatic illusions may take on a hallucinatory character.

TRANSCULTURAL PSYCHIATRY

Culture is defined as a set of meanings, norms, beliefs, values, and behavior patterns shared by people. These values include social relationships, language, nonverbal expression of thoughts and emotions, moral and religious beliefs, rituals, technology, and economic beliefs and practices,

among other items. Culture has six essential components: (1) Culture is learned; (2) culture can be passed on from one generation to the next; (3) culture involves a set of meanings in which words, behaviors, events, and symbols have meanings agreed upon by the cultural group; (4) culture acts as a template to shape and orient future behaviors and perspectives within and between generations, and to take account of novel situations encountered by the group; (5) culture exists in a constant state of change; and (6) culture includes patterns of both subjective and objective components of human behavior. Also, culture shapes which and how psychiatric symptoms are expressed; culture influences the meanings that are given to symptoms; and culture affects the interaction between the patient and the health care system, as well as between the patient and the physician and other clinicians with whom the patient and family interact.

Race is a concept, the scientific validity of which is now considered highly questionable, by which human beings are grouped primarily by physiognomy. Its effect on individuals and groups, however, is considerable, due to its reference to physical, biologic, and genetic underpinnings, and because of the intensely emotional meanings and responses, it generates. *Ethnicity* refers to the subjective sense of belonging to a group of people with a common national or regional origin and shared beliefs, values, and practices, including religion. It is part of every person's identity and self-image.

Cultural Formulation

Culture plays a role in mental health and mental illness; therefore, a cultural assessment should be a component of every complete psychiatric assessment. The outline for cultural formulation found in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) is intended to give clinicians a framework for assessing the role of culture in psychiatric illness. Its purposes are (1) to enhance the application of diagnostic criteria in multicultural environments; (2) cultural conceptualizations of distress; (3) psychosocial stressors and cultural features of vulnerability and resilience; (4) to enable the clinician to systematically describe the patient's cultural and social reference groups and their relevance to clinical care; and (5) to identify the effect that cultural differences may have on the relationship between the patient and

family and the treating clinician, as well as how such cultural differences affect the course and the outcome of treatment provided.

The outline for cultural formulation consists of five areas of assessment: (1) cultural identity of the individual; (2) cultural explanations of the individual's illness; (3) cultural factors related to psychosocial environment and levels of functioning; (4) cultural elements of the relationship between the individual and the clinician; and (5) overall cultural assessment for diagnosis and care.

Cultural Identity of the Individual. *Cultural identity* refers to the characteristics shared by a person's cultural group. Identity allows for a self-definition. Factors that comprise an individual's cultural identity include race, ethnicity, country of origin, language use, religious beliefs, socioeconomic status, migration history, the experience of acculturation, and the degree of affiliation with the individual's group of origin. Cultural identity emerges throughout the individual's life and in a social context. It is not a fixed trait of an individual or of the group of which the individual is part. An individual may have several cultural reference groups.

The clinician should encourage the patient to describe the component aspects of their cultural identity. Evaluating the cultural identity of the patient allows identification of potential areas of strength and support that may enhance treatment effectiveness, as well as vulnerabilities that may interfere with the progress of treatment. Eliciting this data permits the identification of unresolved cultural conflicts that may be addressed during treatment. These conflicts can be between the various aspects of the patient's identity and between traditional and mainstream cultural values and behavioral expectations affecting the individual. Knowledge of the patient's cultural identity allows the clinician to avoid misconceptions based on inadequate background information or stereotypes related to race, ethnicity and other aspects of cultural identity. Also, it helps build rapport because the clinician is attempting to understand the individual as a person and not just a representative of the cultural groups that have shaped the patient's identity.

Cultural Explanations of the Individual's Illness. The explanatory model of illness is the patient's understanding of and attempts to explain why they became ill. The explanatory model defines the culturally acceptable

means of expression of the symptoms of the illness or *idioms of distress,* the particular way individuals within a specific cultural group report symptoms, and their behavioral response to them heavily influenced by cultural values. The cultural explanations of illness may also help define the sick role or behavior the patient assumes. The explanatory model of illness includes the patient's beliefs about their prognosis and the treatment options they would consider. The patient's explanatory model may be only vaguely conceptualized or may be quite clearly defined, and it may include several conceptual perspectives that could conflict with one another. Formulation of a collaborative model that is acceptable to both the clinician and the patient is the sought-for endpoint, which would include an agreed-upon set of symptoms to be treated and an outline of treatment procedures to be used.

Difficulties may arise when there are conceptual differences in the explanatory model of illness between clinician, patient, family, and community. Conflicts between the patient's and the clinician's explanatory models may lead to diminished rapport or treatment noncompliance. Conflicts between the patient's and the family's explanatory models of illness may result in a lack of support from the family and family discord. Conflicts between the patient's and the community's explanatory models could lead to social isolation and stigmatization of the patient.

Examples of the more common explanatory models of illness include the *moral model, the religious model,* the *magical* or *supernatural explanatory model*, the *medical model*, and the *psychosocial stress model.* The *moral model* implies that the patient's illness is caused by a moral defect such as selfishness or moral weakness. The *religious model* suggests that the patient is being punished for a religious failing or transgression. The *magical* or *supernatural explanatory model* may involve attributions of sorcery or witchcraft as being the cause of the symptoms. The *medical model* attributes the patient's illness primarily to a biologic etiology. The *psychosocial model* infers that overwhelming psychosocial stressors cause or are primary contributors to the illness.

Culture has both direct and indirect effects on help-seeking behavior. In many cultural groups, an individual and their family may minimize symptoms due to stigma associated with seeking assistance for psychiatric disorders. Culture affects the patient's expectations of treatment, such as whether the clinician should assume an authoritarian, paternalistic,

egalitarian, or nondirective demeanor in the treatment process.

Cultural Factors Related to Psychosocial Environment and Level of Functioning. Understanding the patient's family dynamics and cultural values are integral to assessing the patient's psychosocial environment. The definition of what constitutes a family and the roles of individuals in the family differ across cultures. This includes an understanding of the patient's cultural group and its relationship to the mainstream culture or cultures. It includes the patient's life experience of racial and ethnic discrimination. For immigrants and refugees, it includes the individual's and family's perceptions of the openness of the host society toward people of their country and region of origin, their racial, ethnic, religious, and other attributes. The patient and family may identify strongly or weakly with communal sources of support familiar from their country or region of origin, or they may identify along the same gradient with communal sources of support in the host culture.

Cultural Elements of the Relationship between the Individual and the Clinician. The cultural identity of the clinician and the mental health team has an impact on patient care. The culture of mental health care professionals influences diagnosis and treatment. Clinicians who have an understanding of their own cultural identity may be better prepared to anticipate the cultural dynamics that may arise in interactions with people of diverse cultural backgrounds. Unacknowledged differences between the clinician's and patient's cultural identity can result in assessment and treatment that is unintentionally biased and stressful for all. Clinicians need to examine their assumptions about other cultures to be optimally effective in serving the culturally diverse patient populations that are the norm in most contemporary medical facilities.

Culture influences transference and counter-transference in the clinical relationship between people seeking psychiatric care and their treating clinicians. Transference relationships and dynamics are affected when the patient and clinician have different cultural background characteristics. A perceived social power differential between the patient and clinician could lead to overcompliance, resistance in the exploration of family and social conflict situations, or to the clinician being conceptualized as a cultural role model or stereotype.

Overall Cultural Assessment for Diagnosis and Care. The treatment plan should include the use of culturally appropriate health care and social services. Interventions also may be focused on the family and social levels. In making a psychiatric diagnosis, the clinician should consider principles of cultural relativism and not fall prone to category fallacy. Many psychiatric disorders show cross-cultural variation. Objective evaluation of the multiple possible effects of culture on psychopathology can be a challenging task for the clinician. Diagnostic dilemmas may arise in dealing with patients of diverse cultural backgrounds. Some of these dilemmas may include problems in judging distortion from reality, problems in assessing unfamiliar behaviors and distinguishing pathologic from normal cultural behavior.

Migration, Acculturation, and Acculturative Stress

From the time of the first significant surge of immigration to the United States in the 1870s, and for the next 100 years, the predominant national sentiment toward immigrants, as in most other host countries, was that they should acculturate to the normative behaviors and values of the majority or mainstream culture of the host population. Most immigrants had the same wish to assimilate, to become part of the *melting pot.* This process of acculturative change can be seen as unidirectional, as individuals who identified themselves as part of immigrant, indigenous, and other minority groups both rejected and progressively lost distinctive aspects of their cultural heritage in favor of becoming part of the mainstream majority culture of the host country. In countries that encouraged this outcome of acculturation, people were expected to progress from unacculturated, through the gradient of minimally, moderately, and fully acculturated.

The intensity of acculturative stress experienced by immigrant and other minority groups, and the individuals comprising those groups, has been directly proportional to the openness of the host government and population. The central issue is to what extent are immigrants' and other minority groups' customs, values, and differences from the majority population of the host country accepted, encouraged, and welcomed as an enrichment of the host country instead of being seen as alien and unwelcome. The *acceptance position* encourages the cultural integration of immigrants, whereas the *rejection position* encourages either cultural exclusion or cultural

assimilation.

To assess the outcome of acculturative stress, for groups and their component individuals, two determining factors need to be considered. The first is the extent to which the group and its members value and wish to preserve their cultural uniqueness, including the language, beliefs, values, and social behaviors that define the group. The second factor is the mirror-image issue of the extent to which the group and its members value and wish to increase their contact and involvement with other groups, particularly the majority culture. This conceptual framework leads to four possible outcomes of acculturative stress that are not conceptualized along the unidirectional gradient from unacculturated to wholly acculturated.

The four possible outcomes are *rejection, integration, assimilation,* and *marginalization. Rejection* is characterized by individuals' wishes, both conscious and intuitive, to maintain their cultural integrity, whether by actively resisting the incorporation of the values and social behavior patterns of another cultural group or groups with whom they have regular contact or by disengaging themselves from contact with and the influence of those other cultural groups. Some religious cults are examples of rejection.

Integration, as an outcome of acculturative stress, derives from the wish to both maintain a firm sense of one's cultural heritage and not abandon those values and behavioral characteristics that define the uniqueness of one's culture of origin. At the same time, such individuals can incorporate enough of the value system and norms of behavior of the other cultural group with which they interact closely, to feel and behave like members of that cultural group, principally the majority host culture. Accordingly, the defining feature of integration is psychological: It is the gradual process of formulation of a bicultural identity, a sense of self that intertwines the unique characteristics of two cultures.

Assimilation is the psychological process of the conscious and unconscious giving up of the unique characteristics of one's culture of origin in favor of the more or less complete incorporation of the values and behavioral characteristics of another cultural group, usually, but not always, the majority culture. Examples include involuntary migration when war and social upheaval necessitate such changes for purposes of survival. However, there are many other life circumstances, including racial, ethnic, and religious discrimination, that motivate people to overlook, suppress, or deny aspects of

their cultural heritage to have a seamless fit within another group. The price of such an effort, in terms of intrapsychic conflict, can be high.

Marginalization is defined by the psychological characteristics of rejection or the progressive loss of valuation of one's cultural heritage, while at the same time rejecting, or being alienated from, the defining values and behavioral norms of another cultural group, usually that of the majority population. This is the psychological outcome of acculturative stress that is closest to the concept of identity diffusion.

Psychiatric Assessment of Immigrants and Refugees

Migration History. Mental illness among immigrants and refugees may have been present before migration, may have developed during the immigration process, such as during months or years living in refugee camps, or presented for the first time in immigration. The immigration process and premigration trauma may precipitate the manifestation of underlying symptoms or result in exacerbation of a preexisting disorder. Obtaining a thorough migration history will help understand the background and precipitating stressors and help guide the development of an appropriate treatment plan.

The premigration history includes inquiry about the patient's social support network, social and psychological functioning, and significant premigration life events. Information about the country and region of origin, the family history in the country of origin—including an understanding of family members who may have decided not to immigrate—educational and work experiences in the country of origin, and prior socioeconomic status should be obtained. Also, premigration political issues, trauma, war, and natural disaster faced by the patient and family in the country or region of origin should be explored. For those who had to escape persecution, warfare, or natural disaster, what were the means of escape, and what type of trauma was suffered before and during migration? Traumatic life events are not limited just to refugees. Immigration may result in losses of social networks, including family and friends, material losses, business, career, property, and loss of the cultural milieu, including their familiar community and religious life. Premigration planning includes reasons for immigrating, duration, and extent of planning, premigration aspirations, and beliefs about the host

country. The type of migration experience, whether as voluntary immigrants or as unprepared refugees, can have profoundly different effects on migrants' mental health.

The Mental Status Examination. As with any patient, conducting a mental status examination is a central component of the psychiatric examination. However, its interpretation in culturally distinct groups and immigrant populations requires caution, as it may be culturally biased. The patient's response is molded by their culture of origin, educational level, and type of acculturative adaptation. The components of the standardized mental status examination are the following: cooperation, appearance, and behavior, speech, affect, thought process, thought content, cognition, insight, and judgment. Cultural differences are wide and varied in dress and grooming. Facial expressions and body movements used in the expression of affect may be more reflective of normal cultural manifestations than pathology. If the clinician is unfamiliar with the individual's culture and the patient's fluency in the language of the host country is limited, the clinician must use caution in interpreting disturbances of speech and thought process, perception, and affect. The presence of hallucinations, for example, can be easily misinterpreted, such as hearing encouraging or clarifying comments from deceased family members, normative experiences in many cultures. The clinician should not assume that the patient understands what the clinician is trying to communicate, and miscommunication involving interpreters is a common problem. The cognitive examination may be particularly tricky. Education and literacy have an important and biasing role. The patient may need adequate time to fully express him- or herself through repeating questions and restating questions to reduce miscommunication. Asking about the meaning of proverbs unfamiliar to the patient may be an inappropriate means of determining abstract thinking. An accurate mental status examination can be accomplished when one allows additional time for clarification of concepts.

Immigration Acculturation and Mental Health

Many countries have had difficulty coping with the surging numbers of migrants. This has led to more significant restrictions on migrant numbers,

partly in response to public sentiment that the social and cultural integrity of the nation has become threatened, even undermined, by waves of migrants from other countries and cultures. During the last 10 years, fears of terrorist violence and civil disruption have led many countries to adopt increasingly restrictive and sometimes punitive policies toward legal and illegal migrants, refugees, and asylum seekers. This trend has been observed in the United States, in some countries of the European Union, and Australia.

Racial and Ethnic Differences in Psychiatric Disorders in the United States

Several community-based epidemiologic studies in the United States have examined the rates of disorders across specific ethnic groups. These studies have found a lower than expected prevalence of psychiatric disorders among disadvantaged racial and ethnic minority groups. African Americans were found to have lower rates of major depression in the Epidemiological Catchment Area study. The lifetime prevalence rates for major depression for whites was 5.1 percent; for Hispanics, 4.4 percent; and for African Americans, 3.1 percent. African Americans, however, had higher rates for all lifetime disorders combined. This finding of differential rates could be explained by adjusting for socioeconomic status.

The National Comorbidity Study (NCS) found lower lifetime prevalence rates of mental illness among African Americans than whites, and in a particular mood, anxiety, and substance use disorders. The lifetime rates for mood disorders were 19.8 percent for whites, 17.9 percent for Hispanic Americans, and 13.7 percent for African Americans. The National Health and Nutrition Examination Survey-III also found lifetime rates of major depression significantly higher among whites, 9.6 percent, than African Americans, 6.8 percent, or Mexican Americans, 6.7 percent. Although African Americans had a lower lifetime risk of mood disorders than whites, once diagnosed, they were more likely to remain persistently ill.

NCS rates for anxiety disorders were 29.1 percent among whites, 28.4 percent for Hispanic Americans, and 24.7 percent for African Americans. The rates for lifetime substance use disorders for the three groups, whites, Hispanic Americans, and African Americans, were 29.5, 22.9, and 13.1 percent. Hispanic Americans, and in particular Mexican Americans, were

found to be at lower risk for substance use and anxiety disorders than whites. In an epidemiologic study conducted in Florida, substantially lower rates were observed among African Americans for depressive disorders and substance use disorders. The lower rate for substance use disorders was also found in the National Epidemiological Survey on Alcohol and Related Conditions, with whites having a prevalence rate of 1-year alcohol use disorders of 8.9 percent; Hispanic Americans, 8.9 percent; African Americans, 6.9 percent; Asian Americans, 4.5 percent; and Native Americans, 12.2 percent. This study also found lower lifetime rates for major depression among Hispanic Americans, 10.9 percent, compared to whites, 17.8 percent. In 2007, the National Survey of American Life compared rates of major depression between Caribbean blacks, African Americans, and whites. Although there were no significant differences in 1-year prevalence between the three groups, lifetime rates were highest among whites, 17.9 percent, followed by Caribbean blacks, 12.9 percent, and African Americans, 10.4 percent. The chronicity of major depressive disorder was higher for African Americans and Caribbean blacks, approximately 56 percent, while much lower for whites, 38.6 percent. This study was consistent with findings from the NCS that concluded that members of disadvantaged racial and ethnic groups in the United States do not have an increased risk for psychiatric disorders; however, once diagnosed, they do tend to have more persistent disorders.

Although African Americans have a lower prevalence rate for mood, anxiety, and substance use disorders, this may not be the case for schizophrenia. The Child Health and Development Study found that African Americans were about threefold more likely than whites to be diagnosed with schizophrenia. The association may be partly explained by African American families having lower socioeconomic status, a significant risk factor for schizophrenia.

A more detailed examination of differences across racial groups was included in the National Comorbidity Study Replication (NCS-R). Non-Hispanic African Americans and Hispanic Americans were at significantly lower risk than non-Hispanic whites for anxiety disorders and mood disorders. Non-Hispanic African Americans had lower rates of substance use disorders than non-Hispanic whites. More specifically, both minority groups were at lower risk for depression, generalized anxiety disorder, and social

phobia. Also, Hispanic Americans had a lower risk for dysthymia, oppositional-defiant disorder, and attention-deficit/hyperactivity disorder. Non-Hispanic African Americans had a lower risk for panic disorder, substance use disorders, and early-onset impulse-control disorders. The lower rates among Hispanic Americans and African Americans compared to non-Hispanic whites appear to be due to reduced lifetime risk of disorders instead of the persistence of chronic disorders. The researchers concluded that the pattern of racial–ethnic differences in risk for psychiatric disorders suggests the presence of protective factors that originate in childhood and have generalized effects, as the lower lifetime risk for both Hispanic Americans and African Americans begins before age 10 years for depression and anxiety disorders. The retention of ethnic identification and participation in communal, religious, and other activities have been suggested as protective factors that may decrease the lifetime risk for psychiatric disorders in close-knit ethnic minority communities. Cultural differences in response to psychiatric diagnostic survey items may be another possible explanation for these findings. However, disadvantaged ethnic groups usually overreport in studies measuring psychological distress, whereas these studies find lower rates.

Discrimination, Mental Health, and Service Utilization

Disparities in Mental Health Services. Studies, including recent ones, have shown that racial and ethnic minorities in the United States receive more limited mental health services than whites. Analysis of medical expenditures in the United States has shown that the mental health care system provides comparatively less care to African Americans and Hispanic Americans than to whites, even after controlling for income, education, and availability of health insurance. African Americans have about a 10 percent probability of receiving any mental health expenditure, compared to 20 percent for whites. Hispanic Americans are about 40 percent less likely than whites to receive any mental health expenditure. Total mental health expenditure for Hispanic Americans is about 60 percent less than for whites.

Also, studies conducted over the last 25 years have shown that regardless of disorder diagnosed, African American psychiatric patients are more likely than white patients to be treated as in-patients, hospitalized involuntarily,

placed in seclusion or restraints without evidence of a greater degree of violence, and treated with higher doses of antipsychotic medications. These differences are not due to the greater severity of the disorders between white and African American patients. One hypothesis for this discrepancy of treatment between African American and white patients is that whites are more likely to seek mental health care voluntarily than African Americans, and African Americans are more likely to enter the mental health care system through more coercive and less voluntary referral systems. African Americans are also more likely than whites to use emergency room services, resulting in more crisis-oriented help-seeking and service utilization. Once hospitalized in an institution with predominantly white staff, African American patients may receive differential care due to discrimination. That is, service personnel who are not familiar with the illness concepts and behavioral norms of nonwhite groups tend to assess minorities as more severely ill and more dangerous than patients of their own racial or ethnic group; consequently, such patients tend more often than white patients to be hospitalized involuntarily, placed in seclusion or restrains, and treated with higher doses of antipsychotic medications.

African American patients assessed in psychiatric emergency services are more likely to be diagnosed with schizophrenia and substance abuse than matched white patients. White patients are more often diagnosed with a mood disorder. The cultural distance between the clinician and the patient can affect the degree of psychopathology inferred and the diagnosis given. These differences in diagnosis by race have also been found when comparable research diagnostic instruments have been used for patient assessment. Semistructured diagnostic instruments based on explicit diagnostic criteria do not necessarily eliminate racial disparities in diagnostic outcomes. It appears that the process that clinicians use to link symptom observations to diagnostic constructs may differ, in particular for schizophrenia, between African American and white patients. The pattern of psychotic symptoms that predicts a clinician making a diagnosis of schizophrenia in African American and white patients is different. Among African American patients, loose associations, inappropriate affect, auditory hallucinations, and vague speech increased the likelihood of a diagnosis of schizophrenia. In white patients the main predictors were vague speech and loose associations. Also, auditory hallucinations are more frequently attributed to African American patients.

African Americans are less likely to have had outpatient treatment and longer delays in seeking care, and they present more severely ill. The reason for hospitalization was also different between African Americans and whites. African American patients were more likely to be admitted for behavioral disturbance, whereas white patients were more likely to be admitted for cognitive or affective disturbances. Also, African Americans were more likely to have police or emergency service involvement, despite no racial differences in violence, suicidality, or substance use when assessed. Furthermore, African American patients are more likely, even after controlling for health insurance status, to be referred to the public rather than private in-patient psychiatric facilities, suggesting racial bias in psychiatric emergency room assessment and recommended treatment.

African American patients diagnosed with major depression are less likely to receive antidepressant medications than whites and less likely to be treated with ECT. Demographic or socioeconomic differences cannot explain these findings. One explanation may be that there are conscious or unconscious biases in psychiatrists' treatment decisions. Although both African Americans and Hispanic Americans were less likely to fill an antidepressant prescription when diagnosed with depression, once a prescription was filled, they were just as likely as whites to receive an adequate course of treatment. These findings indicate that initiating care for depression is the biggest hurdle in overcoming these disparities. African American patients are more likely to be treated with depot neuroleptics than whites after controlling for the type and severity of illness. When treated with antipsychotic drugs, African Americans are less likely to receive second-generation antipsychotics than whites, placing them at increased risk for tardive dyskinesia and dystonia. These differences in antipsychotic prescribing patterns may be due to physicians' concern over an increased risk of diabetes among African Americans compared with whites or may be due to physicians perceiving their symptoms differently. Disparities in mental health care for African Americans and Hispanic Americans have also been noted in studies conducted with adolescents.

A disparity in prescription drug use for mental illness also has been found among Hispanic Americans and Asian Indian Americans. From 1996 to 2000, Asian Indian Americans were found to use prescription drugs 23.6 percent less than whites, whereas the differences between whites and African

Americans and between whites and Hispanic Americans were 8.3 and 6.1 percent, respectively. Disparities in mental health service use among Asian American immigrants may be linked to language-based discrimination, although racial bias cannot be excluded. A study of Chinese Americans found a higher level of informal services and help-seeking from friends and relatives for emotional problems. Those Chinese Americans who reported experiencing language-based discrimination had a more negative attitude toward formal mental health services.

Data on racial and ethnic differences in mental health counseling and psychotherapy are similar to the psychopharmacological studies showing disparities for minorities. A study examining visits to primary care physicians based on the National Ambulatory Medical Care Survey from 1997 to 2000 found that primary care physicians provided similar or higher rates of general health counseling to African Americans than white patients. However, the rates of mental health counseling were significantly lower for African American patients. The lower rate of mental health counseling among African Americans may be due to decreased reporting of depressive symptoms, inadequate communication between African American patients and their primary care physicians, and decreased willingness to discuss mental health issues. On the other hand, another study utilizing the Medical Expenditure Panel Survey from 2000 found that African Americans were more likely than Hispanic Americans or whites to receive an adequate course of psychotherapy for depression. These findings suggest that initiating treatment is the biggest hurdle and that once they are engaged in treatment, African Americans have high compliance with psychotherapy.

Research in Transcultural Psychiatry

There are three perspectives, among other possible approaches, that offer great promise for future research in cultural psychiatry. The first would be based on identifying specific fields in general psychiatry that could be the subject of focused research from a cultural perspective. Topics of epidemiology and neurobiology could be assessed in this way. The former would address issues primarily in the public health arena, including stigmatization, racism, and acculturation. Several cultural variables should be considered in conducting cultural psychiatry research, including language,

religion, traditions, beliefs, ethics, and gender orientation.

The second would aim to explore critical concepts or instruments in culturally relevant clinical research. There are four key concepts: *idioms of distress, social desirability, ethnographic data,* and *explanatory models. Idioms of distress* are the specific ways in which different cultures or societies report ailments; behavioral responses to threatening or pathogenic factors; and the uniqueness in the style of description, nomenclature, and assessment of stress. *Social desirability* stems from the similarities or differences among cultures, vis-à-vis the actual experiencing stressful events. Members of some cultures may be more or less willing to suffer physical or emotional problems, thus showing different levels of vulnerability or resignation, resilience, or acceptance. Issues of stigma in different cultural contexts contribute to this level of desirability or rejection. Third, *ethnographic data* should be included, together with strictly clinical data and laboratory analyses or tests, and narratives of life that enrich the descriptive aspects of the condition and expand on the surrounding sociocultural and interpersonal, and environmental aspects of the experience. The fourth concept is *explanatory models.* Each culture explains the pathology of any kind in its distinctive way. The explanation includes not only the presumptive original cause but also the impact of the adduced factors and the interpersonal exchanges and interactions that lead to the culturally accepted clinical diagnosis.

A third approach attempts to combine the first two by examining different areas of research based on the clinical dimensions of cultural psychiatry. This deals with conceptual, operational, and topical issues in the field now and in the future, including their biocultural connections.

Conceptual Issues in Cultural Psychiatry. One of the primary issues in research in cultural psychiatry is the conceptual differentiation between culture and environment. Although generally accepted as the conceptual opposite of genetic, the environment represents a very broad, polymorphic concept. It is, therefore, essential to establish that, while perhaps part of that environmental set, culture and cultural factors in health and disease are terms of a different, even unique, nature.

To what extent does culture apply to the clinical realities of psychiatry? Culture plays a role in both normality and psychopathology. The role of

culture in psychiatric diagnosis is an excellent example of this conceptual issue. Furthermore, culture impacts treatment approaches based on conventional medical and psychiatric knowledge and explanatory models. Finally, cultural variables have a role in prognosis and outcome.

A conceptual debate exists between those who advocate an *evidence-based* approach to research and practice versus those who assign a *value-based* view to everything clinical, more so if influenced by cultural factors. The value-based approach invokes poverty, unemployment, internal and external migration, and natural and human-made disasters. Evidence may be found to support both positions in scientific research.

Operational Issues in Cultural Psychiatry. The dichotomy of normality and abnormality in human behavior is a crucial operational issue. Culture plays a definitive role in shaping these approaches. This raises the notion of relativism, a strong conceptual pillar in cultural psychiatry. Normality is a relative idea; that is, it varies in different cultural contexts.

Another operational issue is that of the choice of cultural variables. Each one has a specific weight and impact on symptoms, syndromes, or clinical entities in psychiatry. Some of them may be essential in assessing a clinical topic, namely, language, education, religion, and gender orientation. An additional operational factor is a description, assessment, and testing of the strengths and weaknesses of an individual patient. Aspects of an individual's behavior, attitudes, disposition, sociability, occupational skills, and other factors are culturally determined.

Culture plays a significant role in perceiving the severity of symptoms, the disruption of the individual's functionality, and the quality of life. The assessment of severity is also the result of the meaning attributed to causal or pathogenic factors of psychopathology. Judgments about the level of dysfunction and the quality of a patient's life involve elusive concepts such as happiness, well-being, and peace of mind.

Research on cultural psychiatry issues needs to consider the representativeness of the study populations and the generalizability of the findings. Methodologic rigor needs to be applied to collecting demographic data, delineation of and differentiation between ethnic groups or subgroups, and measurement of demographic variables, symptoms, diagnosis, and culturally specific constructs.

Many tests and questionnaires used in clinical settings and research have been developed on English-speaking Western subjects and may not be appropriate for ethnic minority patients or non–English-speaking individuals due to lack of cultural equivalence. Translating items is insufficient to achieve linguistic equivalence, as the meaning and connotation changes and idioms of expression differ between languages. Also, norms may differ between ethnic groups, and tests need to be standardized with representative patients.

The complexity of translating an instrument varies depending on how much the construct being measured differs between the two cultures. There are four different approaches to translation. An ethnocentric approach is one in which the researcher assumes that the concepts overlap entirely in the two cultures. The instrument is used with individuals who differ from the population in which the instrument was initially developed and normed. The pragmatic approach assumes that some overlap between the two cultures and attempts are made to measure the overlapping aspects of the construct, *emic* aspects. An emic plus *etic* approach goes one step further and also attempts to measure culture-specific aspects of the construct. Lastly, sometimes the translation is not possible when the concepts do not overlap at all within the two cultures.

CULTURE-BOUND SYNDROMES

Cross-cultural mental health professionals have introduced several terms to refer to and describe culture-specific forms of expressing and diagnosing emotional distress. The term *culture-bound* was used to describe patterned behaviors of distress or illness whose phenomenology appeared distinct from psychiatric categories and were considered unique to particular cultural settings. The clear implication was that Western psychiatric categories were not culture-bound, but rather universal and that proper characterization would disclose a simple translation key for non-Western syndromes. The dichotomy between syndromes that are “culture-free,” emerging from Euro-American and European societies, and those that are “culture-bound,” emerging from everywhere else, is, of course, patently false. Culture suffuses all forms of psychological distress, the familiar as well as the unfamiliar.

Culture-Bound Syndromes and Their Relationship to Psychiatric Diagnoses

Only a few of the many cultural forms of expressing distress have received sustained research attention to integrating cultural and psychiatric research methods. This chapter focuses on some of those syndromes from diverse cultural regions, which have received the most intensive research and are associated with psychiatric categories: *Amok, ataques de nervios*, possession syndrome, and *shenjing shuairuo*.

Amok. *Amok* is a dissociative episode characterized by a period of depression followed by an outburst of violent, aggressive, or homicidal behavior. Episodes tend to be caused by a perceived insult and are often accompanied by persecutory ideas, automation, amnesia, and exhaustion. Patients return to premorbid states following the episode. *Amok* seems to be prevalent only among males. The term originated in Malaysia, but similar behavior patterns can be found in Laos, Philippines, Polynesia (*cafard* or *cathard*), Papua New Guinea, and Puerto Rico (*mal de pelea*), and among the Navajo (*iich'aa*).

PHENOMENOLOGY. A prototypical episode is composed of the following elements:

1. Exposure to a stressful stimulus or subacute conflict, eliciting in the subject feelings of anger, loss, shame, and lowered self-esteem. The stressor usually appears minor in proportion to the resulting behavior (e.g., an argument with a coworker, verbal insult), but may occasionally be severe (i.e., death of a loved one).
2. A period of social withdrawal and brooding over the precipitating conflict, often involving aimless wandering, and sometimes accompanied by visual perceptual alterations.
3. Transition, usually sudden, to frenzied and extremely violent homicidality, with or without a brief prodromal stage of preparation (e.g., the subject may locate a preferred weapon or reach suddenly for whatever implement is available).
4. Indiscriminate selection of victims who may or may not symbolically represent the original actors in the conflict (e.g., subject attacks only

Chinese people who are strangers to him, after a conflict with a Chinese coworker). Occasionally, the subject also attacks animals or objects in his path, or wounds himself, sometimes severely. The subject perseveres at these violent activities despite external attempts to bring him under control.

5. Verbalizations, when present, may be frenzied and guttural, or express internal conflict (e.g., ask forgiveness of a relative before killing him) or split consciousness (e.g., subject admits to a positive relationship with the victim, but denies this for his "spear").
6. Cessation may be spontaneous but usually results from being overpowered or killed. It is typically abrupt and leads to a change in consciousness, usually stupor or sleep.
7. Subsequent partial or total amnesia and report of "unconsciousness" or description of "darkened vision" (*mata gelap*) during the acute episode.
8. Perceptual disturbances or affective decompensations may occur for days or weeks after the acute attack. Psychosis or depression sometimes ensues.

EPIDEMIOLOGY. Epidemiologic rates of *amok* in Malaysia and Indonesia are unknown and may vary regionally and over time. From the available data, *amok* appears to follow an endemic pattern in Malayo-Indonesia with some epidemic increases, the reverse of which has been found for *amok*-like attacks in Laos.

Amok is essentially unknown in women (only one case was found in the literature, and it was considered atypical in that no deaths occurred). It is thought to occur more frequently in men of Malay extraction, Muslim religion, low education, and rural origin, who are between the ages of 20 and 45 years.

PRECIPITANTS. Precipitants of *amok* in Malaysia and Indonesia typically consisted of experiences eliciting in the subject marked feelings of loss, shame, anger, or lowered self-esteem. Although specific triggers were very diverse in nature and presentation, including sudden and gradual stressors, most consisted of interpersonal or social conflicts superficially appearing to generate only mild to moderate stress. These include arguments with coworkers, nonspecific family tensions, feelings of social humiliation, bouts

of possessive jealousy, gambling debts, and job loss. Rarely, however, *amok* was precipitated by a severe stressor, such as the simultaneous death of the spouse and child of the subject.

ADDITIONAL CLINICAL FEATURES. It is unclear whether *amok* episodes are associated with indirect suicidal intent on the part of the subject. Anecdotes and cultural views supporting a connection are available, but interviews with surviving subjects have refuted the association.

Rates of relapse are unknown. It is considered very likely in the popular view, leading currently in Malaysia to permanent psychiatric hospitalization of surviving subjects, and, in the past, to banishment or execution.

TREATMENT. Afflicted individuals in 20th-century Malaysia have been exempted from legal or moral responsibility for acts committed while in a state of *amok* using a kind of "insanity defense," which characterizes the attack as "unconscious" and beyond the subject's control. They were subsequently hospitalized, sometimes permanently, and frequently received diagnoses of schizophrenia and were treated with antipsychotic medication. Alternatively, trials have sometimes resulted in criminal verdicts and prolonged imprisonment.

Ataque de Nervios. *Ataque de nervios* is an idiom of distress principally reported among Latinos from the Caribbean but recognized among many Latin American and Latin Mediterranean groups. Commonly reported symptoms to include uncontrollable shouting, attacks of crying, trembling, heat in the chest rising into the head, and verbal or physical aggression. Dissociative experiences, seizure-like or fainting episodes, and suicidal gestures are prominent in some attacks but absent in others. A general feature of an *ataque de nervios* is a sense of being out of control. *Ataques de nervios* frequently occur as a direct result of a stressful event relating to the family (e.g., news of a death of a close relative, a separation or divorce from a spouse, conflicts with a spouse or children, or witnessing an accident involving a family member). People may experience amnesia for what occurred during the *ataque de nervios*, but they otherwise return rapidly to their usual level of functioning.

Ataque de nervios (attack of nerves, in Spanish) is a syndrome indigenous

to various Latin American cultures, notably those of the Hispanic Caribbean (Puerto Rico, Cuba, and the Dominican Republic). It has received considerable attention in the psychiatric and anthropologic literature since the mid-1950s, mostly in Puerto Rican communities on the island and in populations within the United States.

PHENOMENOLOGY. An *ataque de nervios* can be described as prototypically composed of the following elements:

1. Exposure to a frequently sudden, stressful stimulus, typically eliciting feelings of fear, grief, or anger, and involving a person close to the subject, such as a spouse, child, family member, or friend. The severity of the trigger ranges from mild–moderate (i.e., marital argument, disclosure of migration plans) to extreme (i.e., physical or sexual abuse, acute bereavement).
2. Initiation of the episode is immediate upon exposure to the stimulus, or after a period of brooding or emotional "shock."
3. Once the acute attack begins, the rapid evolution of an intense affective storm follows, characterized by a primary affect usually congruent with the stimulus (such as anger, fear, grief) and a sense of loss of control (*emotional expressions*).
4. All or some of the following accompany these:
   A. *Bodily sensations:* Trembling, chest tightness, headache, difficulty breathing, heart palpitations, heat in the chest, paresthesias of diverse location, difficulty moving limbs, faintness, blurred vision, or dizziness (*mareos*).
   B. Behaviors (*action dimension*): Shouting, crying, swearing, moaning, breaking objects, striking out at others or self, attempting to harm self with the nearest implement, falling to the ground, shaking with convulsive movements, or lying "as if dead."
5. Cessation may be abrupt or gradual, but it is usually rapid, and often results from the ministration of others, involving expressions of concern, prayers, or use of rubbing alcohol (*alcoholado*). There is a return of ordinary consciousness and reported exhaustion.
6. The attack is frequently followed by partial or total amnesia for the events of the episode, and descriptions such as the following for the acute attack:

Loss of consciousness, depersonalization, mind going blank, or general unawareness of surroundings (*alterations in consciousness*). However, some *ataques* appear to exhibit no alterations in consciousness.

EPIDEMIOLOGY. Risk factors for *ataque de nervios* span a range of social and demographic characteristics. The strongest predictors of *ataque* are female gender, lower formal education, and disrupted marital status (i.e., divorced, widowed, or separated). *Ataque* sufferers also reported less satisfaction in their social interactions, generally and specifically with their spouses. Also, people who experienced an *ataque de nervios* were more likely to describe their health as only fair or poor, to seek help for an emotional problem, and to take medications for this purpose. Persons with *ataque* also reported deriving less satisfaction from leisure time activities and feeling overwhelmed more often.

PRECIPITANTS. Prototypically, *ataque de nervios* was linked by sufferers to an acute precipitating event or to the summation of many life episodes of suffering brought to a head by a trigger that overwhelmed the person's coping ability. In 92 percent of cases, the *ataque* was directly provoked by a distressing situation, and 73 percent of the time, it began within minutes or hours of the event. A majority of first *ataques* (81 percent) occurred in the presence of others, as opposed to when the sufferer was alone and led to a person receiving help (67 percent). Unlike the typical experience of persons with panic disorder, most patients reported feeling better (71 percent) or feeling relieved (81 percent) after their first *ataque*. The first episodes of *ataque de nervios* are closely tied to the interpersonal world of the sufferer, and they result in an unburdening (*desahogarse*) of one's life problems, at least temporarily.

ADDITIONAL CLINICAL FEATURES. The association between *ataque de nervios* and a sense of loss of control and of being overwhelmed highlight the importance of the association between the cultural syndrome and other behaviors associated with acute emotional dysregulation. Most concerning among these is the strong relationship between *ataques* and suicidal ideation and attempts. Other related behaviors include loss of aggression control, expressed as attacks on people or property, and dissociative experiences

related to the acute *ataque* experience.

SPECIFIC CULTURAL FACTORS. The complex relationship between *ataque de nervios* and psychiatric diagnosis may be clarified about its broader popular nosology. In the Hispanic Caribbean and other areas of Latin America, *ataque* is part of a popular nosology of *nervios* (nerves), composed of other related categories. Experiences of adversity are linked in this nosology to ensuing "alterations" of the nervous system, which result in its impaired functioning, including the peripheral nerves. This quasi-anatomical damage is evidenced in emotional symptoms, including interpersonal susceptibility, anxiety, and irritability, as well as in physically mediated symptoms, such as trembling, palpitations, and decreased concentration.

TREATMENT. No treatment studies of *ataque de nervios* have ever been conducted. Typical treatment involves, first, ensuring the safety of the person and those around him or her, given the association between *ataque*, suicidality, and uncontrolled aggressivity. "Talking the person down" is usually helpful, accompanied by expressions of support from relatives and other loved ones; rubbing alcohol (*alcoholado*) to help calm the person is a culturally prescribed way of expressing this support.

"Telling the story" of what led to the *ataque* usually constitutes the principal therapeutic approach in subsequent stages of treatment. Because one of the main functions of the attack is to communicate a feeling of being overwhelmed, indicating receipt of the message and the desire to offer support are usually perceived as therapeutic. The person should be allowed to set the pace of disclosure and to give enough details and circumstances to feel "unburdened" (*desahogado[a]*).

In the case of single or occasional *ataques* in the absence of psychiatric diagnosis, brief follow-up is usually sufficient. This may be discussed with the patient and the family to ensure a full return to the previous healthy state. For recurrent *ataques,* treatment depends on the associated psychopathology, the nature of the precipitants (including traumatic exposure), the degree of family conflict or support, the social context, the previous treatment experiences, and the patient's and family's expectations, among other factors.

Psychotherapy is typically the mainstay of treatment, given the usual source of the overwhelmed behavior in the interpersonal milieu.

Pharmacotherapy may also help treat *ataque*-related psychopathology; the primary emphasis should be placed on treating the underlying disorder. Given the slow crescendo of many *ataques*, judicious use of short-acting benzodiazepines also has a role in helping abort an impending episode. However, this should not be the primary form of treatment for recurrent *ataques*, since it only forestalls the principal function of the syndrome as a mode of communication. Instead, psychotherapy and a social activism stance by the therapist that acknowledges the origins of adversity among low-income Latinos in socioeconomic disenfranchisement and ethnic/racial discrimination are usually required to address the interpersonal and sociocultural roots of *ataque de nervios.*

Possession Syndrome. Involuntary possession trance states are very common presentations of emotional distress around the world. Cognate experiences have been reported in extremely diverse cultural settings, including India, Sri Lanka, Hong Kong, China, Japan, Malaysia, Niger, Uganda, Southern Africa, Haiti, Puerto Rico, and Brazil. *Possession syndrome* is an umbrella English-language term used to describe South Asian presentations of involuntary possession trance that encompasses multiple names in regional languages and dialects of India and Sri Lanka. These presentations are seen as a form of illness by the person's cultural group because they are involuntary, they cause distress, and they do not occur as a normal part of a collective cultural or religious ritual or performance.

PHENOMENOLOGY. It is important to distinguish at the outset between possession syndrome, as an instance of possession trance, and the broader category of possession. The latter refers to a general ideology describing the full range of direct spirit influences on human affairs, including effects on physical, psychological, spiritual, social, and ecologic realms. By contrast, as a subset of general possession experience, possession trance refers to specific alterations in consciousness, memory, behavior, and identity attributed to direct spirit influence. In addition to pathologic possession, trance states, South Asian cultures authorize multiple examples of normal possession and possession trance. When voluntary and normative, these states are typically seen as instances of religious devotion, mystical ecstasy, social commentary, asceticism, interpersonal relations, existential reflection, and the study of

consciousness. This chapter discusses possession syndrome as a pathologic entity with an established phenomenology, that is, as a particular case in the general continuum of etiologic ideas regarding possession illnesses. A prototypical episode is composed of the following elements:

1. Onset occurs typically due to subacute conflict or stress and shows considerable variation. It may be gradual and nonspecific (e.g., diverse somatic complaints, such as dizziness, headaches, abdominal discomfort, hot–cold flashes, listlessness, or difficulty breathing) or sudden and specific, in the form of an abrupt transition to an altered state of consciousness.
2. Behavior during the altered state consists of some or all of the following:
   A. Dramatic, semi-purposeful movements, such as head-bobbing, bodily shaking, thrashing, gyrating, or falling to the ground, accompanied by guttural, incoherent verbalizations, such as mumbling, moaning, or shrieking.
   B. Aggressive or violent actions directed at self or others, including spitting, striking, and impulsive suicidal or homicidal gestures. Verbalizations may be coherent and consist of derogatory comments or threats of violence directed against significant others or the subject (in the third person) and typically considered by observers to be uncharacteristic of the subject's usual behavior.
   C. Specific gestures, comments, or requests denoting the appearance of a known possessing personality by (1) reference to standard attributes of culturally recognizable figures or (2) the name and degree of deceased family members or acquaintances.
3. In all cases, this state is marked by the emergence of one or several secondary personalities distinct from that of the subject. Their specific identities, which may remain undisclosed for some time, adhere to cultural norms regulating permissible agents of possession, which vary by religion, region, and caste. Acceptable agents include spirits of deceased family members, in-law relations, or known village acquaintances who died under specific conditions of distress, and minor supernatural figures of the Hindu pantheon (rarely major deities) and the Islamic spiritual world.
4. Possession by the secondary personality(ies) is episodic, resulting in alternation between the usual personality of the subject and the altered

state. The subject in his or her usual identity appears in a daze, exhausted, distressed, or confused about the situation and may report visual or auditory perceptual disturbances regarding the possessing agent and "unconsciousness" and partial or total amnesia for the altered state.

5. Frequently, the specific identities of possessing personalities remain undisclosed for some time, requiring the active ministrations of family members and the intervention of specialized indigenous practitioners. The process of disclosure is conceived as a struggle between the family members and the beneficent agents possessing the healer on the one side, and the troublesome possessing personalities on the other. It is characterized by remarkable reactivity on the part of the subject to environmental cues, including direct questioning, strategic neglect, and aggressive manipulation.
6. The outcome is variable. Total recovery is often reported at the cessation of a single acute episode, which may be of several weeks' duration. Alternatively, prolonged morbidity may result, or even, rarely, death.

Methodologic considerations limit data on the epidemiology, precipitants, and associated psychopathology of subjects with possession syndrome in South Asia. These include a lack of representative community samples and nonsystematic definitions of the syndrome, which shows considerable regional variation.

EPIDEMIOLOGY. Possession syndrome is more common in women than men, with a female-to-male ratio of approximately 3 to 1 in both community and psychiatric cohorts. The age of onset is usually between 15 and 35 years, but many cases reportedly begin in childhood. Attacks may persist well into middle age, and geriatric cases have also been reported.

PRECIPITANTS. Precipitants of possession syndrome are varied but typically consist of marked social or family conflicts, or stressful life transitions, of subacute duration, eliciting strong feelings of vulnerability in persons without firm emotional support. Examples encountered in the literature included marital conflict, abuse, and neglect, at times associated with alcoholism; the arrival of a new bride to the home of her husband's family; delay in arranging a marriage, or in consummating it; forced marriage; widowhood; postpartum

status; loss of family social standing; the death of a family member; difficulty finding employment and financial difficulties; alienation from family support; and subordination to other family members and in-laws.

SPECIFIC CULTURAL FACTORS. Possession syndrome constitutes a normative cultural category throughout India and Sri Lanka. It may present initially in a variety of forms, linked by the attribution of spirit etiology. When it presents in a nonspecific fashion, indigenous diagnosis is confirmed by the appearance of the altered state during the therapeutic ritual. It is considered an affliction by its painful, involuntary nature and attributed to the intervention of specific spiritual agencies acting independently or at the behest of a witch. Certain castes and persons in transitional states (e.g., puerperium) are considered most vulnerable to a spirit attack, especially when deprived of emotional and material support.

TREATMENT. Specialized indigenous practitioners and ritual therapies are generally available and widely utilized, but psychiatric treatment is typically avoided. Indigenous treatments include neutralization of the conflict or stress via the communal rituals involved in exorcism, as well as the reformulation of the suffering into beneficent individual and communal practice via initiation into a spirit devotion cult, such as the Siri cult of South India, or education into the roles of oracle (diviner), exorcist, or, rarely, avatar (divine incarnation).

Shenjing Shuairuo.

Shenjing shuairuo ("weakness of the nervous system" in Mandarin Chinese) is a translation and cultural adaptation of the term "neurasthenia," which was transmitted into China from the West and Japan in the 1920s and 1930s. Revived in its modern form by the American neurologist George Beard since 1868, his formulation of neurasthenia (Greek for "lack of nerve strength") originally denoted a heterogeneous syndrome of lassitude, pain, poor concentration, headache, irritability, dizziness, insomnia, and over 50 other symptoms. It was considered at first an "American disease," resulting from the "pressures" of a rapidly modernizing society but was later adopted by European diagnosticians. Its pathophysiology was thought to derive from a lowering of nervous system function on a physical rather than emotional basis, due to excessive demand for its use, especially

among the educated and wealthier classes. In Soviet psychiatry, buttressed by Pavlovian research, it was a central component of mental health nosology, which became especially influential in Chinese psychiatry after the communist revolution of 1949.

Although neurasthenia declined in importance in Western classification systems during the 20th century, *Shenjing shuairuo* underwent marked popular and professional development in mainland China, Taiwan, Hong Kong, in Chinese migrant communities, and in Japan, where a similar syndrome is labeled *shinkei suijaku.* From a peak in about 1980, when it may have constituted up to 80 percent of all "neurotic" diagnoses in Chinese societies, *Shenjing shuairuo* has undergone intense psychiatric and anthropologic reexamination. It currently features prominently in the second edition revised *Chinese Classification of Mental Disorders* (CCMD-2-R), under the section on "other neuroses." The CCMD-2-R diagnosis requires three symptoms out of five nonhierarchical symptom clusters, organized as weakness, emotional, excitement, and nervous symptoms, and the fifth category of sleep disturbances. Like other neurotic disorders in the Chinese manual, the condition must last at least 3 months, and should (1) lower the efficiency of work, study, or social function; (2) cause mental distress; or (3) precipitate treatment seeking.

PHENOMENOLOGY. Given the evolution of diagnostic practice regarding *shenjing shuairuo* in Chinese societies over the last decades, which may be labeled the professional approximation of the condition or its "disease" aspect, phenomenologic description in this chapter is based instead on clinical histories of self-identified sufferers, or the "illness" aspect of the syndrome. The following elements are prototypical:

1. Onset is usually gradual, sometimes spanning several years, and typically emerges out of a conflictive, frustrating, or worrying situation that involves work, family, and other social settings, or their combination. A sense of powerlessness in changing the precipitating situation appears central to most illness accounts of the syndrome.
2. Symptoms show substantial individual variation, but usually involve at least some of the following spontaneous complaints: Insomnia, affective dysphoria, headache, bodily pains and distortions (e.g., "swelling" of the

head), dizziness, difficulty concentrating, tension and anxiety, worry, fatigue, weakness, gastrointestinal problems, and "troubled vexation" (,*fan nao*). This last emotion has been described as a form of irritability mixed with worry and distress over "conflicting thoughts and unfulfilled desires," that may be partially concealed for the sake of preserving social harmony.

3. The sufferer frequently seeks the sick role, attributing his or her difficulties in meeting work, school, or other social expectations to the syndrome. Sources of treatment vary substantially across Chinese communities, depending on the availability of formal and traditional service sectors.
4. The course is variable and may respond closely to changing interpersonal and social circumstances. Amelioration of the precipitating stressor(s) typically brings about substantial improvement, although residual symptoms appear common.
5. Response to treatment may be strongly mediated by the illness role and its relationship to the intractability of precipitating stressors.

PRECIPITANTS. An empirical assessment of the precipitants of *shenjing shuairuo* has found high rates of work-related stressors, which were made more intractable by the centrally directed nature of mainland Chinese society. These included unwelcome work assignments, job postings that caused family separations, harsh criticism at work, excessive workloads, monotonous tasks, and feelings of inadequacy or incompatibility of skills and responsibilities. Students usually described less severe study-related precipitants, particularly school failure or anxiety over the mismatch between personal or family aspirations and performance. Other interpersonal and family-related stressors included romantic disappointments, marital conflict, and the death of a spouse or other relative. Chinese etiologic understandings of the syndrome commonly invert the Western view of "psychosomatic" presentations, whereby social–interpersonal precipitants cause psychological distress that is displaced onto bodily experience.

ADDITIONAL CLINICAL FEATURES. The clinical course of the syndrome may depend on the associated psychiatric comorbidity and the degree of persistence of the precipitating stressors. One longitudinal study found a

complete resolution of *shenjing shuairuo* symptoms and reasonable social adjustment 20 years from the index diagnosis in 83 of 89 cases. Only one case was receiving continued treatment, and no subjects reported the onset of depressive disorder after the *shenjing shuairuo* diagnosis.

Chinese psychiatrists have carried out numerous studies of neurophysiologic and cognitive function in *shenjing shuairuo* patients since the 1950s. Most have reported abnormalities compared to normal controls, including in tests of polysomnography, electroencephalography, psychogalvanic reflexes, gastric function, and memory function. These findings need to be replicated with well-controlled samples using contemporary diagnostic instruments.

SPECIFIC CULTURAL FACTORS. The evolving definitions of *shenjing shuairuo* have emerged from a tradition of syncretism in Chinese medicine between indigenous illness understandings and international contributions. Nineteenth-century Western notions of a weakened nervous system due to overuse (neurasthenia) found an ancient cognate expression in Chinese concepts of bodily meridians or channels (*jing*) binding vital organs in balanced networks along which forces (e.g., *qi*, vital energy, in *yin* and *yang* forms) could be disrupted from their normal, harmonious flow. This gave rise to *shenjing shuairuo*, an illness whereby the *jing* that carry *shen*—spirit or vitality, the capacity of the mind to form ideas and the desire of the personality to live life—have become *shuai* (degenerate) and *ruo* (weak) following undue nervous excitement.

TREATMENT. When accessing formal sectors of care, most patients used both Western-trained physicians and traditional Chinese doctors. Nonpsychiatric medical settings were preferred, including neurology and general medicine clinics, in concert with cultural understandings of the somatopsychic etiology of *shenjing shuairuo,* emphasizing its physical mediation. The modality of treatment was usually traditional Chinese medicines, which were prescribed by both Western-trained and Chinese-style doctors. This conformed to the balanced status still ascribed to both types of training among Chinese physicians. Polypharmacy was common, combining sedatives, traditional herbs, antianxiety agents, vitamins, and other tonics. Despite the active suppression of religious healing in China, almost a quarter of patients were

also engaged in such treatment.

▲ 34.4 Theories of Personality and Psychopathology

SIGMUND FREUD: FOUNDER OF CLASSIC PSYCHOANALYSIS

Psychoanalysis was the child of Sigmund Freud's genius. He put his stamp on it from the very beginning, and it can be fairly stated that, although the science and theory of psychoanalysis have advanced far beyond Freud, his influence is still strong and pervasive. In recounting the progressive stages in the evolution of the origins of Freud's psychoanalytic thinking, it is useful to keep in mind that Freud himself was working against the background of his neurologic training and expertise and in the context of the scientific thinking of his era.

The science of psychoanalysis is the bedrock of psychodynamic understanding. It forms the fundamental theoretical frame of reference for a variety of forms of therapeutic intervention, embracing not only psychoanalysis itself but also various forms of psychoanalytically oriented psychotherapy and related forms of therapy employing psychodynamic concepts. Currently, considerable interest has been generated in efforts to connect psychoanalytic understandings of human behavior and emotional experience with emerging findings of neuroscientific research.

At the same time, psychoanalysis is undergoing a creative ferment in which classical perspectives are continually being challenged and revised, leading to a diversity of emphases and viewpoints, all of which can be regarded as representing aspects of psychoanalytic thinking. This has given rise to the question as to whether psychoanalysis is one theory or more than one. The divergence of multiple theoretical variants raises the question of the degree to which newer perspectives can be reconciled to classical perspectives.

Freud himself inaugurated the spirit of creative modifications in theory. Some of the theoretical modifications of the classic theory after Freud have

attempted to reformulate basic analytic propositions while still retaining the spirit and fundamental insights of a Freudian perspective; others have challenged and abandoned fundamental analytic insights in favor of divergent paradigms that seem radically different and even contradictory to basic analytic principles.

Although there is more than one way to approach the diversity of such material, the decision has been made to organize this material along roughly historical lines, tracing the emergence of analytic theory or theories over time, but with a good deal of overlap. However, there is an overall pattern of gradual emergence, progressing from early drive theory to structural theory to ego psychology to object relations, and on to self-psychology, intersubjectivism, and relational approaches.

Psychoanalysis today is recognized as having three crucial aspects: it is a therapeutic technique, a body of scientific and theoretical knowledge, and a method of investigation. This section focuses on psychoanalysis as both a theory and a treatment, but the basic tenets elaborated here have broad applications to nonpsychoanalytic settings in clinical psychiatry.

Life of Freud

Sigmund Freud (1856–1939) (Fig. 34-22) was born in Freiburg, a small town in Moravia, which is now part of the Czech Republic. When Freud was 4 years old, his father, a Jewish wool merchant, moved the family to Vienna, where Freud spent most of his life. Following medical school, he specialized in neurology and studied for a year in Paris with Jean-Martin Charcot. He was also influenced by Ambroise-Auguste Liébeault and Hippolyte-Marie Bernheim, both of whom taught him hypnosis while he was in France. After his education in France, he returned to Vienna and began clinical work with hysterical patients. Between 1887 and 1897, his work with these patients led him to develop psychoanalysis.

Beginnings of Psychoanalysis

In the decade from 1887 to 1897, Freud immersed himself in the serious study of the disturbances in his hysterical patients, resulting in discoveries that contributed to the beginnings of psychoanalysis. These slender beginnings had a threefold aspect: Emergence of psychoanalysis as a method

of investigation, as a therapeutic technique, and as a body of scientific knowledge based on an increasing fund of information and fundamental theoretical propositions. These early researches flowed out of Freud's initial collaboration with Joseph Breuer and then, increasingly, from his independent investigations and theoretical developments.

The Case of Anna O

Breuer was an older physician, a distinguished and well-established medical practitioner in the Viennese community (Fig. 34-23). Knowing Freud's interests in hysterical pathology, Breuer told him about the unusual case of a woman he had treated for approximately 1.5 years, from December 1880 to June 1882. This woman became famous under the pseudonym Fräulein Anna O, and the study of her difficulties proved to be one of the essential stimuli in the development of psychoanalysis.

Anna O was, in reality, Bertha Pappenheim, who later became independently famous as a founder of the social work movement in Germany. When she began to see Breuer, she was an intelligent and strong-minded young woman of approximately 21 years of age who had developed several hysterical symptoms connected with the illness and death of her father. These symptoms included paralysis of the limbs, contractures, anesthesias, visual and speech disturbances, anorexia, and distressing nervous cough. Two distinct phases of consciousness also characterized her illness: One relatively standard, but the other reflected a second and more pathologic personality.

Anna was very fond of and close to her father and shared with her mother the duties of nursing him on his deathbed. During her altered states of consciousness, Anna recalled the vivid fantasies and intense emotions she had experienced while caring for her father. It was with considerable amazement, both to Anna and Breuer, that when she could recall, with the associated expression of affect, the scenes or circumstances under which her symptoms had arisen, the symptoms would disappear. She vividly described this process as the "talking cure" and as "chimney sweeping."

Once the connection between talking through the circumstances of the

symptoms and the disappearance of the symptoms themselves had been established, Anna proceeded to deal with each of her many symptoms, one after another. She was able to recall that on one occasion when her mother had been absent, she had been sitting at her father's bedside and had had a fantasy or daydream in which she imagined that a snake was crawling toward her father and was about to bite him. She struggled forward to try to ward off the snake, but her arm, which had been draped over the back of the chair, had gone to sleep. She was unable to move it. The paralysis persisted, and she was unable to move the arm until, under hypnosis, she could recall this scene. It is easy to see how this kind of material must have made a profound impression on Freud. It provided a convincing demonstration of the power of unconscious memories and suppressed affects in producing hysterical symptoms.

In the course of the somewhat lengthy treatment, Breuer had become increasingly preoccupied with his fascinating and unusual patient and, consequently, spent more and more time with her. Meanwhile, his wife had grown increasingly jealous and resentful. As soon as Breuer began to realize this, the sexual connotations of it frightened him, and he abruptly terminated the treatment. Only a few hours later, however, he was recalled urgently to Anna's bedside. She had never alluded to the forbidden topic of sex during her treatment, but she was now experiencing hysterical childbirth. Freud saw the phantom pregnancy as the logical outcome of the sexual feelings she had developed toward Breuer in response to his therapeutic attention. Breuer himself had been entirely unaware of this development, and the experience was quite unnerving. He was able to calm Anna down by hypnotizing her, but then he left the house in a cold sweat and immediately set out with his wife for Venice on a second honeymoon.

According to a version from Freud through Ernest Jones, the patient was far from cured and later hospitalized after Breuer's departure. It seems ironic that the prototype of a cathartic cure was, in fact, far from successful. Nevertheless, the case of Anna O provided a critical starting point for Freud's thinking and a crucial juncture in the development of psychoanalysis.

The Interpretation of Dreams

In his landmark publication *The Interpretation of Dreams* in 1900, Freud presented a theory of the dreaming process that paralleled his earlier analysis of psychoneurotic symptoms. He viewed the dream experience as a conscious expression of unconscious fantasies or wishes not readily acceptable to conscious waking experience. Thus, dream activity was considered to be one of the usual manifestations of unconscious processes.

The dream images represented unconscious wishes or thoughts, disguised through a process of a symbolization and other distorting mechanisms. This

reworking of unconscious contents constituted the dream work. Freud postulated the existence of a "censor," pictured as guarding the border between the unconscious part of the mind and the preconscious level. The censor functioned to exclude unconscious wishes during conscious states but, during regressive relaxation of sleep, allowed specific unconscious contents to pass the border, only after transforming these unconscious wishes into disguised forms experienced in the manifest dream contents by the sleeping subject. Freud assumed that the censor worked in the service of the ego—that is, as serving the self-preservative objectives of the ego. Although he was aware of the unconscious nature of the processes, he tended to regard the ego at this point in developing his theory more restrictively as the source of conscious processes of reasonable control and volition.

The analysis of dreams elicits material that has been repressed. These unconscious thoughts and wishes include nocturnal sensory stimuli (sensory impressions such as pain, hunger, thirst, urinary urgency), the day residue (thoughts and ideas connected with the activities and preoccupations of the dreamer's current waking life), and repressed unacceptable impulses. Because the sleep state blocks motility, the dream enables partial but limited gratification of the repressed impulse that gives rise to the dream.

Freud distinguished between two layers of dream content. The *manifest* content refers to what is recalled by the dreamer; the *latent* content involves the unconscious thoughts and wishes that threaten to awaken the dreamer. Freud described the unconscious mental operations by which latent dream content is transformed into the manifest dream as the *dream work.* Repressed wishes and impulses must attach themselves to innocent or neutral images to pass the scrutiny of the dream censor. This process involves selecting meaningless or trivial images from the dreamer's current experience, which are dynamically associated with the latent images that they resemble in some respect.

Condensation. *Condensation* is the mechanism by which several unconscious wishes, impulses, or attitudes can be combined into a single image in the manifest dream content. Thus, in a child's nightmare, an attacking monster may come to represent not only the dreamer's father but may also represent some aspects of the mother and even some of the child's primitive hostile impulses as well. The converse of condensation can also

occur in the dream work, namely, irradiation or diffusion of a single latent wish or impulse distributed through multiple representations in the manifest dream content. The combination of mechanisms of condensation and diffusion provides the dreamer with a highly flexible and economic device for facilitating, compressing, and diffusing or expanding the manifest dream content, which is derived from latent or unconscious wishes and impulses.

Displacement. The mechanism of *displacement* refers to the transfer of amounts of energy (cathexis) from an original object to a substitute or symbolic representation of the object. Because the substitute object is relatively neutral—that is, less invested with affective energy—it is more acceptable to the dream censor and can pass the borders of repression more easily. Thus, whereas symbolism can be taken to refer to the substitution of one object for another, displacement facilitates distortion of unconscious wishes through the transfer of affective energy from one object to another. Despite the transfer of cathectic energy, the aim of the unconscious impulse remains unchanged. For example, in a dream, the mother may be represented visually by an unknown female figure (at least one who has less emotional significance for the dreamer), but the naked content of the dream nonetheless continues to derive from the dreamer's unconscious instinctual impulses toward the mother.

Symbolic Representation. Freud noted that the dreamer would often represent highly charged ideas or objects by using innocent images that were in some way connected with the idea or object being represented. In this manner, an abstract concept or a complex set of feelings toward a person could be symbolized by a simple, concrete, or sensory image. Freud noted that symbols have unconscious meanings that can be discerned through the patient's associations to the symbol, but he also believed that certain symbols have universal meanings.

Secondary Revision. The mechanisms of condensation, displacement, and symbolic representation are characteristic of a type of thinking that Freud referred to as *primary process.* This primitive mode of cognitive activity is characterized by illogic, bizarre, and absurd images that seem incoherent. Freud believed that a more mature and reasonable aspect of the ego works

during dreams to organize primitive aspects of dreams into a more coherent form. *Secondary revision* is Freud's name for this process, in which dreams become somewhat more rational. The process is related to mature activity characteristic of waking life, which Freud termed *secondary process.*

Affects in Dreams. Secondary emotions may not appear in the dream at all, or they may be experienced in somewhat altered form. For example, repressed rage toward a person's father may take the form of mild annoyance. Feelings may also appear as their opposites.

Anxiety Dreams. Freud's dream theory preceded his development of a comprehensive theory of the ego. Hence, his understanding of dreams stresses the importance of discharging drives or wishes through the hallucinatory contents of the dream. He viewed such mechanisms as condensation, displacement, symbolic representation, projection, and secondary revision primarily as facilitating the discharge of latent impulses, rather than as protecting dreamers from anxiety and pain. Freud understood anxiety dreams as reflecting a failure in the protective function of the dream-work mechanisms. The repressed impulses succeed in working their way into the manifest content in a more or less recognizable manner.

Punishment Dreams. Dreams in which dreamers experience punishment represented a unique challenge for Freud because they appear to represent an exception to his wish-fulfillment theory of dreams. He came to understand such dreams as reflecting a compromise between the repressed wish and the repressing agency or conscience. In a punishment dream, the ego anticipates condemnation on the dreamer's conscience if the latent unacceptable impulses are allowed direct expression in the manifest dream content. Hence, the wish for punishment on the part of the patient's conscience is satisfied by giving expression to punishment fantasies.

Topographical Model of the MIND

The publication of *The Interpretation of Dreams* in 1900 heralded the arrival of Freud's topographical model of the mind, in which he divided the mind into three regions: the conscious system, the preconscious system, and the unconscious system. Each system has its unique characteristics.

The Conscious. The conscious system in Freud's topographical model is the part of the mind in which perceptions coming from the outside world or within the body or mind are brought into awareness. Consciousness is a subjective phenomenon whose content can be communicated only using language or behavior. Freud assumed that consciousness used a form of neutralized psychic energy that he referred to as *attention cathexis,* whereby persons were aware of a particular idea or feeling as a result of investing a discrete amount of psychic energy in the idea or feeling.

The Preconscious. The preconscious system is composed of those mental events, processes, and contents that can be brought into conscious awareness by focusing attention. Although most persons are not consciously aware of the appearance of their first-grade teacher, they ordinarily can bring this image to mind by deliberately focusing attention on the memory. Conceptually, the preconscious interfaces with both unconscious and conscious regions of the mind. To reach conscious awareness, the contents of the unconscious must become linked with words and thus become preconscious. The preconscious system also serves to maintain the repressive barrier and to censor unacceptable wishes and desires.

The Unconscious. The unconscious system is dynamic. Its mental contents and processes are kept from conscious awareness through the force of censorship or repression, and it is closely related to instinctual drives. At this point in Freud's theory of development, instincts were thought to consist of sexual and self-preservative drives, and the unconscious was thought to contain the mental representations and derivatives of the sexual instinct primarily.

The content of the unconscious is limited to wishes seeking fulfillment. These wishes motivate dream and neurotic symptom formation. This view is now considered reductionist.

The unconscious system is characterized by *primary process thinking,* principally aimed at facilitating wish fulfillment and instinctual discharge. It is governed by the pleasure principle and, therefore, disregards logical connections; it has no concept of time, represents wishes as fulfillments, permits contradictions to exist simultaneously, and denies the existence of negatives. The primary process is also characterized by extreme mobility of

drive cathexis; the investment of psychic energy can shift from object to object without opposition. Memories in the unconscious have been divorced from their connection with verbal symbols. Hence, when words are reapplied to forgotten memory traits, as in psychoanalytic treatment, the verbal cathexis allows the memories to reach consciousness again.

The contents of the unconscious can become conscious only by passing through the preconscious. When censors are overpowered, the elements can enter consciousness.

Limitations of the Topographical Theory. Freud soon realized that two primary deficiencies in the topographical theory limited its usefulness. First, many patients' defense mechanisms that guard against distressing wishes, feelings, or thoughts were not initially accessible to consciousness. Thus, repression cannot be identical with preconscious, because, by definition, this region of the mind is accessible to consciousness. Second, Freud's patients frequently demonstrated an unconscious need for punishment. This clinical observation made it unlikely that the moral agency making the demand for punishment could be allied with anti-instinctual forces available to conscious awareness in the preconscious. These difficulties led Freud to discard the topographical theory. However, certain concepts derived from the theory continue to be useful, mainly primary and secondary thought processes, the fundamental importance of wish fulfillment, the existence of a dynamic unconscious, and a tendency toward regression under frustrating conditions.

Instinct or Drive Theory

After the development of the topographical model, Freud turned his attention to the complexities of instinct theory. Freud was determined to anchor his psychological theory in biology. His choice led to terminologic and conceptual difficulties when he used terms derived from biology to denote psychological constructs. *Instinct,* for example, refers to a pattern of species-specific behavior that is genetically derived and, therefore, is more or less independent of learning. Modern research demonstrating that instinctual patterns are modified through experiential learning has made Freud's instinctual theory problematic. Further confusion has stemmed from the ambiguity inherent in a concept on the borderland between the biologic and

the psychological: Should the mental representation aspect of the term and the physiologic component be integrated or separated? Although *drive* may have been closer than the instinct to Freud's meaning, in contemporary usage, the two terms are often used interchangeably.

In Freud's view, an instinct has four principal characteristics: source, impetus, aim, and object. The *source* refers to the part of the body from which the instinct arises. The *impetus* is the amount of force or intensity associated with the instinct. The *aim* refers to any action directed toward tension discharge or satisfaction, and the *object* is the target (often a person) for this action.

Instincts

LIBIDO. The ambiguity in the term *instinctual drive* is also reflected in the use of the term *libido.* Briefly, Freud regarded the sexual instinct as a psychophysiological process that had both mental and physiologic manifestations. Essentially, he used the term *libido* to refer to "the force by which the sexual instinct is represented in mind." Thus, in its accepted sense, libido refers specifically to the mental manifestations of the sexual instinct. Freud recognized early that the sexual instinct did not originate in a finished or final form, as represented by genital primacy. Instead, it underwent a complex process of development, at each phase of which the libido had specific aims and objects that diverged in varying degrees from the simple aim of genital union. The libido theory thus came to include all of these manifestations and the complicated paths they followed in the course of psychosexual development.

EGO INSTINCTS. From 1905 on, Freud maintained a dual instinct theory, subsuming sexual instincts and ego instincts connected with self-preservation. Until 1914, with the publication of *On Narcissism*, Freud had paid little attention to ego instincts; in this communication, however, Freud invested ego instinct with libido for the first time by postulating an ego libido and an object libido. Freud thus viewed narcissistic investment as an essentially libidinal instinct and called the remaining nonsexual components the *ego instincts.*

AGGRESSION. When psychoanalysts today discuss the dual instinct theory,

they are generally referring to libido and aggression. Freud, however, originally conceptualized aggression as a component of the sexual instincts in the form of sadism. As he became aware that sadism had nonsexual aspects, he made finer gradations, which enabled him to categorize aggression and hate as part of the ego instincts and the libidinal aspects of sadism as components of the sexual instincts. Finally, in 1923, to account for the clinical data he was observing, he was compelled to conceive of aggression as a separate instinct in its own right. The source of this instinct, according to Freud, was mostly in skeletal muscles, and the aim of the aggressive instincts was destruction.

LIFE AND DEATH INSTINCTS. Before designating aggression as a separate instinct, Freud, in 1920, subsumed the ego instincts under a broader category of life instincts. These were juxtaposed with death instincts and were referred to as *Eros* and *Thanatos* in *Beyond the Pleasure Principle.* Life and death instincts were regarded as forces underlying sexual and aggressive instincts. Although Freud could not provide clinical data that directly verified the death instinct, he thought the instinct could be inferred by observing *repetition compulsion,* a person's tendency to repeat past traumatic behavior. Freud thought that the dominant force in biologic organisms had to be the death instinct. In contrast to the death instinct, eros (the life instinct) refers to the tendency of particles to reunite or bind to one another, as in sexual reproduction. The prevalent view today is that the dual instincts of sexuality and aggression suffice to explain most clinical phenomena without recourse to a death instinct.

Pleasure and Reality Principles. In 1911, Freud described two basic tenets of mental functioning: the pleasure principle and the reality principle. He essentially recast the primary process and secondary process dichotomy into the pleasure and reality principles and thus took an essential step toward solidifying the notion of the ego. Both principles, in Freud's view, are aspects of ego functioning. The *pleasure principle* is defined as an inborn tendency of the organism to avoid pain and to seek pleasure through the discharge of tension. The *reality principle,* on the other hand, is considered to be a learned function closely related to the maturation of the ego; this principle modifies the pleasure principle and requires delay or postponement of immediate

gratification.

Infantile Sexuality. Freud set forth the three central tenets of psychoanalytic theory when he published *Three Essays on the Theory of Sexuality.* First, he broadened the definition of sexuality to include forms of pleasure that transcend genital sexuality. Second, he established a developmental theory of childhood sexuality that delineated the vicissitudes of erotic activity from birth through puberty. Third, he forged a conceptual linkage between neuroses and perversions.

Freud's notion that sexual drives influence children has made some persons reluctant to accept psychoanalysis. Freud noted that infants are capable of erotic activity from birth, but the earliest manifestations of infantile sexuality are nonsexual and are associated with such bodily functions as feeding and bowel–bladder control. As libidinal energy shifts from the oral zone to the anal zone to the phallic zone, each stage of development is thought to build on and to subsume the accomplishments of the preceding stage. The *oral stage,* which occupies the first 12 to 18 months of life, centers on the mouth and lips and is manifested in chewing, biting, and sucking. The dominant erotic activity of the anal stage, from 18 to 36 months of age, involves bowel function and control. The *phallic stage,* from 3 to 5 years of life, initially focuses on urination as the source of erotic activity. Freud suggested that phallic erotic activity in boys is a preliminary stage leading to adult genital activity. Whereas the penis remains the principal sexual organ throughout male psychosexual development, Freud postulated that females have two principal erotogenic zones: the vagina and the clitoris. He thought that the clitoris was the chief erotogenic focus during the infantile genital period, but that erotic primacy shifted to the vagina after puberty. Studies of human sexuality have subsequently questioned the validity of this distinction.

Freud discovered that in the psychoneuroses, only a limited number of the sexual impulses that had undergone repression and were responsible for creating and maintaining the neurotic symptoms were normal. For the most part, these were the same impulses that were given overt expression in the perversions. The neuroses, then, were the negative of perversions.

Object Relationships in Instinct Theory. Freud suggested that the

choice of a love object in adult life, the love relationship itself, and the nature of all other object relationships depend primarily on the nature and quality of children's relationships. In describing the libidinal phases of psychosexual development, Freud repeatedly referred to the significance of a child's relationships with parents and other significant persons in the environment.

The awareness of the external world of objects develops gradually in infants. Soon after birth, they are primarily aware of physical sensations, such as hunger, cold, and pain, which give rise to tension, and caregivers are regarded primarily as persons who relieve their tension or remove painful stimuli. Recent infant research, however, suggests that awareness of others begins much sooner than Freud initially thought. Table 34-10 summarizes the stages of psychosexual development and the object relationships associated with each stage. Although the table goes only as far as young adulthood, development is now recognized as continuing throughout adult life.

Concept of Narcissism. According to Greek myth, Narcissus, a beautiful youth, fell in love with his reflection in the water of a pool and drowned in his attempt to embrace his beloved image. Freud used the term *narcissism* to describe situations in which an individual's libido was invested in the ego itself rather than other persons. This concept of narcissism presented him with vexing problems for his instinct theory and essentially violated his distinction between libidinal instincts and ego or self-preservative instincts. Freud's understanding of narcissism led him to use the term to describe a wide array of psychiatric disorders, very much in contrast to the term's contemporary use to describe a specific personality disorder. Freud grouped several disorders as the narcissistic neuroses, in which a person's libido is withdrawn from objects and turned inward. He believed that this withdrawal of libidinal attachment to objects accounted for the loss of reality testing in psychotic patients; grandiosity and omnipotence in such patients reflected excessive libidinal investment in the ego.

Freud did not limit his use of narcissism to psychoses. In states of physical illness and hypochondriasis, he observed that libidinal investment was frequently withdrawn from external objects and outside activities and interests. Similarly, he suggested that in normal sleep, libido was also withdrawn and reinvested in a sleeper's own body. Freud regarded homosexuality as an instance of a narcissistic form of object choice, in which

persons fall in love with an idealized version of themselves projected onto another person. He also found narcissistic manifestations in the beliefs and myths of primitive people, especially those involving the ability to influence external events through the magical omnipotence of thought processes. In the course of normal development, children also exhibit this belief in their omnipotence.

Table 34-10
Stages of Psychosexual Development

Oral Stage	
Definition	Earliest stage of development in which the infant's needs, perceptions, and modes of expression are primarily centered in mouth, lips, tongue, and other organs related to oral zone and around the sucking reflex.
Description	Oral zone maintains dominance in psychic organization through approximately first 18 mo of life. Oral sensations include thirst, hunger, pleasurable tactile stimulations evoked by the nipple or its substitute, and sensations related to swallowing and satiation. Oral drives consist of two components: libidinal and aggressive. States of oral tension lead to seeking oral gratification, as in quiescence at the end of nursing. Oral triad consists of wishes to eat, sleep, and reach that relaxation that occurs at the end of sucking just before onset of sleep. Libidinal needs (oral erotism) predominate in early oral phase, whereas they are mixed with more aggressive components later (oral sadism). Oral aggression is expressed in biting, chewing, spitting, or crying. Oral aggression is connected with primitive wishes and fantasies of biting, devouring, and destroying.

Objectives	To establish a trusting dependence on nursing and sustaining objects, establish comfortable expression and gratification of oral libidinal needs without excessive conflict or ambivalence from oral sadistic wishes.
Pathologic traits	Excessive oral gratifications or deprivation can result in libidinal fixations contributing to pathologic traits. Such traits can include excessive optimism, narcissism, pessimism (as in depressive states), or demandingness. Envy and jealousy are often associated with oral traits.
Character traits	Successful resolution of the oral phase results in capacities to give to and receive from others without excessive dependence or envy and to rely on others with a sense of trust as well as with a sense of self-reliance and self-trust. Oral characters are often excessively dependent and require others to give to them and look after them and are often extremely dependent on others for maintaining self-esteem. These are readily amalgamated with narcissistic needs.
Anal Stage	
Definition	The stage of psychosexual development promoted by maturation of neuromuscular control over sphincters, particularly the anal sphincter, permitting greater voluntary control over retention or expulsion of feces.
Description	This period extends roughly from 1 to 3 yr of age, marked by recognizable intensification of aggressive drives mixed with libidinal components in sadistic impulses. Acquisition of voluntary sphincter control is associated with an increasing shift from passivity to activity. Conflicts over anal

	control and struggles with parents over retaining or expelling feces in toilet training give rise to increased ambivalence, together with conflicts over separation, individuation, and independence. Anal erotism refers to sexual pleasure in anal functioning, both in retaining precious feces and presenting them as a precious gift to the parent. Anal sadism refers to expression of aggressive wishes connected with discharging feces as powerful and destructive weapons. These wishes are often displayed in fantasies of bombing or explosions.
Objectives	The anal period is marked by greater striving for independence and separation from dependence on and control of parents. Objectives of sphincter control without overcontrol (fecal retention) or loss of control (messing) are matched by attempts to achieve autonomy and independence without excessive shame or self-doubt from loss of control.
Pathologic traits	Maladaptive character traits, often apparently inconsistent, derive from anal erotism and defenses against it. Orderliness, obstinacy, stubbornness, willfulness, frugality, and parsimony are features of anal character. When defenses against anal traits are less effective, anal character reveals traits of heightened ambivalence, lack of tidiness, messiness, defiance, rage, and sadomasochistic tendencies. Anal characteristics and defenses are typically seen in obsessive-compulsive neuroses.
Character traits	Successful resolution of the anal phase provides the basis for development of personal autonomy, a capacity for independence and personal initiative without guilt, a capacity for self-determining

	behavior without a sense of shame or self-doubt, a lack of ambivalence, and a capacity for willing cooperation without either excessive willfulness or self-diminution or defeat.
Urethral Stage	
Definition	This stage was not explicitly treated by Freud but serves as a transitional stage between anal and phallic stages. It shares some characteristics of anal phase and some from subsequent phallic phase.
Description	Characteristics of the urethral phase are often subsumed under phallic phase. Urethral erotism, however, refers to pleasure in urination as well as pleasure in urethral retention analogous to anal retention. Similar issues of performance and control are related to urethral functioning. Urethral functioning may also have sadistic quality, often reflecting persistence of anal sadistic urges. Loss of urethral control, as in enuresis, may frequently have regressive significance that reactivates anal conflicts.
Objectives	At stake are issues of control and urethral performance and loss of control. It is not clear whether or to what extent objectives of urethral functioning differ from those of anal period, except that they are expressed in a later developmental stage.
Pathologic traits	The predominant urethral trait is competitiveness and ambition, probably related to compensation for shame due to loss of urethral control. This may instigate development of penis envy, related to feminine sense of shame and inadequacy in being unable to match male urethral performance. This

	may also be related to issues of control and shaming.
Character traits	Besides healthy effects analogous to those from the anal period, urethral competence provides a sense of pride and self-competence based on performance. Urethral performance is an area in which the small boy can imitate and try to match his father's more adult performance. Resolution of urethral conflicts sets the stage for budding gender identity and subsequent identifications.
Phallic Stage	
Definition	Phallic stage begins sometime during year 3 and continues until approximately the end of year 5.
Description	The phallic phase is characterized by a primary focusing of sexual interests, stimulation, and excitement in the genital area. The penis becomes the organ of principal interest to children of both sexes, with lack of penis in females being considered as evidence of castration. The phallic phase is associated with an increase in genital masturbation accompanied by predominantly unconscious fantasies of sexual involvement with the opposite-sex parent. Threats of castration and the related anxiety are connected with guilt over masturbation and oedipal wishes. During this phase oedipal involvement and conflict are established and consolidated.
Objectives	To focus erotic interest in genital area and genital functions. This lays the foundation for gender identity and serves to integrate residues of previous stages into a predominantly genital–sexual orientation. Establishing the oedipal situation is essential for furtherance of subsequent

	identifications, serving as a basis for important and perduring dimensions of character organization.
Pathologic traits	Derivation of pathologic traits from phallic–oedipal involvement is sufficiently complex and subject to such a variety of modifications that it encompasses nearly the whole of neurotic development. Issues, however, focus on castration in males and penis envy in females. Patterns of internalization developed from resolution of the Oedipus complex provide another important focus of developmental distortions. The influence of castration anxiety and penis envy, defenses against them, and patterns of identification are primary determinants of the development of human character. They also subsume and integrate residues of previous psychosexual stages, so that fixations or conflicts deriving from preceding stages can contaminate and modify oedipal resolution.
Character traits	The phallic stage provides the foundation for an emerging sense of sexual identity, curiosity without embarrassment, initiative without guilt, as well as mastery not only over objects and persons in the environment but also over internal processes and impulses. Resolution of the oedipal conflict gives rise to internal structural capacities for regulation of drive impulses and their direction to constructive ends. The internal sources of such regulation are the ego and superego, based on introjections and identifications derived primarily from parental figures.
Latency Stage	
Definition	This is the stage of relative instinctual quiescence or inactivity of sexual drive during the period from the

	resolution of the Oedipus complex until pubescence (from about 5–6 yr until about 11–13 yr).
Description	The institution of the superego at the close of the oedipal period and further maturation of ego functions allow for considerably greater degrees of control of instinctual impulses and motives. Sexual interests are generally thought to be quiescent. This is a period of primarily homosexual affiliations for both boys and girls, as well as a sublimation of libidinal and aggressive energies into energetic learning and play activities, exploring the environment, and becoming more proficient in dealing with the world of things and persons around them. It is a period for development of important skills. The relative strength of regulatory elements often gives rise to patterns of behavior that are somewhat obsessive and hypercontrolling.
Objectives	The primary objective is further integration of oedipal identifications and consolidation of gender and sex-role identity. Relative quiescence and control of instinctual impulses allow for development of ego apparatuses and mastery of skills. Further identificatory components may be added to the oedipal ones on the basis of broadening contacts with other significant figures outside the family (e.g., teachers, coaches, and other adult figures).
Pathologic traits	Dangers in the latency period can arise either from the lack of development of inner controls or an excess of them. Lack of control can lead to failure to sufficiently sublimate energies in the interest of learning and the development of skills; an excess of inner control, however, can lead to premature closure of personality development and precocious

	elaboration of obsessive character traits.
Character traits	The latency period is frequently regarded as a period of relatively unimportant inactivity in the developmental schema. More recently, greater respect has been gained for the developmental processes in this period. Important consolidations and additions are made to basic postoedipal identifications and to processes of integrating and consolidating previous attainments in psychosexual development and establishing decisive patterns of adaptive functioning. The child can develop a sense of industry and capacity for mastery of objects and concepts that allows autonomous functioning and a sense of initiative without risk of failure or defeat or a sense of inferiority. These are all important attainments that need to be further integrated, ultimately as the essential basis for a mature adult life of satisfaction in work and love.
Genital Stage	
Definition	The genital or adolescent phase extends from the onset of puberty from approximately ages 11–13 until young adulthood. Current thinking tends to subdivide this stage into preadolescent, early adolescent, middle adolescent, late adolescent, and even postadolescent periods.
Description	Physiologic maturation of systems of genital (sexual) functioning and attendant hormonal systems leads to intensification of instinctual, particularly libidinal, drives. This produces a regression in personality organization, which reopens conflicts of previous stages of psychosexual development and provides opportunity for re-resolution of these conflicts in the context of achieving a mature sexual and adult

	identity. This period has been described as a "second individuation."
Objectives	Primary objectives are the ultimate separation from dependence on and attachment to parents and establishment of mature, nonincestuous, heterosexual object relations. Related are the achievement of a mature sense of personal identity and acceptance and integration of adult roles and functions that permit new adaptive integrations with social expectations and cultural values.
Pathologic traits	Pathologic deviations due to failure to achieve successful resolution of this stage of development are multiple and complex. Defects can arise from a whole spectrum of psychosexual residues, since the developmental task of adolescence is in a sense a partial reopening, reworking, and reintegration of all of these aspects of development. Previous unsuccessful resolutions and fixations in various phases or aspects of psychosexual development will produce pathologic defects in the emerging adult personality and defects in identity formation.
Character traits	Successful resolution and reintegration of previous psychosexual stages in the adolescent genital phase set the stage normally for a fully mature personality with the capacity for full and satisfying genital potency and a self-integrated and consistent sense of identity. This provides the basis for a capacity for self-realization and meaningful participation in areas of work, love, and in creative and productive application to satisfying and meaningful goals and values.

Freud postulated a state of primary narcissism at birth in which the libido is stored in the ego. He viewed the neonate as completely narcissistic, with the entire libidinal investment in physiologic needs and satisfaction. He referred to this self-investment as *ego libido.* The infantile state of self-absorption changes only gradually, according to Freud, with the dawning awareness that a separate person—the mothering figure—is responsible for gratifying an infant's needs. This realization leads to the gradual withdrawal of the libido from the self and its redirection toward the external object. Hence, the development of object relations in infants parallels the shift from primary narcissism to object attachment. The libidinal investment in the object is referred to as *object libido.* If a developing child suffers rebuffs or trauma from the caretaking figure, object libido may be withdrawn and reinvested in the ego. Freud called this regressive posture *secondary narcissism.*

Freud used the term *narcissism* to describe many different dimensions of human experience. At times, he used it to describe a perversion in which persons used their bodies or body parts as objects of sexual arousal. At other times, he used the term to describe a developmental phase, as in primary narcissism. In still other instances, the term referred to a particular object choice. Freud distinguished love objects who are chosen "according to the narcissistic type," in which case the object resembles the subject's idealized or fantasied self-image, from objects chosen according to the "anaclitic," in which the love object resembles a caretaker from early in life. Finally, Freud also used the word *narcissism* interchangeably and synonymously with *self-esteem.*

Ego Psychology

Although Freud had used the construct of the ego throughout the evolution of psychoanalytic theory, ego psychology, as it is known today, really began with the publication in 1923 of *The Ego and the Id.* This landmark publication also represented a transition in Freud's thinking from the topographical model of the mind to the tripartite structural model of ego, id, and superego. He had observed repeatedly that not all unconscious processes could be relegated to a person's instinctual life. Elements of the conscience, as well as functions of the ego, are also unconscious.

Structural Theory of the Mind. The structural model of the psychic apparatus is the cornerstone of ego psychology. The three provinces—id, ego, and superego—are distinguished by their different functions.

ID. Freud used the term *id* to refer to a reservoir of unorganized instinctual drives. Operating under the domination of the primary process, the id cannot delay or modify the instinctual drives with which an infant is born. The id, however, should not be viewed as synonymous with the unconscious, because both the ego and the superego have unconscious components.

EGO. The ego spans all three topographical dimensions of conscious, preconscious, and unconscious. Logical and abstract thinking and verbal expression are associated with conscious and preconscious functions of the ego. Defense mechanisms reside in the unconscious domain of the ego. The ego, the executive organ of the psyche, controls motility, perception, contact with reality, and, through the defense mechanisms available to it, the delay and modulation of drive expression.

Freud believed that the id is modified due to the impact of the external world on the drives. The pressures of external reality enable the ego to appropriate the energies of the id to do its work. As the ego brings influences from the external world to bear on the id, it simultaneously substitutes the reality principle for the pleasure principle. Freud emphasized the role of conflict within the structural model and observed that conflict occurs initially between the id and the outside world, only to be transformed later to conflict between the id and the ego.

The third component of the tripartite structural model is the superego. The superego establishes and maintains an individual's moral conscience based on a complex system of ideals and values internalized by parents. Freud viewed the superego as the heir to the Oedipus complex. Children internalize parental values and standards at about the age of 5 or 6 years. The superego then serves as an agency that provides ongoing scrutiny of a person's behavior, thoughts, and feelings; it makes comparisons with expected standards of behavior and offers approval or disapproval. These activities occur mostly unconsciously.

The ego-ideal is often regarded as a component of the superego. It is an agency that prescribes what a person should do according to internalized

standards and values. The superego, by contrast, is an agency of moral conscience that *proscribes*—that is, dictates what a person should not do. Throughout the latency period and after that, persons continue to build on early identifications through their contact with admired figures who contribute to the formation of moral standards, aspirations, and ideals.

Functions of the Ego. Modern ego psychologists have identified a set of essential ego functions that characterizes the operations of the ego. These descriptions reflect the ego activities that are generally regarded as fundamental.

CONTROL AND REGULATION OF INSTINCTUAL DRIVES. The development of the capacity to delay or postpone drive discharge, like the capacity to test reality, is closely related to the early childhood progression from the pleasure principle to the reality principle. This capacity is also an essential aspect of the ego's role as a mediator between the id and the outside world. Part of infants' socialization to the external world is acquiring language and secondary process or logical thinking.

JUDGMENT. A closely related ego function is judgment, which involves the ability to anticipate the consequences of actions. As with the control and regulation of instinctual drives, judgment develops in parallel with the growth of *secondary process thinking.* The ability to think logically allows assessment of how contemplated behavior may affect others.

RELATION TO REALITY. The mediation between the internal world and external reality is a crucial function of the ego. Relations with the outside world can be divided into three aspects: the sense of reality, reality testing, and adaptation to reality. The *sense of reality* develops in concert with an infant's dawning awareness of bodily sensations. The ability to distinguish outside the body from the inside is an essential aspect of the sense of reality, and disturbances of body boundaries, such as depersonalization, reflect impairment in this ego function. *Reality testing,* an ego function of paramount importance, refers to the capacity to distinguish internal fantasy from external reality. This function differentiates persons who are psychotic from those who are not. *Adaptation to reality* involves persons' ability to use their

resources to develop effective responses to changing circumstances based on previous experience with reality.

Table 34-11
Parallel Lines of Development

Instinctual Phases	Separation–Individuation	Object Relations	Psychosocial Crises
Oral	Autism, symbiosis	Primary narcissism, need-satisfying	Trust or mistrust
Anal	Differentiation, practicing, rapprochement	Need-satisfying, object constancy	Autonomy or shame, self-doubt
Phallic	Object constancy, Oedipal complex	Object constancy, ambivalence	Initiative or guilt
Latency	—	—	Industry or inferiority
Adolescence	Genitality, secondary individuation	Object love	Identity or identity confusion
Adulthood	Mature genitality	—	Intimacy or isolation, generativity or stagnation, integrity or despair

OBJECT RELATIONSHIPS. The capacity to form mutually satisfying relationships is related in part to patterns of internalization stemming from

early interactions with parents and other significant figures. This ability is also a fundamental function of the ego, in that satisfying relatedness depends on the ability to integrate positive and negative aspects of others and self and to maintain an internal sense of others even in their absence. Similarly, mastery of drive derivatives is also crucial to the achievement of satisfying relationships. Although Freud did not develop an extensive object relations theory, British psychoanalysts, such as Ronald Fairbairn (1889–1964) and Michael Balint (1896–1970), elaborated extensively on the early stages in infants' relationships with need-satisfying objects and on the gradual development of a sense of separateness from the mother. Another of their British colleagues, Donald W. Winnicott (1896–1971), described the *transitional object* (e.g., a blanket, teddy bear, or pacifier) as the link between developing children and their mothers. A child can separate from the mother because a transitional object provides feelings of security in her absence. The stages of human development and object relations theory are summarized in Table 34-11.

SYNTHETIC FUNCTION OF THE EGO. First described by Herman Nunberg in 1931, the *synthetic function* refers to the ego's capacity to integrate diverse elements into an overall unity. Different aspects of self and others, for example, are synthesized into a consistent representation that endures over time. The function also involves organizing, coordinating, and generalizing or simplifying large amounts of data.

PRIMARY AUTONOMOUS EGO FUNCTIONS. Heinz Hartmann described the so-called primary autonomous functions of the ego as rudimentary apparatuses present at birth that develop independently of intrapsychic conflict between drives and defenses. These functions include perception, learning, intelligence, intuition, language, thinking, comprehension, and motility. In the course of development, some of these conflict-free aspects of the ego may eventually become involved in a conflict. They will develop normally if the infant is raised in what Hartmann referred to as an *average expectable environment.*

SECONDARY AUTONOMOUS EGO FUNCTIONS. Once the sphere where primary autonomous function develops becomes involved with conflict, the so-called

secondary autonomous ego functions arise in the defense against drives. For example, a child may develop caretaking functions as a reaction formation against murderous wishes during the first few years. Later, the defensive functions may be neutralized or deinstinctualized when the child grows up to be a social worker and cares for homeless persons.

Defense Mechanisms. At each phase of libidinal development, specific drive components evoke characteristic ego defenses. The anal phase, for example, is associated with reaction formation, as manifested by the development of shame and disgust concerning anal impulses and pleasures.

Defenses can be grouped hierarchically according to the relative degree of maturity associated with them. Narcissistic defenses are the most primitive and appear in children and persons who are psychotically disturbed. Immature defenses are seen in adolescents and some nonpsychotic patients. Neurotic defenses are encountered in obsessive-compulsive and hysterical patients as well as in adults under stress. Table 34-12 lists the defense mechanisms, according to George Valliant's classification of the four types.

Theory of Anxiety. Freud initially conceptualized anxiety as "dammed-up libido." Essentially, a physiologic increase in sexual tension leads to a corresponding increase in libido, the mental representation of the physiologic event. This buildup causes the actual neuroses. Later, with the development of the structural model, Freud developed a new theory of a second type of anxiety that he referred to as *signal anxiety.* In this model, anxiety operates at an unconscious level and serves to mobilize the ego's resources to avert danger. Either external or internal sources of danger can produce a signal that leads the ego to marshal specific defense mechanisms to guard against or reduce instinctual excitation.

Freud's later theory of anxiety explains neurotic symptoms as the ego's partial failure to cope with distressing stimuli. The drive derivatives associated with danger may not have been adequately contained by the defense mechanisms used by the ego. In phobias, for example, Freud explained that fear of an external threat (e.g., dogs or snakes) is an externalization of internal danger.

Danger situations can also be linked to developmental stages and can create a developmental hierarchy of anxiety. The earliest dangerous situation

is a fear of disintegration or annihilation, often associated with concerns about fusion with an external object. As infants mature and recognize the mothering figure as a separate person, separation anxiety, or fear of the loss of an object, becomes more prominent. During the oedipal psychosexual stage, girls are most concerned about losing the love of the most crucial figure in their lives, their mother. Boys are primarily anxious about bodily injury or castration. After resolving the oedipal conflict, a more mature form of anxiety occurs, often termed *superego anxiety*. This latency-age concern involves the fear that internalized parental representations, contained in the superego, will cease to love, or will angrily punish, the child.

Table 34-12
Classification of Defense Mechanisms

Narcissistic-Psychotic Defenses	
These defenses are usually found as part of a psychotic process, but may also occur in young children and adult dreams or fantasies. They share the common note of avoiding, negating, or distorting reality.	
Projection	Perceiving and reacting to unacceptable inner impulses and their derivatives as though they were outside the self. On a psychotic level, this takes the form of frank delusions about external reality, usually persecutory, includes both perception of one's own feelings and those of another with subsequent acting on the perception (psychotic paranoid delusions). Impulses may derive from id or superego (hallucinated recriminations).
Denial	Psychotic denial of external reality, unlike repression, affects perception of external reality more than perception of internal reality. Seeing, but refusing to acknowledge what one sees, or hearing and negating what is actually heard are

	examples of denial and exemplify the close relationship of denial to sensory experience. Not all denial, however, is necessarily psychotic. Like projection, denial may function in the service of more neurotic or even adaptive objectives. Denial avoids becoming aware of some painful aspect of reality. At the psychotic level, the denied reality may be replaced by a fantasy or delusion.
Distortion	Grossly reshaping the experience of external reality to suit inner needs, including unrealistic megalomanic beliefs, hallucinations, wish-fulfilling delusions, and employing sustained feelings of delusional grandiosity, superiority, or entitlement.

Immature Defenses

These mechanisms are fairly common in preadolescent years and in adult character disorders. They are often mobilized by anxieties related to intimacy or its loss. Although they are regarded as socially awkward and undesirable, they often moderate with improvement in interpersonal relationships or with increased personal maturity.

Acting out	The direct expression of an unconscious wish or impulse in action to avoid being conscious of the accompanying affect. The unconscious fantasy, involving objects, is lived out and impulsively enacted in behavior, thus gratifying the impulse more than the prohibition against it. On a chronic level, acting out involves giving in to impulses to avoid the tension that would result from postponement of their expression.
Blocking	An inhibition, usually temporary in nature, of affects especially, but possibly also thinking

	and impulses. It is close to repression in its effects but has a component of tension arising from the inhibition of the impulse, affect, or thought.
Hypochondriasis	Transformation of reproach toward others arising from bereavement, loneliness, or unacceptable aggressive impulses, into self-reproach in the form of somatic complaints of pain, illness, and so forth. Real illness may also be overemphasized or exaggerated for its evasive and regressive possibilities. Thus, responsibility may be avoided, guilt may be circumvented, and instinctual impulses may be warded off.
Introjection	In addition to the developmental functions of the process of introjection, it also can serve specific defensive functions. The introjection of a loved object involves the internalization of characteristics of the object with the goal of ensuring closeness to and constant presence of the object. Anxiety consequent to separation or tension arising out of ambivalence toward the object is thus diminished. If the object is lost, introjection nullifies or negates the loss by taking on characteristics of the object, thus in a sense internally preserving the object. Even if the object is not lost, the internalization usually involves a shift of cathexis reflecting a significant alteration in the object relationship. Introjection of a feared object serves to avoid anxiety through internalizing the aggressive characteristic of the object, thereby putting the aggression under one's own control. The aggression is no longer felt as coming from outside, but is taken within and utilized defensively, thus turning the subject's weak,

	passive position into an active, strong one. The classic example is “identification with the aggressor.” Introjection can also take place out of a sense of guilt in which the self-punishing introject is attributable to the hostile-destructive component of an ambivalent tie to an object. Thus, the self-punitive qualities of the object are taken over and established within one’s self as a symptom or character trait, which effectively represents both the destruction and the preservation of the object. This is also called *identification with the victim.*
Passive-aggressive behavior	Aggression toward an object expressed indirectly and ineffectively through passivity, masochism, and turning against the self.
Projection	On a nonpsychotic level, projection involves attributing one’s own unacknowledged feelings to others; it includes severe prejudice, rejection of intimacy through suspiciousness, hypervigilance to external danger, and injustice collecting. Projection operates correlatively to introjection, such that the material of the projection derives from the internalized but usually unconscious configuration of the subject’s introjects. At higher levels of function, projection may take the form of misattributing or misinterpreting motives, attitudes, feelings, or intentions of others.
Regression	A return to a previous stage of development or functioning to avoid the anxieties or hostilities involved in later stages. A return to earlier points of fixation embodying modes of behavior previously given up. This is often the result of a disruption of equilibrium at a later phase of

	development. This reflects a basic tendency to achieve instinctual gratification or to escape instinctual tension by returning to earlier modes and levels of gratification when later and more differentiated modes fail or involve intolerable conflict.
Schizoid fantasy	The tendency to use fantasy and to indulge in autistic retreat for the purpose of conflict resolution and gratification.
Somatization	The defensive conversion of psychic derivatives into bodily symptoms; tendency to react with somatic rather than psychic manifestations. Infantile somatic responses are replaced by thought and affect during development (desomatization); regression to earlier somatic forms or response (resomatization) may result from unresolved conflicts and may play an important role in psychophysiological and psychosomatic reactions.

Neurotic Defenses

These are common in apparently normal and healthy individuals as well as in neurotic disorders. They function usually in the alleviation of distressing affects and may be expressed in neurotic forms of behavior. Depending on circumstances, they can also have an adaptive or socially acceptable aspect.

Controlling	The excessive attempt to manage or regulate events or objects in the environment in the interest of minimizing anxiety and solving internal conflicts.
Displacement	Involves a purposeful, unconscious shifting of impulses or affective investment from one object to another in the interest of solving a

	conflict. Although the object is changed, the instinctual nature of the impulse and its aim remain unchanged.
Dissociation	A temporary but drastic modification of character or sense of personal identity to avoid emotional distress; it includes fugue states and hysterical conversion reactions.
Externalization	A general term, correlative to internalization, referring to the tendency to perceive in the external world and in external objects components of one's own personality, including instinctual impulses, conflicts, moods, attitudes, and styles of thinking. It is a more general term than projection, which is defined by its derivation from and correlation with specific introjects.
Inhibition	The unconsciously determined limitation or renunciation of specific ego functions, singly or in combination, to avoid anxiety arising out of conflict with instinctual impulses, superego, or environmental forces or figures.
Intellectualization	The control of affects and impulses by way of thinking about them instead of experiencing them. It is a systematic excess of thinking, deprived of its affect, to defend against anxiety caused by unacceptable impulses.
Isolation	The intrapsychic splitting or separation of affect from content resulting in repression of either idea or affect or the displacement of affect to a different or substitute content.
Rationalization	A justification of attitudes, beliefs, or behavior that might otherwise be unacceptable by an incorrect application of justifying reasons or the

	invention of a convincing fallacy.
Reaction formation	The management of unacceptable impulses by permitting expression of the impulse in antithetical form. This is equivalently an expression of the impulse in the negative. Where instinctual conflict is persistent, reaction formation can become a character trait on a permanent basis, usually as an aspect of obsessional character.
Repression	Consists of the expelling and withholding from conscious awareness of an idea or feeling. It may operate either by excluding from awareness what was once experienced on a conscious level (secondary repression) or it may curb ideas and feelings before they have reached consciousness (primary repression). The “forgetting” associated with repression is unique in that it is often accompanied by highly symbolic behavior, which suggests that the repressed is not really forgotten. The important discrimination between repression and the more general concept of defense has been discussed.
Sexualization	The endowing of an object or function with sexual significance that it did not previously have, or possesses to a lesser degree, to ward off anxieties connected with prohibited impulses.

Mature Defenses

These mechanisms are healthy and adaptive throughout the life cycle. They are socially adaptive and useful in the integration of personal needs and motives, social demands, and interpersonal relations. They can underlie seemingly admirable and virtuous patterns of behavior.

Altruism	The vicarious but constructive and instinctually gratifying service to others, even to the detriment of the self. This must be distinguished from altruistic surrender, which involves a masochistic surrender of direct gratification or of instinctual needs in favor of fulfilling the needs of others to the detriment of the self, with vicarious satisfaction only being gained through introjection.
Anticipation	The realistic anticipation of or planning for future inner discomfort: Implies overly concerned planning, worrying, and anticipation of dire and dreadful possible outcomes.
Asceticism	The elimination of directly pleasurable affects attributable to an experience. The moral element is implicit in setting values on specific pleasures. Asceticism is directed against all “base” pleasures perceived consciously, and gratification is derived from the renunciation.
Humor	The overt expression of feelings without personal discomfort or immobilization and without unpleasant effect on others. Humor allows one to bear, and yet focus on, what is too terrible to be borne, in contrast to wit, which always involves distraction or displacement away from the affective issue.
Sublimation	The gratification of an impulse whose goal is retained but whose aim or object is changed from a socially objectionable one to a socially valued one. Libidinal sublimation involves a desexualization of drive impulses and the placing of a value judgment that substitutes what is valued by the superego or society.

	Sublimation of aggressive impulses takes place through pleasurable games and sports. Unlike neurotic defenses, sublimation allows instincts to be channeled rather than dammed up or diverted. Thus, in sublimation, feelings are acknowledged, modified, and directed toward a relatively significant person or goal so that modest instinctual satisfaction results.
Suppression	The conscious or semiconscious decision to postpone attention to a conscious impulse or conflict.

Character. In 1913, Freud distinguished between neurotic symptoms and personality or character traits. *Neurotic symptoms* develop due to the failure of repression; *character traits* owe their existence to the success of repression, that is, to the defense system that achieves its aim through a persistent pattern of reaction formation and sublimation. In 1923, Freud also observed that the ego could only give up important objects by identifying with them or introjecting them. This accumulated pattern of identifications and introjections also contributes to character formation. Freud specifically emphasized the importance of superego formation in character construction.

Contemporary psychoanalysts regard character as a person's habitual or typical pattern of adaptation to internal drive forces and external environmental forces. *Character* and *personality* are used interchangeably and are distinguished from the ego in that they mostly refer to styles of defense and directly observable behavior rather than feeling and thinking.

Character is also influenced by constitutional temperament, the interaction of drive forces with early ego defenses and with environmental influences, and various identifications with, and internalizations of, other persons throughout life. The extent to which the ego has developed a capacity to tolerate the delay of impulse discharge and to neutralize instinctual energy

determines the degree to which such character traits emerge in later life. Exaggerated development of individual character traits at the expense of others can lead to personality disorders or produce a vulnerability or predisposition to psychosis.

Classic Psychoanalytic Theory of Neuroses

The classic view of the genesis of neuroses regards conflict as essential. The conflict can arise between instinctual drives and external reality or internal agencies, such as the id and the superego or the id and the ego. Moreover, because the conflict has not been worked through to a realistic solution, the drives or wishes that seek discharge have been expelled from consciousness through repression or another defense mechanism. Their expulsion from conscious awareness, however, does not make the drives any less powerful or influential. As a result, the unconscious tendencies (e.g., the disguised neurotic symptoms) fight their way back into consciousness. This theory of the development of neurosis assumes that a rudimentary neurosis based on the same type of conflict existed in early childhood.

Deprivation during the first few months of life because of absent or impaired caretaking figures can adversely affect ego development. This impairment, in turn, can fail to make appropriate identifications. The resulting ego difficulties create problems in mediating between the drives and the environment. Lack of capacity for the constructive expression of drives, especially aggression, can lead some children to turn their aggression on themselves and become overtly self-destructive. Parents who are inconsistent, excessively harsh, or overly indulgent can influence children to develop disordered superego functioning. The severe conflict that cannot be managed through symptom formation can lead to extreme restrictions in ego functioning and fundamentally impair the capacity to learn and develop new skills.

Traumatic events that seem to threaten survival can break through defenses when the ego has been weakened. More libidinal energy is then required to master the excitation that results. The libido thus mobilized, however, is withdrawn from the supply that is usually applied to external objects. This withdrawal further diminishes the strength of the ego and produces a sense of inadequacy. Frustrations or disappointments in adults may revive infantile

longings that are then dealt with through symptom formation or further regression.

In his classic studies, Freud described four different types of childhood neuroses, three of which had later neurotic developments in adult life. This well-known series of cases shown in tabulated form in Table 34-13 exemplifies some of Freud's important conclusions: (1) neurotic reactions in the adult are associated frequently with neurotic reactions in childhood; (2) the connection is sometimes continuous but more often is separated by a latent period of nonneurosis; and (3) infantile sexuality, both fantasized and real, occupies a memorable place in the early history of the patient.

Table 34-13
Classic Psychoneurotic Reactions of Childhood

	Conversion Reaction (Dora)	Phobic Reaction (Hans)	Obsessive-Compulsive Reaction (Rat Man)	Mixed Neurotic Reaction (Wolf Man)
Family history	Striking family history of psychiatric and physical illness	Both parents treated for neurotic conflict but not severe	No family history of mental illness	Striking family history of psychiatric and physical illness
Symptoms	Enuresis and masturbation, 6–8 yr; onset of neurosis at 8; migraine, nervous cough, and hoarseness at 12; aphonia at 16; "appendicitis" at 16; convulsions at 16; facial neuralgia at 19; change of personality at 8 from "wild creature" to quiet child	Compulsive questions at 3–3 1/2 yr in regard to sex difference; jealous reaction to sibling birth at 3 1/2; overt castration threat; overt masturbation at 3 1/2; overeating and constipation at 4–5; phobic reaction at 4–5; attack of flu at 5 worsens phobia; tonsillectomy at 5 worsens phobia	Naughty period at 3–4 yr; marked timidity after beating by father at 4; recognizing people by their smells as a child (Renifleur); precocious ego development; onset of obsessive ideas at 6–7	Tractable and quiet up to 3 1/4 yr; "naughty" period at 3 1/4–4 yr; phobias at 4–5 with nightmares; obsessional reaction at 6–7 (pious ceremonials). Disappearance of neuroses at 8
Causes	Seduction by older man; father's illness; father's affair	Seductive care by mother; sibling birth at 3 1/2	Seduction by governess at 4; death of sibling at 4; beating by father at 4	Seduction by older sister at 3 1/4; mother's illness; conflict between maid and governess

Courtesy of E. James Anthony, M.D.

Specific differences are worth noting in the four cases shown in Table 34-13. First, the phobic reactions tend to start at about 4 or 5 years of age, the obsessional reactions between 6 and 7 years, and the conversion reactions at 8 years. The degree of background disturbance is most significant in the conversion reaction and the mixed neurosis, and it seems only slight in the phobic and obsessional reactions. The course of the phobic reaction seems little influenced by severe traumatic factors, whereas traumatic factors, such as sexual seductions, play an essential role in the three other subgroups. It was during this period that Freud elaborated his seduction hypothesis for the cause of the neuroses, in terms of which the obsessive-compulsive and

hysterical reactions were alleged to originate in active and passive sexual experiences.

Treatment and Technique

The cornerstone of psychoanalytic technique is free association, in which patients say whatever comes to mind. Free association not only provides analytic content, it helps to induce the regression needed for establishing and working through the transference neurosis. When this development occurs, all the original wishes, drives, and defenses associated with the infantile neurosis are transferred to the person of the analyst.

As patients attempt to free associate, they soon learn that they have difficulty saying whatever comes to mind without censoring specific thoughts. They develop conflicts about their wishes and feelings toward the analyst that reflect childhood conflicts. The *transference* that develops toward the analyst may also serve as resistance to the process of free association. Freud discovered that *resistance* was not merely a stoppage of a patient's associations, but also an essential revelation of the patient's internal object relations as they were externalized and manifested in the transference relationship with the analyst. The systematic analysis of transference and resistance is the essence of psychoanalysis. Freud was also aware that the analyst might have transferences to the patient, which he called *countertransference*. Countertransference, in Freud's view, was an obstacle that the analyst needed to understand so that it did not interfere with treatment. In this spirit, he recognized the need for all analysts to have been analyzed themselves. Variations in transference and their descriptions are contained in Table 34-14. The basic mechanisms by which transferences are effected—displacement, projection, and projective identification—are described in Table 34-15.

Table 34-14
Transference Variants

Libidinal Transferences
Follow the classic model and usually in milder forms as positive *transference reactions* but can take the form of more intense and

disturbing *erotic transferences.* They are derivatives of phallic-oedipal, libidinal impulses and may be permeated variously by pregenital influences. They can occur with varying degrees of intensity, and in mild forms, may not even require interpretation if they contribute to and support the therapeutic relation. Sigmund Freud recommended that they call for interpretation only when they begin to serve as a resistance.

Aggressive Transferences

Take the form either of negative or more pathologic paranoid transferences. *Negative transferences* are seen at all levels of psychopathology but can predominate in some borderline patients who tend to see the therapeutic relationship in terms of power and victimization, regarding the therapist as omnipotent and powerful, whereas the patient experiences him- or herself as helpless, weak, and vulnerable. Negative transferences are identifiable in varying degrees in all analyses and usually require specific intervention and interpretation.

Transferences of Defense

Opposed to *transferences of impulse;* defense against impulses finds its way into the transference rather than the impulses themselves. In this form of transference, attention shifts from drives to the ego's defensive functioning so that transference is no longer merely repetition of instinctual cathexes but includes aspects of ego functioning as well.

Transference Neurosis

Involves the recreation or more ample expression of the patient's neurosis enacted anew within the analytical relation and at least theoretically mirroring aspects of the infantile neurosis. The transference neurosis usually develops in the middle phase of analysis, when the patient, at first eager for improved mental health, no longer consistently displays such motivation but engages in a continuing battle with the analyst over the desire to attain some kind of emotional satisfaction from the analyst so that this becomes the most compelling reason for continuing analysis.

At this point of the treatment, the transference emotions become more important to the patient than alleviation of distress sought initially, and the major, unresolved, unconscious problems of childhood begin to dominate the patient's behavior. They are now reproduced in the transference, with all their pent-up emotion.

The transference neurosis is governed by three outstanding characteristics of instinctual life in early childhood: the pleasure principle (before effective reality testing), ambivalence, and repetition compulsion. Emergence of the transference neurosis is usually a slow and gradual process, although in certain patients with a propensity for *transference regression,* particularly more hysterical patients, elements of transference and transference neurosis may manifest themselves relatively early in the analytical process. One situation after another in the life of the patient is analyzed and progressively interpreted until the original infantile conflict is sufficiently revealed. Only then does the transference neurosis begin to subside. At that point, termination begins to emerge as a more central concern.

Contemporary opinion is divided to its importance and centrality, whether it forms to the extent Freud believed, and whether it is necessary for successful analysis—for some, it remains an essential vehicle for analytical interpretation and therapeutic effectiveness; for others, it may never develop or, to the extent that it does, may play a less central role in the process of cure.

Transference Psychosis

Occurs when failure of reality testing leads to loss of self–object differentiation and diffusion of self and object boundaries. This may reflect an attempt to refuse with an omnipotent object, investing the self with omnipotent powers as defense against underlying fears of vulnerability and powerlessness. Transference psychosis can also include negative transference elements in which fusion carries the threat of engulfment and loss of self that may precipitate a *paranoid transference reaction.*

Narcissistic Transferences

Clarified by Heinz Kohut (1971) as variations of patterns of projection of archaic narcissistic configurations onto the therapist. They are based on projections of narcissistic introjective configurations, both superior and inferior—the superior form reflecting narcissistic superiority, grandiosity, and enhanced self-esteem, and the inferior opposite qualities of inferiority, self-depletion, and diminished self-esteem. The therapist comes to represent, in Kohut's terms, either the grandiose self in *mirror transferences* or the idealized parental imago in *idealizing transferences.* In idealizing transferences, all power and strength are attributed to the idealized object, leaving the subject feeling empty and powerless when separated from that object. Union with the idealized object enables the subject to regain narcissistic equilibrium. Idealizing transferences may reflect developmental disturbances in the idealized parent imago, particularly at the time of formation of the ego-ideal by introjection of the idealized object. In some individuals, narcissistic fixation leads to development of the grandiose self. Reactivation in analysis of the grandiose self provides the basis of mirror transferences formation, which occur in three forms: *archaic merger transference,* a less archaic *alter-ego* or *twinship transference,* and *mirror transference in the narrow sense.* In the most primitive merger transference, the analyst is experienced only as an extension of the subject's grandiose self and, thus, becomes the repository of the patient's grandiosity and exhibitionism. In the alter-ego or twinship transference, activation of the grandiose self leads to experience of the narcissistic object as similar to the grandiose self. In the most mature form of mirror transference, the analyst is experienced as a separate person but, nonetheless, one who becomes important to the patient and is accepted by him or her only to the degree that he or she is responsive to the narcissistic needs of the reactivated grandiose self.

Self–Object Transferences

Represent extensions of the self-psychology paradigm beyond merely narcissistic configurations. The self–object involves investment of the self in the object so that the object comes to serve a self-sustaining function that the self cannot perform for itself—either in maintaining fragile self-cohesion or in regulating self-esteem. The other, thus, is not experienced as an autonomous and separate object or agency in its own right but as present only to serve the needs of the self. Transference in this sense reflects a continuing developmental need that seeks satisfaction in the analytical relation.

Self–object transferences reflect the underlying need structure the patient brings to the therapeutic relationship based on the predominant pattern of self–object deprivation or frustration and the corresponding seeking for the appropriate form of self–object involvement. These configurations have been described as the *understimulated self,* the *overstimulated self,* the *overburdened self,* and the *fragmenting self.* Other descriptions of self–object need translate patterns of transference interaction based on narcissistic dynamics into the perspective of the relationship between self and self–object, as in mirror-hungry personalities and ideal-hungry personalities. Variations on the mirroring transference theme include the alter-ego–hungry personality, the merger-hungry personality, and, in contrast, the contact-shunning personality. In transferences derived from such personality configurations, the classic meaning of transference has undergone radical modification. Rather than displacements or projections from earlier object relational contexts, the patient brings to bear a need based in his or her own currently deficient capacity and defective character structure—a need to involve the object in a dependent relationship to complete or stabilize his or her own psychic integration.

Transitional Relatedness

This transference model is based on Donald Winnicott's notion of the transitional object. Transference in more primitive character

structures is regarded as a form of *transitional object relation* in which the therapist is perceived as outside the self but is invested with qualities from the patient's own archaic self-image. The transference field in this view is envisioned as a transitional space in which the transference illusion is allowed to play itself out.

Transference as Psychic Reality

Reflects the need of each participant in analysis to draw the other into a stance corresponding to his or her own intrapsychic configuration and needs as a reflection of the individual subject's psychic reality. This regards the classic view of transference, based on displacement or projection from past objects, as inadequate, resulting in further diffusion of meaning of transference as equivalent to the individual's capacity to create a meaningful world or to inform the world with meaning. In this rendition, transference becomes equivalent to the patient's psychic reality so that any distinction between the meanings given to reality and the meanings inherent in transference is lost. Transference in these terms becomes all-encompassing, and whatever distinguishing and dynamic significance it may have had fades into obscurity. In this form of transference, no definable mechanism seems to be at work other than whatever is involved in the subject's psychic reality. The subject's view of his or her environment and impression of objects of his or her experience, including the analytical object, are indistinguishable from ordinary cognitive and affective processes characterizing personal involvement and responsiveness to the world about him or her.

Transference as Relational or Intersubjective

The relational or intersubjective view of transference as emerging from or cocreated by the subjective interaction between analyst and analysand transforms transference into an interactive phenomenon in which individual intrapsychic contributions from either participant are obscured. Transference in this sense is not anything individual to, or intrapsychically derived from, the patient but is based on the present ongoing interaction between analyst

and patient coconstructing transference. On these terms, analysis of transference has little to do with past derivatives and everything to do with the ongoing relation with the analyst, primarily in the form of interpersonal enactments. Transference in this sense is no longer a one-person phenomenon but reflects a two-person transference–countertransference interaction. The supposition is that no such thing as transference exists without countertransference and no such thing as countertransference exists without transference. The patient is thus relieved of any burden of a personal dynamic unconscious reflecting developmental vicissitudes and residues of a life history. Transference is created anew in the immediacy of present analytical interaction as the product of mutual influence and communication between analyst and analysand, probably relying on some form of mutual projective identification to sustain the interactive connotation.

Table 34-15
Transference Mechanisms

Displacement

The basic mechanism of classic transference paradigms in which an object representation derived from any level or combination of levels of the subject's developmental experience is displaced to the representation of the new object, namely, the analyst, in the therapeutic relationship. Displacement is the basic mechanism for libidinally based transferences, both positive and erotic, as well as for aggressive and especially negative transferences. By and large, displacement transferences tend to play a more dominant role in neurotic disorders in which phallic–oedipal (and to a lesser degree preoedipal) dynamics tend to play a dominant, although not exclusive, role.

Projection

Process by which qualities or characteristics of the self-as-object, usually involving introjections or self-representations, are

attributed to an external object, and the subsequent interaction with the object is determined by the projected characteristics. Thus, the analyst or object may be seen as sadistic—that is, as possessing the sadistic character of the analysand or subject, an aspect of the subject's self that is denied or disowned by the subject. Projection tends to play a more prominent, although again not exclusive, role in formation of transferences in more primitive character disorders but can be found in variously modified forms throughout the spectrum of neuroses. Because projections derive primarily from the configuration of introjects constituting the patient's self-as-object, the effect of projective or externalizing transferences is that the image of the therapist comes to represent part of the patient's own self-organization rather than simply an object representation.

Projections derived from destructive introjects can provide the basis for both negative and paranoid transference reactions. Those based on the victim or introject result in the patient relating to the therapist as his or her victim and him- or herself assuming a hostile or sadistic position as a destructive aggressor or victimizer to the therapist's victim. Then again, projection based on the aggressor or introject results in the patient relating to the therapist as an aggressor and him- or herself assuming a weak, vulnerable, or masochistic position in which he or she becomes a passive and vulnerable victim to the therapist's destructive aggression. Similar patterns can take place around narcissistic issues involving introjective configurations of narcissistic superiority and inferiority.

Projective dynamics in self–object transferences, however, seem to involve more than narcissistic projections because these forms of transference tend to draw the analyst into meeting the pathologic needs of the self. If anything is projected, it is an infantile wished-for imago, one lacking earlier in the patient's experience, as, for example, an empathic and idealized parental figure. On the other hand, transitional transferences, despite their considerable overlap with self–object phenomena, tend to involve a more explicit projective element as the self-related contribution to the

transitional experience.

Projective Identification

The concept of projective identification was first proposed by Melanie Klein, arguing that the projection of impulses or feelings into another person brought about an identification with that person based on attribution of one's own qualities to that other. This attribution served as the basis for a sense of empathy and connection with the other. On these terms, projective identification was a fantasy taking place solely in the mind of the one projecting.

Projective identification is often appealed to as a mechanism of transference, or more exactly transference–countertransference interactions, particularly in Kleinian usage. Confusion arises from the failure to clearly distinguish between projection and projective identification. The notion of projective identification added to the basic concept of projection of the notes of diffusion of ego boundaries, a loss or diminishing of self–object differentiation, and inclusion of the object as part of the self.

Later elaborations of the notion of projective identification transformed it from a one-body to a two-body phenomenon, describing interaction between two subjects, one of whom projects something onto or into the other, whereon the other introjects or internalizes what has been projected. Instead of the projection and introjection taking place in the same subject, the projection now takes place in one and the internalization in the other. This latter usage has led to extensive extrapolation of the concept of projective identification to apply to all sorts of object relations, including transference. The emphasis in Kleinian transference is less on the influence of the past on the present but rather the influence of the internal world on the external in the here-and-now interaction with the analyst.

Analysts after Freud began to recognize that countertransference was not only an obstacle but also a source of useful information about the patient. In other words, the analyst's feelings in response to the patient reflect how other

persons respond to the patient and indicate the patient's own internal object relations. By understanding the intense feelings in the analytic relationship, the analyst can help the patient broaden the understanding of past and current relationships outside the analysis. The development of insight into neurotic conflicts also expands the ego and provides an increased sense of mastery.

ERIK H. ERIKSON

Erik H. Erikson (Fig. 34-24) was one of America's most influential psychoanalysts. Throughout six decades in the United States, he distinguished himself as an illuminator and expositor of Freud's theories and as a brilliant clinician, teacher, and pioneer in psychohistorical investigation. Erikson created an original and highly influential theory of psychological development and crisis occurring in periods that extended across the entire life cycle. His theory grew out of his work first as a teacher, then as a child psychoanalyst, next as an anthropologic field worker, and, finally, as a biographer. Erikson identified dilemmas or polarities in the ego's relations with the family and larger social institutions at nodal points in childhood, adolescence, and early, middle, and late adulthood. Two of his psychosexual historical studies, *Young Man Luther* and *Gandhi's Truth* (published in 1958 and 1969, respectively), were widely hailed as profound explorations of how crucial circumstances can interact with the crises of certain great persons at particular moments in time. The interrelationships of the psychological development of the person and the historical developments of the times were more fully explored in *Life History and the Historical Moment*, written by Erikson in 1975.

Erik Homburger Erikson was born on June 15, 1902, in Frankfurt, Germany, the son of Danish parents. He died in 1994. His father abandoned his mother before he was born, and he was brought up by his mother, a Danish Jew, and her second husband, Theodor Homburger, a German-Jewish pediatrician. Erikson's parents chose to keep his real parentage a secret from him, and for many years he was known as Erik Homburger. Erikson never knew his biologic father; his mother withheld that information from him all her life. Undoubtedly, the man who introduced the term "identity crisis" into the language struggled with his sense of identity. Compounding his parents' deception about his biologic father—their "loving deceit," as he called it—was the fact that, as a blond, blue-eyed, Scandinavian-looking son of a Jewish father, he was taunted as a "goy" among Jews, at the same time being called a Jew by his classmates. His being a Dane living in Germany added to his identity confusion. Erikson was later described as a man of the borders. Much of what he was to study was concerned with how group values are implanted

in the very young, how young people grasp onto group identity in the limbo period between childhood and adulthood, and how a few persons, like Gandhi, transcend their local, national. Even temporal identities to form a small band of people with wider sympathies who span the ages.

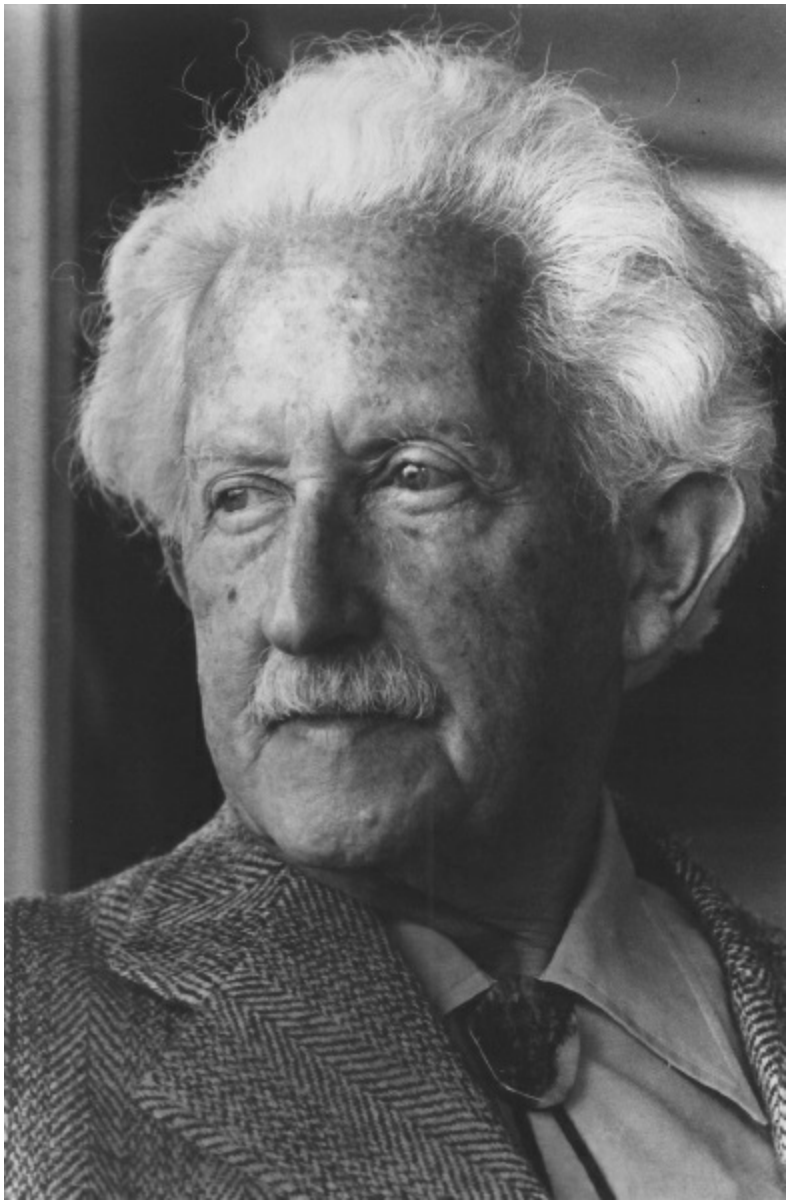

FIGURE 34-24
Erik Erikson (1902–1994).

The concepts of identity, identity crisis, and identity confusion are central to Erikson's thought. In his first book *Childhood and Society* (published in 1950), Erikson observed that "the study of identity…becomes as strategic in

our time as the study of sexuality was in Freud's time." By identity, Erikson meant a sense of sameness and continuity "in the inner core of the individual" maintained amid external change. A sense of identity, emerging at the end of adolescence, is a psychosocial phenomenon preceded in one form or another by an identity crisis; that crisis may be conscious or unconscious, with the person being aware of the present state and future directions but also unconscious of the fundamental dynamics and conflicts that underlie those states. The identity crisis can be acute and prolonged in some people.

The young Erikson did not distinguish himself in school, although he did show artistic talent. On graduation, he spent a year traveling through the Black Forest, Italy, and the Alps, pondering life, drawing, and making notes. After that year of roaming, he studied art in his home city of Karlsruhe and later in Munich and Florence.

In 1927 Peter Blos, a high school friend, invited Erikson to join him in Vienna. Blos, not yet a psychoanalyst, had met Dorothy Burlingham, a New Yorker who had come to Vienna to be psychoanalyzed; she had brought her four children with her and hired Blos to tutor them. Blos was looking for a fellow teacher in his new school for the children of English and American parents and students of his new discipline of psychoanalysis. Erikson accepted his offer.

Blos and Erikson informally organized their school—much in the style of the so-called progressive or experimental schools prevalent in the United States. Children were encouraged to participate in curriculum planning and to express themselves freely. Erikson, still very much the artist, taught drawing and painting, but he also exposed his pupils to history and foreign ways of life, including the cultures of the American Indian and Eskimo.

During that period, Erikson became involved with the Freud family, friends of Mrs. Burlingham. He became particularly close to Anna Freud, with whom he began psychoanalysis. Anna Freud, who had been an elementary school teacher, was at that time formulating the new science of child psychiatry, trying to turn attention from the adult's corrective backward look to a neurosis-preventative study of childhood itself. Under Anna Freud's tutelage, Erikson began more and more to turn his attention to childhood, both his own and that of the children whom he saw in the classroom. The analysis was not then the rigidly structured procedure into which it later developed; Erikson met with Miss Freud daily for his analytic hour and

frequently saw her socially and as part of the circle of Freud's followers and associates. Still undecided about his future, Erikson continued to teach school while studying psychoanalysis at the Vienna Psychoanalytic Institute. He also studied to become accredited as a Montessori teacher.

In 1929 he married Joan Mowat Serson, an American of Canadian birth. He was hastily made a full member, rather than an associate member of the Vienna Psychoanalytic Society—unorthodoxy that allowed him to leave a Vienna threatened by fascism immediately after his graduation in 1933. Earlier, Erikson had met the Viennese Hanns Sachs, co-founder, along with Otto Rank of the psychoanalytically oriented journal *Imago*. Sachs—who had settled in Boston, where he was associated with the Harvard Medical School—was sure that Erikson would be welcome at Harvard and suggested that he make Boston his home. After a brief stay in Denmark, the Eriksons moved to Boston, where he became the city's only child analyst. He held positions at the Harvard Medical School and Massachusetts General Hospital, served as a consultant at the Judge Baker Guidance Center, and maintained a private practice.

Erikson was much influenced by Cambridge's circle of young social scientists, including anthropologists Margaret Mead and Ruth Benedict. Exposure to the views of those vigorous thinkers helped to shape his theories of child psychology and his cross-cultural approach to human development. Classical psychoanalysis had traditionally concerned itself with pathology and with treating disturbed people. However, Erikson found himself more interested in the normal personality and applying his observations about how young people function and how childhood play affects character formation. Although he remained in the Boston area for only 3 years, he established a solid reputation as a skilled clinician and researcher before moving to Yale University's Institute of Human Relations. There he furthered an interest sparked at Harvard in the work of American anthropologists. In 1938 he traveled to South Dakota to study the children of the Sioux Indians of the Pine Ridge Reservation. His observations about how communal and historical forces powerfully influence child-rearing became a vital contribution to psychology and the study of humans in society.

In 1939 Erikson moved to a post at Berkeley, from which he studied the Yurok Indians, a group of salmon fishers. He left Berkeley in 1950 after refusing to sign what he called a vague, fearful addition to the loyalty oath.

He resettled at the Austen Riggs Center in Stockbridge, Massachusetts, working with young people. In 1960 he was appointed to a professorship at Harvard. After he retired from Harvard in 1972, Erickson joined Mount Zion Hospital in San Francisco as a senior consultant in psychiatry. Until his death in 1994, he continued to focus on many of his earlier interests, examining the individual in this historical context and elaborating on concepts of the human life cycle, especially those of old age.

Epigenetic Principle

Erikson's formulations were based on the concept of *epigenesis*, a term borrowed from embryology. His *epigenetic principle* holds that development occurs in sequential, clearly defined stages and that each stage must be satisfactorily resolved for development to proceed smoothly. According to the epigenetic model, if a successful resolution of a particular stage does not occur, all subsequent stages reflect that failure in physical, cognitive, social, or emotional maladjustment.

Relation to Freudian Theory. Erikson accepted Freud's concepts of instinctual development and infantile sexuality. For each of Freud's psychosexual stages (e.g., oral, anal, and phallic), Erikson described a corresponding zone with a specific pattern or mode of behavior. Thus, the oral zone is associated with sucking or taking-in behavior; the anal zone is associated with holding on and letting go. Erikson emphasized that the development of the ego is more than the result of intrapsychic wants or inner psychic energies. It is also a matter of mutual regulation between growing children and a society's culture and traditions.

Eight Stages of the Life Cycle. Erikson's conception of the eight stages of ego development across the life cycle is the centerpiece of his life's work, and he elaborated on the conception throughout his subsequent writings (Table 34-16). The eight stages represent points along a continuum of development. Physical, cognitive, instinctual, and sexual changes combine to trigger an internal crisis, the resolution of which results in either psychosocial regression or growth and the development of specific virtues. In *Insight and Responsibility*, Erikson defined virtue as "inherent strength," as in the active quality of medicine or liquor. He wrote in *Identity: Youth and Crisis* that

"crisis" refers not to a "threat of catastrophe, but a turning point, a crucial period of increased vulnerability and heightened potential, and therefore, the ontogenetic source of generational strength and maladjustment."

STAGE 1: TRUST VERSUS MISTRUST (BIRTH TO ABOUT 18 MONTHS). In *Identity: Youth and Crisis*, Erikson noted that the infant "lives through and loves with" its mouth. Indeed, the mouth forms the basis of its first mode or pattern of behavior, incorporation. The infant is taking the world through the mouth, eyes, ears, and sense of touch. The baby is learning a cultural modality that Erikson termed *to get*, that is, to receive what is offered and elicit what is desired. As the infant's teeth develop, and it discovers the pleasure of biting, it enters the second oral stage, the active-incorporative mode. The infant is no longer passively receptive to stimuli; it reaches out for sensation and grasps at its surroundings—the social modality shifts to that of *taking and holding* on to things.

Table 34-16
Erikson's Psychosocial Stages

Psychosocial Stage	Associated Virtue	Related Forms of Psychopathology	Positive and Negative Forerunners of Identity Formation	Enduring Aspects of Identity Formation
Trust vs. mistrust (birth–)	Hope	Psychosis Addictions Depression	Mutual recognition vs. autistic isolation	Temporal perspective vs. time confusion
Autonomy vs. shame and doubt (~18 mo–)	Will	Paranoia Obsessions Compulsions Impulsivity	Will to be oneself vs. self-doubt	Self-certainty vs. self-consciousness
Initiative vs. guilt (~3 yr–)	Purpose	Conversion disorder Phobia Psychosomatic disorder Inhibition	Anticipation of roles vs. role inhibition	Role experimentation vs. role fixation
Industry vs. inferiority (~5 yr–)	Competence	Creative inhibition Inertia	Task identification vs. sense of futility	Apprenticeship vs. work paralysis
Identity vs. role confusion (~13 yr–)	Fidelity	Delinquent behavior Gender-related identity disorders Borderline psychotic episodes		Identity vs. identity confusion
Intimacy vs. isolation (~20s–)	Love	Schizoid personality disorder Distantiation		Sexual polarization vs. bisexual confusion
Generativity vs. stagnation (~40s–)	Care	Mid-life crisis Premature invalidism		Leadership and followership vs. abdication of responsibility
Integrity vs. despair (~60s–)	Wisdom	Extreme alienation Despair		Ideologic commitment vs. confusion of values

Adapted from Erikson E. *Insight and Responsibility*. New York: WW Norton; 1964 and Erikson E. *Identity: Youth and Crisis*. New York: WW Norton; 1968, with permission.

The infant's development of essential trust in the world stems from its earliest experiences with its mother or primary caretaker. In *Childhood and Society,* Erikson asserts that trust depends not on "absolute quantities of food or demonstrations of love, but rather on the quality of the maternal relationship." A baby whose mother can anticipate and respond to its needs in a consistent and timely manner despite its oral aggression will learn to tolerate the inevitable moments of frustration and deprivation. The defense mechanisms of introjection and projection provide the infant with the means to internalize pleasure and externalize pain such that "consistency, continuity, and sameness of experience provide a rudimentary sense of ego identity." Trust will predominate over mistrust, and hope will crystallize. For Erikson, the element of society corresponding to this stage of ego identity is religion, as both are founded on "trust born of care."

In keeping with his emphasis on the epigenetic character of psychosocial change, Erikson conceived of many forms of psychopathology as examples of what he termed *aggravated development crisis,* development, which having gone awry at one point, affects subsequent psychosocial change. A person who, as a result of severe disturbances in the earliest dyadic relationships, fails to develop a basic sense of trust or the virtue of hope may be predisposed as an adult to the profound withdrawal and regression characteristic of schizophrenia. Erikson hypothesized that the depressed patient's experience of being empty and being no good is an outgrowth of a developmental derailment that causes oral pessimism to predominate. Addictions may also be traced to the mode of oral incorporation.

STAGE 2: AUTONOMY VERSUS SHAME AND DOUBT (ABOUT 18 MONTHS TO ABOUT 3 YEARS). In the development of speech and sphincter and muscular control, the toddler practices the social modalities of *holding on and letting go* and experiences the first stirrings of the virtue that Erikson termed *will.* Much depends on the amount and type of control exercised by adults over the child. Control that is exerted too rigidly or too early defeats the toddler's attempts to develop its internal controls, and regression or false progression results. Parental control that fails to protect the toddler from the consequences of their lack of self-control or judgment can be equally disastrous to the child's development of a healthy sense of autonomy. In *Identity: Youth and Crisis,* Erikson asserted: "This stage, therefore, becomes decisive for the ratio

between loving goodwill and hateful self-insistence, between cooperation and willfulness, and between self-expression and compulsive self-restraint or meek compliance."

Where that ratio is favorable, the child develops an appropriate sense of autonomy and the capacity to "have and to hold"; where it is unfavorable, doubt and shame will undermine free will. According to Erikson, the principle of law and order has at its roots this early preoccupation with the protection and regulation of will. In *Childhood and Society,* he concluded, "The sense of autonomy fostered in the child and modified as life progresses, serves (and is served by) the preservation in the economic and political life of a sense of justice."

A person who becomes fixated at the transition between the development of hope and autonomous will, with its residue of mistrust and doubt, may develop paranoiac fears of persecution. When psychosocial development is derailed in the second stage, other forms of pathology may emerge. The perfectionism, inflexibility, and stinginess of the person with an obsessive-compulsive personality disorder may stem from conflicting tendencies to hold on and to let go. The ruminative and ritualistic behavior of the person with an obsessive-compulsive disorder may be an outcome of the triumph of doubt over autonomy and the subsequent development of a primitively harsh conscience.

STAGE 3: INITIATIVE VERSUS GUILT (ABOUT 3 YEARS TO ABOUT 5 YEARS). The child's increasing mastery of locomotor and language skills expands its participation in the outside world and stimulates omnipotent fantasies of broader exploration and conquest. Here the youngster's mode of participation is active and intrusive; its social modality is that of being on the make. The intrusiveness is manifested in the child's fervent curiosity and genital preoccupations, competitiveness, and physical aggression. The Oedipus complex is in ascendance as the child competes with the same-sex parent for the fantasized possession of the other parent. In *Identity: Youth and Crisis,* Erikson wrote that "jealousy and rivalry now come to a climax in a final contest for a favored position with one of the parents: the inevitable and necessary failure leads to guilt and anxiety."

Guilt over the drive for conquest and anxiety over the anticipated punishment are both assuaged in the child through repression of the forbidden

wishes and development of a superego to regulate its initiative. This conscience, the faculty of self-observation, self-regulation, and self-punishment, is an internalized version of parental and societal authority. Initially, the conscience is harsh and uncompromising; however, it constitutes the foundation for the subsequent development of morality. Having renounced oedipal ambitions, the child begins to look outside the family for arenas in which it can compete with less conflict and guilt. This is the stage that highlights the child's expanding initiative and forms the basis for the subsequent development of realistic ambition and the virtue of *purpose.* As Erikson noted in *Childhood and Society,* "The 'oedipal' stage sets the direction toward the possible and the tangible which permits the dreams of early childhood to be attached to the goals of active adult life." Toward this end, social institutions provide the child with an economic ethos in adult heroes who begin to replace their storybook counterparts.

When there has been an inadequate resolution of the conflict between initiative and guilt, a person may ultimately develop a conversion disorder, inhibition, or phobia. Those who overcompensate for the conflict by driving themselves too hard may experience sufficient stress to produce psychosomatic symptoms.

STAGE 4: INDUSTRY VERSUS INFERIORITY (ABOUT 5 YEARS TO ABOUT 13 YEARS). With the onset of latency, the child discovers the pleasures of production. He or she develops industry by learning new skills and takes pride in the things made. Erikson wrote in *Childhood and Society* that the child's "ego boundaries include his tools and skills: the work principle teaches him the pleasure of work completion by steady attention and persevering diligence." Across cultures, this is when the child receives systematic instruction and learns the fundamentals of technology and how to use necessary utensils and tools. As children work, they identify with their teachers and imagine themselves in various occupational roles.

A child unprepared for this stage of psychosocial development, either through an insufficient resolution of previous stages or by current interference, may develop a sense of inferiority and inadequacy. In the form of teachers and other role models, society becomes crucially important in the child's ability to overcome that sense of inferiority and achieve the virtue known as competence. In *Identity: Youth and Crisis,* Erikson noted: "This is

socially a most decisive stage. Since industry involves doing things beside and with others, a first sense of division of labor and of differential opportunity, that is, a sense of the technological ethos of a culture, develops at this time."

The pathologic outcome of a poorly navigated stage of industry versus inferiority is less well defined than in previous stages. However, it may concern the emergence of a conformist immersion into the world of production in which creativity is stifled, and identity is subsumed under the worker's role.

STAGE 5: IDENTITY VERSUS ROLE CONFUSION (ABOUT 13 YEARS TO ABOUT 21 YEARS). With the onset of puberty and its myriad social and physiologic changes, adolescents become preoccupied with identity. Erikson noted in *Childhood and Society* that youth are now "primarily concerned with what they appear to be in the eyes of others as compared to what they feel they are, and with the question of how to connect the roles and skills cultivated earlier with the occupational prototypes of the day." Childhood roles and fantasies are no longer appropriate, yet the adolescent is far from equipped to become an adult. In *Childhood and Society,* Erikson writes that the integration that occurs in the formation of ego identity encompasses far more than the summation of childhood identifications. "It is the accrued experience of the ego's ability to integrate these identifications with the vicissitudes of the libido, with the aptitudes developed out of endowment, and with the opportunities offered in social roles."

The formation of cliques and an identity crisis occur at the end of adolescence. Erikson calls the crisis normative because it is a typical event. Failure to negotiate this stage leaves adolescents without a stable identity; they suffer from identity diffusion or role confusion, characterized by not having a sense of self and by confusion about their place in the world. Role confusion can manifest in such behavioral abnormalities as running away, criminality, and overt psychosis. Problems in gender identity and sexual role may manifest at this time. Adolescents may defend against role diffusion by joining cliques or cults or by identifying with folk heroes. Intolerance of individual differences is how the young person attempts to ward off a sense of identity loss. Falling in love, a process by which the adolescent may clarify a sense of identity by projecting a diffused self-image onto the partner and

gradually seeing it assume a more distinctive shape. An overidentification with idealized figures is how the adolescent seeks self-definition. With the attainment of a more sharply focused identity, the youth develops the virtue of *fidelity*—faithfulness not only to the nascent self-definition but also to an ideology that provides a version of self-in-world. As Erik Erikson, Joan Erikson, and Helen Kivnick wrote in *Vital Involvement in Old Age*, "Fidelity is the ability to sustain loyalties freely pledged in spite of the inevitable contradictions of value systems. It is the cornerstone of identity and receives inspiration from confirming ideologies and affirming companionships." Role confusion ensues when the youth is unable to formulate a sense of identity and belonging. Erikson held that delinquency, gender-related identity disorders, and borderline psychotic episodes can result from such confusion.

STAGE 6: INTIMACY VERSUS ISOLATION (ABOUT 21 YEARS TO ABOUT 40 YEARS). Freud's famous response to the question of what a normal person should be able to do well, "Lieben und arbeiten" (to love and to work), is one that Erikson often cited in his discussion of this psychosocial stage, and it emphasizes the importance he placed on the virtue of love within a balanced identity. Erikson asserted in *Identity: Youth and Crisis* that Freud's use of the term love referred to "the generosity of intimacy as well as genital love; when he said love and work, he meant a general work productiveness which would not preoccupy the individual to the extent that he might lose his right or capacity to be a sexual and a loving being."

Intimacy in the young adult is closely tied to fidelity; it can make and honor commitments to concrete affiliations and partnerships even when that requires sacrifice and compromise. The person who cannot tolerate the fear of ego loss arising out of self-abandonment (e.g., sexual orgasm, moments of intensity in friendships, aggression, inspiration, and intuition) is apt to become profoundly isolated and self-absorbed. *Distantiation*, an awkward term coined by Erikson to mean "the readiness to repudiate, isolate, and, if necessary, destroy those forces and persons whose essence seems dangerous to one's own," is the pathologic outcome of conflicts surrounding intimacy and, in the absence of an ethical sense where intimate, competitive, and combative relationships are differentiated, forms the basis for various forms of prejudice, persecution, and psychopathology.

Erikson's separation of the psychosocial task of achieving identity from

achieving intimacy and his assertion that substantial progress on the former task must precede development on the latter have engendered much criticism and debate. Critics have argued that Erikson's emphasis on separation and occupationally based identity formation fails to consider the importance for women of continued attachment and the formation of an identity based on relationships.

STAGE 7: GENERATIVITY VERSUS STAGNATION (ABOUT 40 YEARS TO ABOUT 60 YEARS). Erikson asserted in *Identity: Youth and Crisis* that "generativity is primarily the concern for establishing and guiding the next generation." The term *generativity* applies not so much to rearing and teaching one's offspring as it does to a protective concern for all the generations and social institutions. It encompasses productivity and creativity, as well. Having achieved the capacity to form intimate relationships, the person now broadens the investment of ego and libidinal energy to include groups, organizations, and society. *Care* is the virtue that coalesces at this stage. In *Childhood and Society,* Erikson emphasized the importance to the mature person of feeling needed. "Maturity needs guidance as well as encouragement from what has been produced and must be taken care of." Through generative behavior, the individual can pass on knowledge and skills while obtaining a measure of satisfaction in having achieved a role with senior authority and responsibility in the tribe.

When persons cannot develop true generativity, they may settle for pseudoengagement in occupation. Often, such persons restrict their focus to the technical aspects of their roles, at which they may now have become highly skilled, eschewing greater responsibility for the organization or profession. This failure of generativity can lead to profound personal stagnation, masked by various escapisms, such as alcohol and drug abuse, and sexual and other infidelities. Mid-life crisis or premature invalidism (physical and psychological) can occur. In this case, pathology appears not only in middle-aged persons but also in the organizations that depend on them for leadership. Thus, the failure to develop at midlife can lead to sick, withered, or destructive organizations that spread the effects of failed generativity throughout society; examples of such failures have become so common that they constitute a defining feature of modernity.

STAGE 8: INTEGRITY VERSUS DESPAIR (ABOUT 60 YEARS TO DEATH). In *Identity: Youth and Crisis,* Erikson defined integrity as "the acceptance of one's one and only life cycle and of the persons who have become significant to it as something that had to be and that, by necessity, permitted of no substitutions." From the vantage point of this stage of psychosocial development, the individual relinquishes the wish that important persons in his life had been different and can love in a more meaningful way—one that reflects accepting responsibility for one's own life. The individual in possession of the virtue of wisdom and a sense of integrity has room to tolerate the proximity of death and to achieve what Erikson termed in *Identity: Youth and Crisis,* a "detached yet active concern with life."

Erikson underlined the social context for this final stage of growth. In *Childhood and Society,* he wrote, "The style of integrity developed by his culture or civilization thus becomes the 'patrimony' of his soul …. In such final consolidation, death loses its sting."

When attempting to attain integrity has failed, the individual may become deeply disgusted with the external world and contemptuous of persons and institutions. Erikson wrote in *Childhood and Society* that such disgust masks a fear of death and a sense of despair that "time is now short, too short for the attempt to start another life and to try out alternate roads to integrity." Looking back on the eight ages of man, he noted the relation between adult integrity and infantile trust, "Healthy children will not fear life if their elders have integrity enough not to fear death."

Psychopathology

Each stage of the life cycle has its psychopathological outcome if it is not mastered successfully.

Basic Trust. An impairment of basic trust leads to basic mistrust. In infants, social trust is characterized by ease of feeding, depth of sleep, smiling, and general physiologic homeostasis. Prolonged separation during infancy can lead to hospitalism or anaclitic depression. In later life, this lack of trust may be manifested by dysthymic disorder, a depressive disorder, or a sense of hopelessness. Persons who develop and rely on the defense of projection—in which, according to Erikson, "we endow significant persons with the evil

which actually is in us"—experienced a sense of social mistrust in the first years of life and are likely to develop paranoid or delusional disorders. Basic mistrust is a significant contributor to the development of schizoid personality disorder and, in most severe cases, to the development of schizophrenia. Substance-related disorders can also be traced to social mistrust; substance-dependent personalities have strong oral-dependency needs and use chemical substances to satisfy themselves because of their belief that human beings are unreliable and, at worst, dangerous. If not appropriately nurtured, infants may feel empty, starved not just for food but also sensual and visual stimulation. As adults, they may become seekers after stimulating thrills that do not involve intimacy, which helps ward off feelings of depression.

Autonomy. The stage in which children attempt to develop into autonomous beings is often called the *terrible twos*, referring to toddlers' willfulness at this period of development. If shame and doubt dominate over autonomy, compulsive doubting can occur. The inflexibility of the obsessive personality also results from an overabundance of doubt. Too rigorous toilet training, commonplace in today's society, requires a clean, punctual, and deodorized body, can produce an overly compulsive personality that is stingy, meticulous, and selfish. Known as anal personalities, such persons are parsimonious, punctual, and perfectionistic (the three P's).

Too much shaming causes children to feel evil or dirty and may pave the way for delinquent behavior. In effect, children say, "If that's what they think of me, that's the way I'll behave." Paranoid personalities feel that others are trying to control them, a feeling that may have its origin during the stage of autonomy versus shame and doubt. When coupled with mistrust, the seeds are planted for persecutory delusions. Impulsive disorder may be explained as a person's refusal to be inhibited or controlled.

Initiative. Erikson stated: "In pathology, the conflict over initiative is expressed either in hysterical denial, which causes the repression of the wish or the abrogation of its executive organ by paralysis or impotence; or in overcompensatory showing off, in which the scared individual, so eager to 'duck,' instead 'sticks his neck out.'" In the past, hysteria was the usual form of pathologic regression in this area, but a plunge into a psychosomatic

disease is now common.

Excessive guilt can lead to a variety of conditions, such as generalized anxiety disorder and phobias. Patients feel guilty because of normal impulses, and they repress these impulses, with resulting symptom formation. Punishment or severe prohibitions during the stage of initiative versus guilt can produce sexual inhibitions. Conversion disorder or specific phobia can result when the oedipal conflict is not resolved. As sexual fantasies are accepted as unrealizable, children may punish themselves for these fantasies by fearing harm to their genitals. Under the brutal assault of the developing superego, they may repress their wishes and begin to deny them. If this pattern is carried forward, paralysis, inhibition, or impotence can result. Sometimes, in fear of not being able to live up to what others expect, children may develop a psychosomatic disease.

Industry. Erikson described industry as a "sense of being able to make things and make them well and even perfectly." When children's efforts are thwarted, they are made to feel that personal goals cannot be accomplished or are not worthwhile, and a sense of inferiority develops. In adults, this sense of inferiority can result in severe work inhibitions and a character structure marked by feelings of inadequacy. For some persons, the feelings may result in a compensatory drive for money, power, and prestige. Work can become the main focus of life at the expense of intimacy.

Identity. Many disorders of adolescence can be traced to identity confusion. The danger is role diffusion. Erikson stated:

Where this is based on a strong previous doubt on one's sexual identity, delinquent and outright psychotic incidents are not uncommon. If diagnosed and treated correctly, those incidents do not have the same fatal significance that they have at other ages. It is primarily the inability to settle on an occupational identity that disturbs young persons. Keeping themselves together, they temporarily overidentify, to the point of apparent complete loss of identity, with the heroes of cliques and crowds.

Other disorders during the stage of identity versus role diffusion include conduct disorder, disruptive behavior disorder, gender identity disorder, schizophreniform disorder, and other psychotic disorders. The ability to leave home and live independently is an essential task during this period. An

inability to separate from the parent and prolonged dependence may occur.

Intimacy. The successful formation of a stable marriage and family depends on the capacity to become intimate. The years of early adulthood are crucial for deciding whether to get married and to whom. Gender identity determines object choice, either straight or gay, but making an intimate connection with another person is a significant task. Persons with schizoid personality disorder remain isolated from others because of fear, suspicion, inability to take risks, or the lack of a capacity to love.

GENERATIVITY. From about 40 to 65 years, the period of middle adulthood, specific disorders are less clearly defined than in the other stages described by Erikson. Middle-aged persons show a higher incidence of depression than younger adults, which may be related to middle-aged persons' disappointments and failed expectations as they review the past, consider their lives, and contemplate the future. The increased use of alcohol and other psychoactive substances also occurs during this time.

INTEGRITY. Anxiety disorders often develop in older persons. In Erikson's formulation, this development may be related to persons' looking back on their lives with a sense of panic. Time has run out, and chances are used up. The decline in physical functions can contribute to psychosomatic illness, hypochondriasis, and depression. The suicide rate is highest in persons over the age of 65. Persons facing dying and death may find it intolerable not to have been generative or make significant attachments in life. Integrity, for Erikson, is characterized by an acceptance of life. Without acceptance, persons feel despair and hopelessness that can result in severe depressive disorders.

Treatment

Although no independent Eriksonian psychoanalytic school exists in the same way that Freudian and Jungian schools do, Erikson made many vital contributions to the therapeutic process. Among his most important contributions is his belief that establishing a state of trust between doctor and patient is the essential requirement for successful therapy. When psychopathology stems from basic mistrust (e.g., depression), a patient must

reestablish trust with the therapist, whose task, like that of the good mother, is sensitive to the patient's needs. The therapist must have a sense of personal trustworthiness that can be transmitted to the patient.

Techniques. For Erikson, a psychoanalyst is not a blank slate in the therapeutic process, as the psychoanalyst commonly is in Freudian psychoanalysis. On the contrary, effective therapy requires that therapists actively convey to patients the belief that they are understood. This is done through both empathetic listening and verbal assurances, which enable a positive transference built on mutual trust to develop.

Beginning as an analyst for children, Erikson tried to provide this mutuality and trust while he observed children recreating their worlds by structuring dolls, blocks, vehicles, and miniature furniture into the dramatic situations that were bothering them. Then, Erikson correlated his observations with statements by the children and their family members. He began treatment of a child only after eating an evening meal with the entire family, and his therapy was usually conducted with much cooperation from the family. After each regressive episode in the treatment of a schizophrenic child, for instance, Erikson discussed with every member of the family what had been going on with them before the episode. Only when he was thoroughly satisfied that he had identified the problem did treatment begin. Erikson sometimes provided corrective information to the child—for instance, telling a boy who could not release his feces and had made himself ill from constipation that food is not an unborn infant.

Erikson often turned to play, which, along with specific recommendations to parents, proved fruitful as a treatment modality. Play, for Erikson, is diagnostically revealing and thus helpful for a therapist who seeks to promote a cure, but it is also curative in its own right. Play is a function of the ego and gives children a chance to synchronize social and bodily processes with the self. Children playing with blocks or adults playing out an imagined dramatic situation can manipulate the environment and develop the sense of control that the ego needs. Play therapy is not the same for children and adults, however. Children create models to gain control of reality; they look ahead to new areas of mastery. Adults use play to correct the past and to redeem their failures.

Mutuality, which is essential in Erikson's system of health, is also vital to a

cure. Erikson applauded Freud for the moral choice of abandoning hypnosis because hypnosis heightens both the demarcation between the healer and the sick and the inequality that Erikson compares with the inequality of child and adult. Erikson urged that the relationship of the healer to the sick person be one of equals "in which the observer who has learned to observe himself teaches the observed to become self-observant."

Dreams and Free Association. As with Freud, Erikson worked with the patient's associations to the dream as the "best leads" to understanding the dream's meaning. He valued the first association with the dream, which he believed to be powerful and essential. Ultimately, Erikson listened for "a central theme which, once found, gives added meaning to all the associated material."

Erikson believed that interpretation was the primary therapeutic agent, sought as much by the patient as the therapist. He emphasized free-floating attention as the method that enabled discovery to occur. Erikson once described this attentional stance by commenting that in clinical work, "You need a history and you need a theory, and then you must forget them both and let each hour stand for itself." This frees both parties from counterproductive pressures to advance in the therapy and allows them to notice the gaps in the patient's narrative that signal the unconscious.

Goals. Erikson discussed four dimensions of the psychoanalyst's job. The patient's desire to be cured and the analyst's desire to cure is the first dimension. Mutuality exists in that patient and therapist are motivated by cure, and labor is divided. The goal is always to help the patient's ego get stronger and cure itself. The second dimension Erikson called objectivity-participation. Therapists must keep their minds open. "Neuroses change," wrote Erikson. New generalizations must be made and arranged in new configurations. The third dimension runs along the axis of knowledge-participation. The therapist "applies selected insights to more strictly experimental approaches." The fourth dimension is tolerance-indignation. Erikson stated: "Identities based on Talmudic argument, on messianic zeal, on punitive orthodoxy, on faddist sensationalism, on professional and social ambition" are harmful and tend to control patients. Control widens the gap of inequality between the doctor and the patient and makes the realization of the

recurrent idea in Erikson's thought—mutuality—difficult.

According to Erikson, therapists have the opportunity to work through past unresolved conflicts in the therapeutic relationship. Erikson encouraged therapists not to shy away from guiding patients; he believes therapists must offer patients both prohibitions and permissions. Nor should therapists be so engrossed in patients' past life experiences that current conflicts are overlooked.

The goal of therapy is to recognize how patients have passed through the various stages of the life cycle and how the various crises in each stage have or have not been mastered. Equally important, future stages and crises must be anticipated so that they can be negotiated and mastered appropriately. Unlike Freud, Erikson does not believe that the personality is so inflexible that change cannot occur in middle and late adulthood. For Erikson, psychological growth and development occur throughout the entire span of the life cycle.

The Austen Riggs Center in Stockbridge, Massachusetts, is a repository of Erikson's work, and many of his theories are put into practice there. Erik's wife, Joan, developed an activities program at the Austen Riggs Center as an "interpretation-free zone," where patients could take up work roles or function as students with artists and craftspersons, without the burden of the patient role. This workspace encouraged the play and creativity required for the patients' work development to parallel the process of their therapy.

OTHER PSYCHODYNAMIC SCHOOLS

The men and women discussed in this chapter contributed to psychiatric thought and practice in the early and middle years of the 20th century. Many of these theories of psychopathology evolved as direct offshoots of Freudian psychoanalysis. This, however, is derived from various aspects of psychology, such as learning theory and quantitative methods of personality assessment. The theories selected for the discussion in this section have stood the test of time and are most relevant for psychiatry.

Brief synopses of the theories that exert the most significant influence on current psychiatric thought are listed below in alphabetical order of their proponent. Each of these theories contains insights that merit consideration because they enhance our understanding of the complexities of human

behavior. They also illustrate the diversity of theoretical orientation that characterizes psychiatry today.

Karl Abraham (1877–1925)

Karl Abraham, one of Sigmund Freud's earliest disciples, was the first psychoanalyst in Germany. He is best known for his explication of depression from a psychoanalytic perspective and for his elaboration of Freud's stages of psychosexual development. Abraham divided the oral stage into a biting phase and a sucking phase; the anal stage into a destructive-expulsive (anal-sadistic) phase and a mastering-retentive (anal-erotic) phase; and the phallic stage into an early phase of partial genital love (true phallic phase) and a later mature genital phase. Abraham also linked the psychosexual stages to specific syndromes. For example, he postulated that obsessional neurosis resulted from fixation at the anal-sadistic phase and depression from fixation at the oral stage.

Alfred Adler (1870–1937)

Alfred Adler (Fig. 34-25) was born in Vienna, Austria, where he spent most of his life. A general physician, he became one of the original four members of Freud's circle in 1902. Adler never accepted the primacy of the libido theory, the sexual origin of a neurosis, or the importance of infantile wishes. Adler thought that aggression was far more critical, specifically in its manifestation as a striving for power, which he believed to be a masculine trait. He introduced the term *masculine protest* to describe the tendency to move from a passive, feminine role to a masculine, active role. Adler's theories are collectively known as *individual psychology*.

Adler saw individuals as unique, unified biologic entities whose psychological processes fit together into an individual lifestyle. He also postulated a principle of dynamism, in which every individual is future-directed and moves toward a goal. Adler also emphasized the interface between individuals and their social environment: the primacy of action in the real work over fantasy.

FIGURE 34-25
Alfred Adler (print includes signature). (Courtesy of Alexandra Adler.)

Adler coined the term *inferiority complex* to refer to a sense of inadequacy and weakness that is universal and inborn. A physical defect compromises a developing child's self-esteem, and Adler referred to this phenomenon as *organ inferiority*. He also thought that basic inferiority tied to children's oedipal longings could never be gratified.

Adler was one of the first developmental theorists to recognize the

importance of children's birth order in their origin. The firstborn child reacts with anger to the birth of siblings and struggles against giving up the powerful position of an only child. They tend not to share and become conservative. The second-born child must continuously strive to compete with the firstborn. Youngest children feel secure because they have *never* been displaced. Adler thought that a child's sibling position results in lifelong influences on character and lifestyle.

The primary therapeutic approach in Adlerian therapy is encouragement, through which Adler believed his patients could overcome feelings of inferiority. Consistent human relatedness, in his view, leads to greater hope, less isolation, and more significant affiliation with society. He believed that patients needed to develop a greater sense of their dignity and worth and a renewed appreciation of their abilities and strengths.

Franz Alexander (1891–1964)

Franz Alexander (Fig. 34-26) emigrated from his native Germany to the United States, where he settled in Chicago and founded the Chicago Institute for Psychoanalysis. He wrote extensively about the association between specific personality traits and certain psychosomatic ailments, a point of view that came to be known as the *specificity hypothesis.* Alexander fell out of favor with classic analysts for advocating the *corrective emotional experience* as part of the analytic technique. In this approach, Alexander suggested that an analyst must deliberately adopt a particular mode of relatedness with a patient to counteract noxious childhood influences from the patient's parents. He believed that the trusting, supportive relationship between patient and analyst enabled the patient to master childhood traumas and grow from the experience.

FIGURE 34-26
Franz Alexander. (Courtesy of Franz Alexander.)

Gordon Allport (1897–1967)

Gordon Allport (Fig. 34-27), a psychologist in the United States, is known as the founder of the humanistic school of psychology, which holds that each person has an inherent potential for autonomous function and growth. At Harvard University, he taught the first course in the psychology of personality offered at a college in the United States.

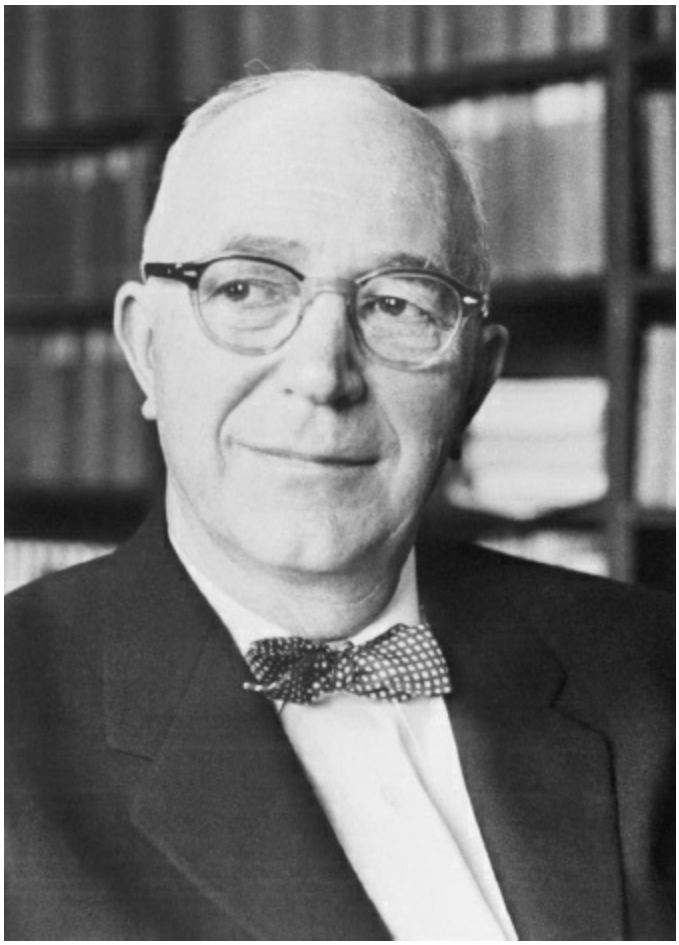

FIGURE 34-27
Gordon Allport. (© Bettmann/Corbis.)

Allport believed that a person's only real guarantee of personal existence is a sense of self. Selfhood develops through a series of stages, from awareness of the body to self-identity. Allport used the term *propriem* to describe strivings related to the maintenance of self-identity and self-esteem. He used the term *traits* to refer to the chief units of personality structure. *Personal dispositions* are individual traits that represent the essence of an individual's unique personality. Maturity is characterized by a capacity to relate to others with warmth and intimacy and an expanded sense of self. In Allport's view, mature persons have security, humor, insight, enthusiasm, and zest. Psychotherapy is geared to helping patients realize these characteristics.

Michael Balint (1896–1970)

Michael Balint was considered a member of the independent or middle group

of object relations theorists in the United Kingdom. Balint believed that the urge for the primary love object underlies virtually all psychological phenomena. Infants wish to be loved totally and unconditionally, and when a mother is not forthcoming with appropriate nurturance, a child devotes his or her life to a search for the love missed in childhood. According to Balint, the *basic fault* is the feeling of many patients that something is missing. As with Ronald Fairbairn and Donald W. Winnicott, Balint understood this deficit in internal structure to result from maternal failures. He viewed all psychological motivations stemming from the failure to receive adequate maternal love.

Unlike Fairbairn, however, Balint did not entirely abandon drive theory. He suggested that libido, for example, is both pleasure-seeking and object seeking. He also worked with seriously disturbed patients, and like Winnicott, he thought that certain aspects of psychoanalytic treatment occur at a more profound level than that of the ordinary verbal explanatory interpretations. Although some material involving genital psychosexual stages of development can be interpreted from the perspective of intrapsychic conflict, Balint believed that certain preverbal phenomena are reexperienced in the analysis. The relationship itself is decisive in dealing with this realm of early experience.

Eric Berne (1910–1970)

Eric Berne (Fig. 34-28) began his professional life as a training and supervising analyst in classic psychoanalytic theory and technique, but ultimately developed his school, known as *transactional analysis.* A *transaction* is a stimulus presented by one person that evokes a corresponding response in another. Berne defined psychological games as stereotyped and predictable transactions that persons learn in childhood and continue to play throughout their lives. *Strokes,* the basic motivating factors of human behavior, consist of specific rewards, such as approval and love. All persons have three ego states that exist within them: the *child,* which represents primitive elements that become fixed in early childhood; the *adult,* which is the part of the personality capable of objective appraisals of reality; and the *parent,* which is an introject of the values of a person’s actual parents. The therapeutic process is geared toward helping patients understand whether

they are functioning in the child, adult, or parent mode in their interactions with others. As patients learn to recognize characteristic games repeatedly played throughout life, they can ultimately function in the adult mode as much as possible in interpersonal relationships.

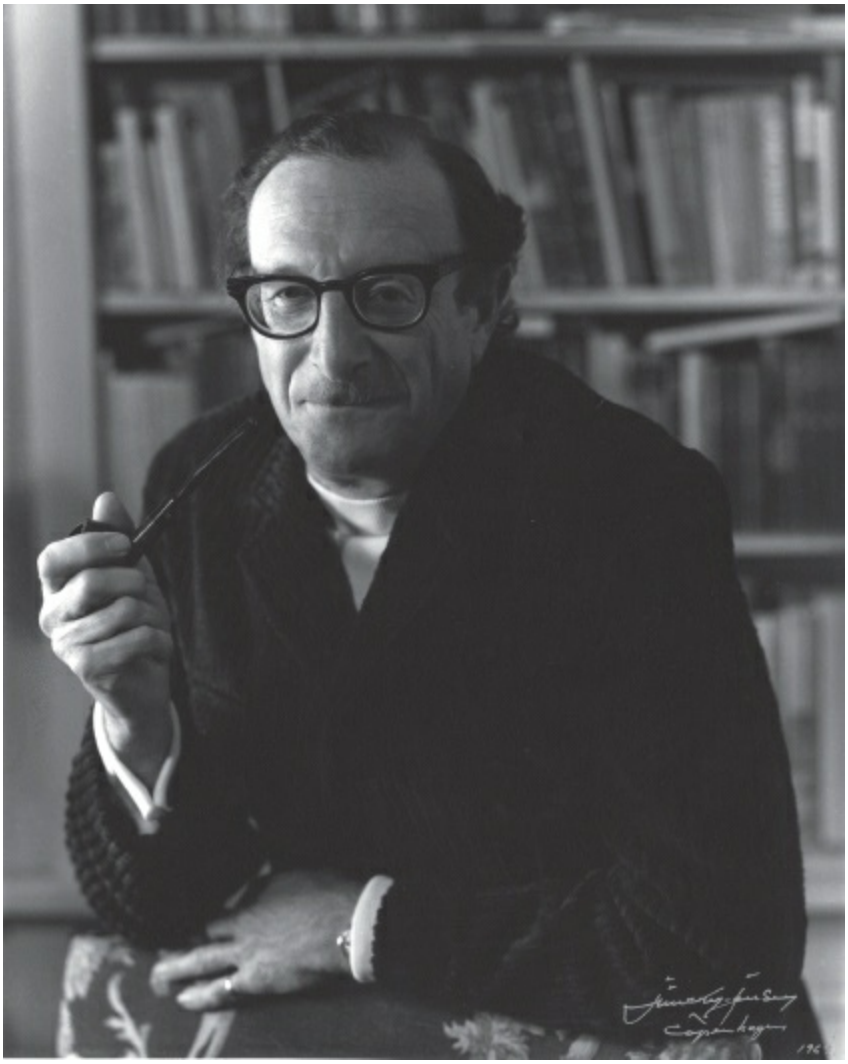

FIGURE 34-28
Eric Berne. (Courtesy of Creative Commons Attribution-Share Alike 4.0 International.)

Wilfred Bion (1897–1979)

Wilfred Bion expanded Melanie Klein's concept of *projective identification* to include an interpersonal process in which a therapist feels coerced by a patient into playing a particular role in the patient's internal world. He also developed the notion that the therapist must contain what the patient has

projected so that it is processed and returned to the patient in a modified form. Bion believed that a similar process occurs between mother and infant. He also observed that "psychotic" and "nonpsychotic" aspects of the mind function simultaneously as sub-organizations. Bion is probably best known for his application of psychoanalytic ideas to groups. Whenever a group gets derailed from its task, it deteriorates into one of three primary states: dependency, pairing, or fight-flight.

John Bowlby (1907–1990)

John Bowlby is generally considered the founder of attachment theory. He formed his ideas about attachment in the 1950s while consulting with the World Health Organization (WHO) on homelessness in children. He stressed that the essence of attachment is *proximity* (i.e., the tendency of a child to stay close to the mother or caregiver). His theory of the mother–infant bond was firmly rooted in biology and drew extensively from ethology and evolutionary theory. A basic sense of security and safety is derived from a continuous and close relationship with a caregiver, according to Bowlby. This readiness for attachment is biologically driven, and Bowlby stressed that attachment is reciprocal. Maternal bonding and caregiving are always intertwined with the child's attachment behavior. Bowlby felt that without this early proximity to the mother or caregiver, the child does not develop a *secure base,* which he considered a launching pad for independence. In the absence of a secure base, the child feels frightened or threatened, and development is severely compromised. Bowlby and attachment theory are discussed in detail in Section 34.1.

Raymond Cattell (1905–1998)

Raymond Cattell obtained his Ph.D. in England before moving to the United States. He introduced *multivariate analysis* and *factor analysis*—statistical procedures that simultaneously examine the relations among multiple variables and factors—to personality. By examining a person's life record objectively, using personal interviewing and questionnaire data, Cattell described various traits representing the building blocks of personality.

Traits are both biologically based and environmentally determined or learned. Biologic traits include sex, gregariousness, aggression, and parental

protectiveness. Environmentally learned traits include cultural ideas, such as work, religion, intimacy, romance, and identity. An important concept is the *law of coercion* to the biosocial mean, which holds that society exerts pressure on genetically different persons to conform to social norms. For example, a person with a strong genetic tendency toward dominance is likely to receive social encouragement for restraint, whereas the naturally submissive person will be encouraged toward self-assertion.

Ronald Fairbairn (1889–1964)

Ronald Fairbairn, a Scottish analyst who worked most of his life in relative isolation, was one of the significant psychoanalytic theorists in the British school of object relations. He suggested that infants are not primarily motivated by the drives of libido and aggression but are by an object seeking instinct. Fairbairn replaced the Freudian ideas of energy, ego, and id with the notion of *dynamic structures.* When an infant encounters frustration, a portion of the ego is defensively split off in the course of development and functions as an entity to internal objects and other subdivisions of the ego. He also stressed that both an object and an object *relationship* are internalized during development, so that a self is always with an object, and the two are connected with an affect.

Sándor Ferenczi (1873–1933)

Although Sándor Ferenczi, a Hungarian analyst, had been analyzed by Freud and was influenced by him, he later discarded Freud's techniques and introduced his method of analysis. He understood the symptoms of his patients as related to sexual and physical abuse in childhood and proposed that analysts need to love their patients in a way that compensates for the love they did not receive as children. He developed a procedure known as *active therapy,* in which he encouraged patients to develop an awareness of reality through active confrontation by the therapist. He also experimented with *mutual analysis,* in which he would analyze his patient for a session and then allow the patient to analyze him for a session.

Viktor Frankl (1905–1997)

His experience in Nazi concentration camps profoundly shaped the Austrian

neurologist and philosopher Viktor Frankl's distinctive view of human nature and psychopathology. There he concluded that even the most appalling circumstances could be endured if one found a way of making them meaningful. He described his experience in *Man's Search for Meaning*, a book that has been read by millions around the world.

Frankl was both a humanist and an existentialist. He believed that human beings shared with other animals somatic and psychological dimensions, but that humans alone also had a spiritual dimension that confers both freedom and responsibility. People find meaning in their lives through creative and productive work, through an appreciation of the world and others, and by freely adopting positive attitudes even in the face of suffering. Those who fail to find meaning face alienation, despair, and existential neuroses. Traditional societies provided a framework of meaning in religion and shared cultural values; in modern society, people must find their sources of meaning, and Frankl attributed many social problems, such as drug abuse and suicide, to their failures to do so.

Because of the spiritual dimension, human beings show self-transcendence and self-distancing. The former refers to the capacity to put other values (e.g., the well-being of a loved one) above self-interest. The latter is the ability to take an external perspective, as seen in a sense of humor. These capacities form the basis for therapeutic interventions in Frankl's version of psychotherapy known as logotherapy. Logotherapy is derived from the Greek word logos, which means thought or reason, and Frankl believed that man instinctively attempts to find universal understanding and harmony in life experiences.

Anna Freud (1895–1982)

Anna Freud (Fig. 34-29), the daughter of Sigmund Freud, ultimately made her own unique contributions to psychoanalysis. Although her father focused primarily on repression as the central defense mechanism, Anna Freud extensively elaborated on individual defense mechanisms, including reaction formation, regression, undoing, introjection, identification, projection, turning against the self, reversal, and sublimation. She was also a key figure in the development of modern ego psychology in that she emphasized that there was "depth in the surface." The defenses marshaled by the ego to avoid

unacceptable wishes from the id were in and of themselves complex and worthy of attention. Up to that point, the primary focus had been on uncovering unconscious sexual and aggressive wishes. She also made seminal contributions to child psychoanalysis and studied the function of the ego in personality development. She founded the Hampstead child therapy course and clinic in London in 1947 and served as its director.

FIGURE 34-30
Erich Fromm. (© Bettmann/Corbis.)

Erich Fromm (1900–1980)

Erich Fromm (Fig. 34-30) came to the United States in 1933 from Germany, where he had received his Ph.D. He was instrumental in founding the William Alanson White Institute for Psychiatry in New York. Fromm identified five character types common to, and determined by, Western culture; each person may possess qualities from one or more types. The types are (1) the *receptive personality* is passive; (2) the *exploitative personality* is manipulative; (3) the *marketing personality* is opportunistic and changeable; (4) the *hoarding personality* saves and stores; and (5) the *productive personality* is mature and enjoys love and work. The therapeutic process

involves strengthening the person's sense of ethical behavior toward others and developing productive love, characterized by care, responsibility, and respect for other persons.

Kurt Goldstein (1878–1965)

Kurt Goldstein (Fig. 34-31) was born in Germany and received his M.D. from the University of Breslau. He was influenced by existentialism and Gestalt psychology—every organism has dynamic properties, which are energy supplies that are relatively constant and evenly distributed. When states of tension-disequilibrium occur, an organism automatically attempts to return to its normal state. What happens in one part of the organism affects every other part, a phenomenon known as *holocoenosis.*

Self-actualization was a concept Goldstein used to describe persons' creative powers to fulfill their potentialities. Because each person has a different set of innate potentialities, persons strive for self-actualization along different paths. Sickness severely disrupts self-actualization. Responses to disruption of an organism's integrity may be rigid and compulsive; regression to more primitive modes of behavior is characteristic. One of Goldstein's significant contributions was his identification of the *catastrophic reaction* to brain damage, in which a person becomes fearful and agitated and refuses to perform simple tasks because of the fear of possible failure.

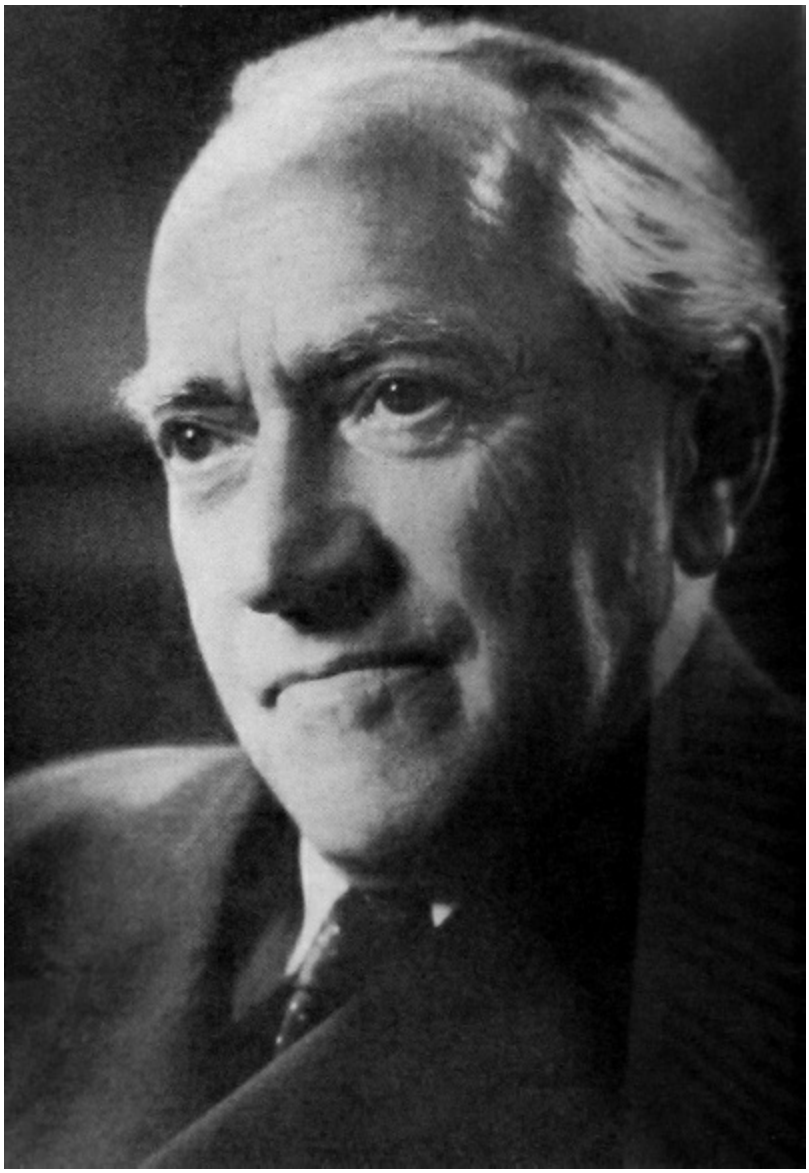

FIGURE 34-31
Kurt Goldstein. (Courtesy of New York Academy of Medicine, New York.)

Karen Horney (1885–1952)

German-born physician-psychoanalyst Karen Horney (Fig. 34-32), who emphasized the preeminence of social and cultural influences on psychosexual development, focused her attention on the differing psychology of men and women and explored the vicissitudes of marital relationships. She taught at the Institute of Psychoanalysis in Berlin before immigrating to the United States. Horney believed that a person's current personality attributes result from the interaction between the person and the environment and are

not solely based on infantile libidinal strivings carried over from childhood. Her theory, known as *holistic psychology,* maintains that a person needs to be seen as a unitary whole who influences, and is influenced by, the environment. She thought that the Oedipus complex was overvalued in terms of its contribution to adult psychopathology, but she also believed that rigid parental attitudes about sexuality led to an excessive concern with the genitals.

FIGURE 34-32
Karen Horney. (Courtesy of the Association for the Advancement of Psychoanalysis, New York.)

She proposed three separate concepts of the self: the *actual self,* the total of

a person's experience; the *real self*, the harmonious, healthy person; and the *idealized self*, the neurotic expectation, or glorified image that a person feels he or she should be. A person's *pride system* alienates him or her from the real self by overemphasizing prestige, intellect, power, strength, appearance, sexual prowess, and other qualities that can lead to self-effacement or self-hatred. Horney also established the concepts of *basic anxiety* and *basic trust.* The therapeutic process, in her view, aims for *self-realization* by exploring distorting influences that prevent the personality from growing.

Edith Jacobson (1897–1978)

Edith Jacobson, a psychiatrist in the United States, believed that the structural model and an emphasis on object relations are not fundamentally incompatible. She thought that the ego, self-images, and object images exert reciprocal influences on one's development. She also stressed that the infant's disappointment with the maternal object is not necessarily related to the mother's actual failure. In Jacobson's view, disappointment is related to a specific, drive-determined demand, rather than a global striving for contact or engagement. She viewed an infant's experience of pleasure or "unpleasure" as the core of the early mother–infant relationship. Satisfactory experiences lead to the formation of good or gratifying images, whereas unsatisfactory experiences create bad or frustrating images. Normal and pathologic development is based on the evolution of these self-images and object images. Jacobson believed that *fixation* refers to modes of object relatedness rather than modes of gratification.

Carl Gustav Jung (1875–1961)

Carl Gustav Jung (Fig. 34-33), a Swiss psychiatrist, formed a psychoanalytic school known as *analytic psychology*, which includes basic ideas related to but going beyond, Freud's theories. After initially being Freud's disciple, Jung broke with Freud over the latter's emphasis on infantile sexuality. He expanded on Freud's concept of the unconscious by describing the *collective unconscious* as consisting of all humankind's common, shared mythologic and symbolic past. The collective unconscious includes *archetypes*—representational images and configurations with universal symbolic meanings. Archetypal figures exist for the mother, father, child, and hero,

among others. Archetypes contribute to *complexes,* feeling-toned ideas that develop from personal experience interacting with archetypal imagery. Thus, a mother complex is determined not only by the mother–child interaction but also by the conflict between archetypal expectation and experience with the real woman who functions in a motherly role.

Jung noted that there are two types of personality organizations: introversion and extroversion. *Introverts* focus on their inner world of thoughts, intuitions, emotions, and sensations; *extroverts* are more oriented toward the outer world, other persons, and material goods. Each person has a mixture of both components. The *persona,* the mask covering the personality, is the face a person presents to the outside world. The persona may become fixed, and the real person hidden from him- or herself. *Anima* and *animus* are unconscious traits possessed by men and women, respectively, and contrast with the persona. *Anima* refers to a man's undeveloped femininity, whereas *animus* refers to a woman's undeveloped masculinity.

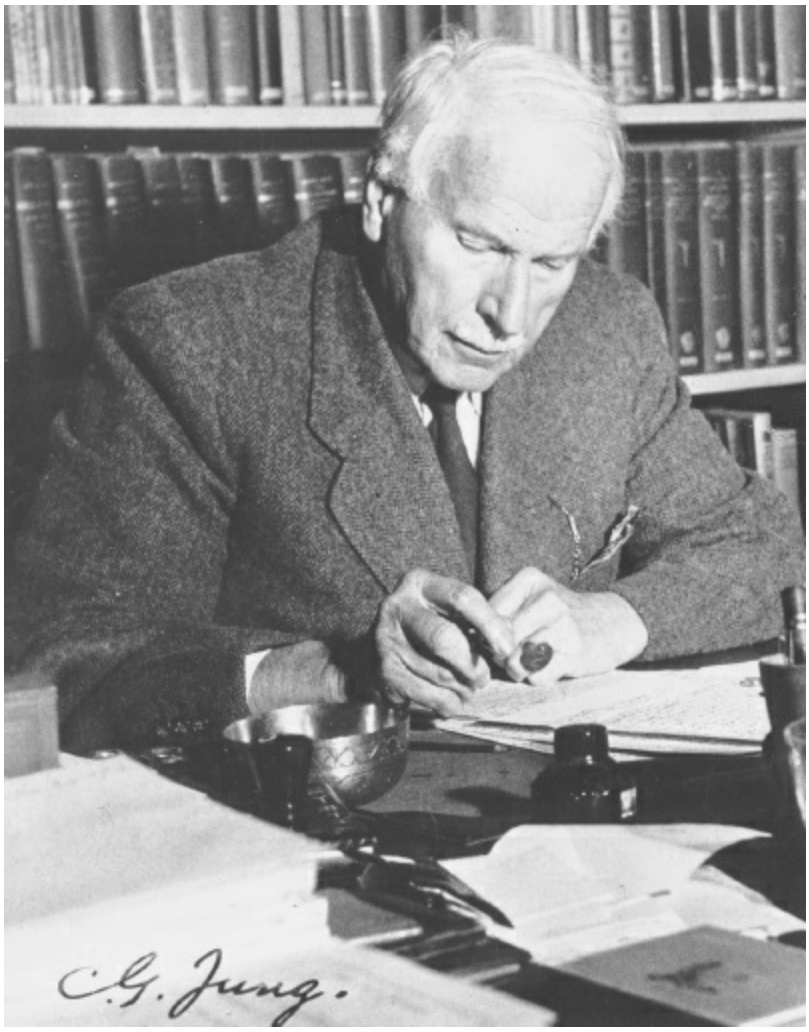

FIGURE 34-33
Carl Gustav Jung (print includes signature). (Courtesy of National Library of Medicine, Bethesda, MD.)

Jungian treatment aims to bring about an adequate adaptation to reality, which involves a person fulfilling their creative potentialities. The ultimate goal is to achieve *individuation*, a process continuing throughout life whereby persons develop a unique sense of their own identity. This developmental process may lead them down new paths away from their previous directions in life.

Otto Kernberg (1928–Present)

Otto Kernberg is perhaps the most influential object relations theorist in the United States. Influenced by both Klein and Jacobson, much of his theory is derived from his clinical work with patients who have borderline personality

disorder. Kernberg places great emphasis on the splitting of the ego and the elaboration of good and bad self-configurations and object configurations. Although he has continued to use the structural model, he views the id as composed of self-images, object images, and their associated affects. Drives appear to manifest themselves only in the context of internalized interpersonal experience. Good and bad self-representations and object relations become associated, respectively, with libido and aggression. Object relations constitute the building blocks of both structure and drives. Goodness and badness in relational experiences precede drive cathexis. The dual instincts of libido and aggression arise from object-directed affective states of love and hate.

Kernberg proposed the term *borderline personality organization* for a broad spectrum of patients characterized by a lack of an integrated sense of identity, ego weakness, absence of superego integration, reliance on primitive defense mechanisms such as splitting and projective identification, and a tendency to shift into primary process thinking. He suggested a specific type of psychoanalytic psychotherapy for such patients in which transference issues are interpreted early in the process.

Melanie Klein (1882–1960)

Melanie Klein (Fig. 34-34) was born in Vienna, worked with Abraham and Ferenczi, and later moved to London. Klein evolved a theory of internal object relations that was intimately linked to drives. Her unique perspective grew mainly from her psychoanalytic work with children, in which she became impressed with the role of unconscious intrapsychic fantasy. She postulated that the ego undergoes a splitting process to deal with the terror of annihilation. She also thought that Freud's concept of the death instinct was central to understanding aggression, hatred, sadism, and other forms of "badness," all of which she viewed as derivatives of the death instinct.

Klein viewed projection and introjection as the primary defensive operations in the first months of life. Infants project derivatives of the death instinct into the mother and then fear attack from the "bad mother," a phenomenon that Klein referred to as *persecutory anxiety.* This anxiety is intimately associated with the *paranoid-schizoid position,* infants' mode of organizing experience in which all aspects of infant and mother are split into

good and bad elements. As the disparate views are integrated, infants become concerned that they may have harmed or destroyed the mother through the hostile and sadistic fantasies directed toward her. At this developmental point, children have arrived at the *depressive position,* in which the mother is viewed ambivalently as having both positive and negative aspects and as the target of a mixture of loving and hateful feelings. Klein was also instrumental in developing child analysis, which evolved from an analytic play technique in which children used toys and played in a symbolic fashion that allowed analysts to interpret the play.

FIGURE 34-34
Melanie Klein. (Courtesy of Melanie Klein and Douglas Glass.)

FIGURE 34-35
Heinz Kohut. (Courtesy of New York Academy of Medicine, New York.)

Heinz Kohut (1913–1981)

Heinz Kohut (Fig. 34-35) is best known for his writings on narcissism and the development of self-psychology. He viewed the development and maintenance of self-esteem and self-cohesion as more critical than sexuality or aggression. Kohut described Freud's concept of narcissism as judgmental, in that development was supposed to proceed toward object relatedness and away from narcissism. He conceived of two separate lines of development, one moving in the direction of object relatedness and the other in the direction of greater enhancement of the self.

In infancy, children fear losing the protection of the early mother–infant bliss and resort to one of three pathways to save the lost perfection: the grandiose self, the alter ego or twinship, and the idealized parental image. These three poles of the self manifest themselves in psychoanalytic treatment in terms of characteristic transferences, known as *self-object transferences.* The *grandiose self* leads to a *mirror transference,* in which patients attempt to capture the gleam in the analyst's eye through exhibitionistic self-display. The *alter ego* leads to the *twinship transference,* in which patients perceive the analyst as a twin. The *idealized parental image* leads to an *idealizing transference,* in which patients feel enhanced self-esteem by being in the presence of the exalted figure of the analyst.

Kohut suggested that empathic failures in the mother lead to a developmental arrest at a particular stage when children need to use others to perform self-object functions. Although Kohut originally applied this formulation to narcissistic personality disorder, he later expanded it to apply to all psychopathology.

Jacques Lacan (1901–1981)

Born in Paris and trained as a psychiatrist, Jacques Lacan founded his institute, the Freudian School of Paris. He attempted to integrate the intrapsychic concepts of Freud with concepts related to linguistics and semiotics (the study of language and symbols). Whereas Freud saw the unconscious as a seething cauldron of needs, wishes, and instincts, Lacan saw it as a sort of language that helps to structure the world. His two principal concepts are that the unconscious is structured like a language, and the unconscious is a discourse. Primary process thoughts are uncontrolled free-flowing sequences of meaning. Symptoms are signs or symbols of underlying processes. The role of the therapist is to interpret the semiotic text of the personality structure. Lacan's most basic phase is the mirror stage; it is here that infants learn to recognize themselves by taking the perspective of others. In that sense, the ego is not part of the self but is something outside of, and viewed by, the self. The ego comes to represent parents and society more than it represents the actual self of the person.

Lacan's therapeutic approach involves the need to become less alienated from the self and more involved with others. Relationships are often

fantasized, which distorts reality and must be corrected. Among his most controversial beliefs was that the resistance to understanding the real relationship with the therapist can be reduced by shortening the length of the therapy session and that psychoanalytic sessions need to be standardized not to time but, instead, to content and process.

Kurt Lewin (1890–1947)

Kurt Lewin received his Ph.D. in Berlin, came to the United States in the 1930s, and taught at Cornell, Harvard, and the Massachusetts Institute of Technology. He adapted the field approach of physics to a concept called *field theory*. A *field* is the totality of coexisting, mutually interdependent parts. Behavior becomes a function of persons and their environment, which together make up the *life space.* The life space represents a field in constant flux, with *valences* or needs that require satisfaction. A hungry person is more aware of restaurants than someone who has just eaten, and a person who wants to mail a letter is aware of mailboxes.

Lewin applied field theory to groups. *Group dynamics* refers to the interaction among members of a group, each of whom depends on the others. The group can exert pressure on a person to change behavior, but the person also influences the group when change occurs.

Abraham Maslow (1908–1970)

Abraham Maslow (Fig. 34-36) was born in Brooklyn, New York, and completed his undergraduate and graduate work at the University of Wisconsin. Along with Goldstein, Maslow believed in *self-actualization theory*—the need to understand the totality of a person. A leader in humanistic psychology, Maslow described a hierarchical organization of needs present in everyone. As the more primitive needs, such as hunger and thirst, are satisfied, more advanced psychological needs, such as affection and self-esteem, become the primary motivators. Self-actualization is the highest need.

A peak experience, frequently occurring in self-actualizers, is an episodic, brief occurrence in which a person suddenly experiences a powerful transcendental state of consciousness—a sense of heightened understanding, an intense euphoria, an integrated nature, unity with the universe, and an

altered perception of time and space. This powerful experience tends to occur most often in the psychologically healthy and can produce long-lasting beneficial effects.

FIGURE 34-36
Abraham H. Maslow. (© Bettmann/Corbis.)

Karl A. Menninger (1893–1990)

Karl A. Menninger was one of the first physicians in the United States to receive psychiatric training. With his brother, Will, he pioneered the concept of a psychiatric hospital based on psychoanalytic principles and founded the Menninger Clinic in Topeka, Kansas. He also was a prolific writer; *The Human Mind,* one of his most famous books, brought psychoanalytic understanding to the lay public. He made a compelling case for the validity of Freud's death instinct in *Man Against Himself.* In *The Vital Balance,* his

magnum opus, he formulated a unique theory of psychopathology. Menninger maintained a lifelong interest in the criminal justice system and argued in *The Crime of Punishment* that many convicted criminals needed treatment rather than punishment. Finally, his volume titled *Theory of Psychoanalytic Technique* was one of the few books to examine the theoretical underpinnings of psychoanalysts' interventions.

Adolf Meyer (1866–1950)

Adolf Meyer (Fig. 34-37) came to the United States from Switzerland in 1892 and eventually became director of the psychiatric Henry Phipps Clinic of the Johns Hopkins Medical School. Not interested in metapsychology, he espoused a commonsense psychobiological methodology for the study of mental disorders, emphasizing the interrelationship of symptoms and individual psychological and biologic functioning. His approach to the study of personality was biographical; he attempted to bring psychiatric patients and their treatment out of isolated state hospitals and into communities and was also a strong advocate of social action for mental health. Meyer introduced the concept of *common sense psychiatry* and focused on how a patient's current life situation could be realistically improved. He coined the concept of *ergasia*, the action of the total organism. His goal in therapy was to aid patients' adjustment by helping them modify unhealthy adaptations. One of Meyer's tools was an autobiographical life chart constructed by the patient during therapy.

FIGURE 34-37
Adolf Meyer. (From the National Library of Medicine, Bethesda, MD.)

Gardner Murphy (1895–1979)

Gardner Murphy (Fig. 34-38) was born in Ohio and received his Ph.D. from Columbia University. He was among the first to publish a comprehensive history of psychology and made significant contributions to social, general, and educational psychology. According to Murphy, three essential stages of personality development are the stage of undifferentiated wholeness, the stage of differentiation, and the stage of integration. This development is frequently uneven, with both regression and progression occurring along the way. The four inborn human needs are visceral-, motor-, sensory-, and

emergency-related. These needs become increasingly specific in time as a person's experiences mold them in various social and environmental contexts. *Canalization* brings about these changes by establishing a connection between a need and a specific way of satisfying the need.

Murphy was interested in parapsychology. States such as sleep, drowsiness, specific drug, toxic conditions, hypnosis, and delirium tend to be favorable to paranormal experiences. Impediments to paranormal awareness include various intrapsychic barriers, conditions in the general social environment, and heavy investment in ordinary sensory experiences.

Henry Murray (1893–1988)

Henry Murray (Fig. 34-39) was born in New York City, attended medical school at Columbia University, and was a founder of the Boston Psychoanalytic Institute. He proposed the term *personology* to describe the study of human behavior. He focused on *motivation,* a need aroused by internal or external stimulation; once aroused, motivation produces continued activity until the need is reduced or satisfied. He developed the *Thematic Apperception Test* (TAT), a projective technique used to reveal unconscious and conscious mental processes and problem areas.

Frederick S. Perls (1893–1970)

Gestalt theory developed in Germany under the influence of several men: Max Wertheimer (1880–1943), Wolfgang Köhler (1887–1967), and Lewin. Frederick "Fritz" Perls (Fig. 34-40) applied Gestalt theory to a therapy that emphasizes the current experiences of the patient in the here and now, as contrasted to the there and then of psychoanalytic schools. In terms of motivation, patients learn to recognize their needs at any given time and how the drive to satisfy these needs may influence their current behavior. According to the Gestalt point of view, behavior represents more than the sum of its parts. A *gestalt,* or a whole, includes and goes beyond the sum of smaller, independent events; it deals with essential characteristics of experience, such as value, meaning, and form.

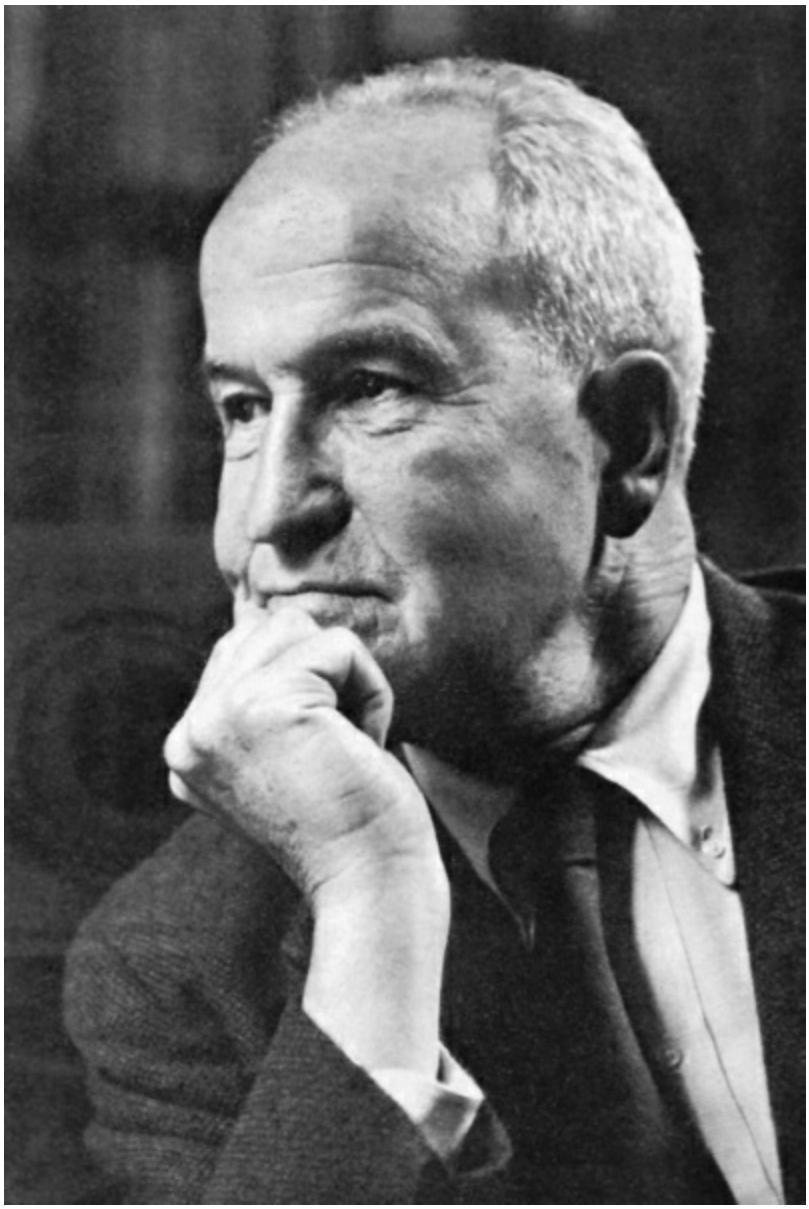

FIGURE 34-39
Henry Murray. (Courtesy of New York Academy of Medicine, New York.)

Sandor Rado (1890–1972)

Sandor Rado (Fig. 34-41) came to the United States from Hungary in 1945 and founded the Columbia Psychoanalytic Institute in New York. His theories of *adaptational dynamics* hold that the organism is a biologic system operating under hedonic control, which is somewhat similar to Freud's pleasure principle. Cultural factors often cause excessive hedonic control and disordered behavior by interfering with the organism's ability for *self-*

regulation. In therapy, the patient needs to relearn how to experience pleasurable feelings.

Otto Rank (1884–1939)

An Austrian psychologist and a protégé of Sigmund Freud, Otto Rank (Fig. 34-42) broke with Freud in his 1924 publication, *The Trauma of the Birth,* and developed a new theory called *birth trauma.* Anxiety is correlated with separation from the mother—specifically, with separation from the womb, the source of effortless gratification. This painful experience results in primal anxiety. Sleep and dreams symbolize the return to the womb.

FIGURE 34-42
Otto Rank. (Courtesy of New York Academy of Medicine.)

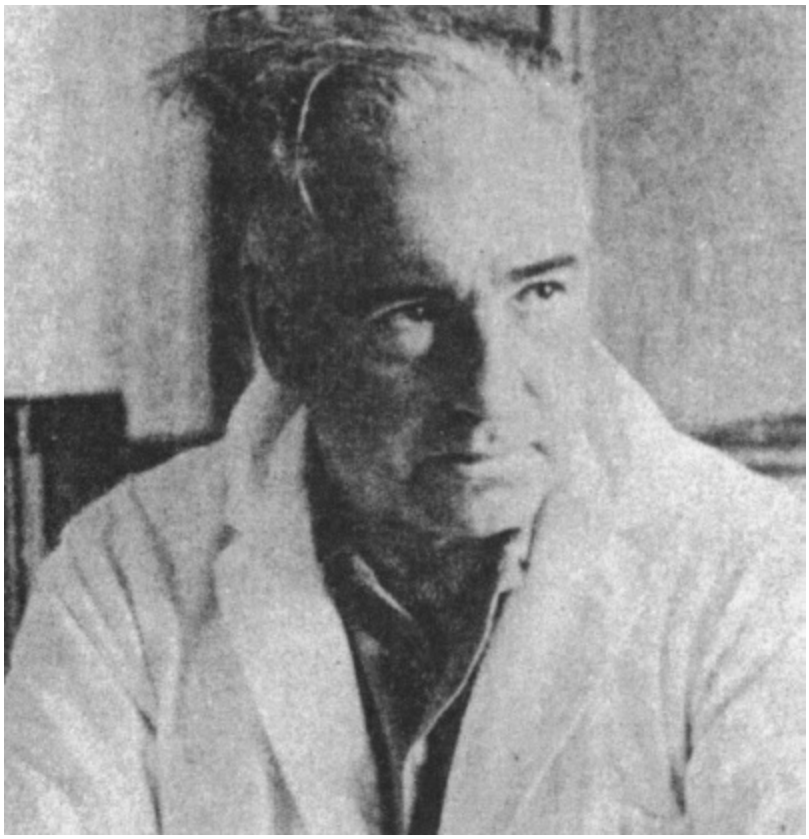

FIGURE 34-43
Wilhelm Reich. (Courtesy of New York Academy of Medicine.)

The personality is divided into impulses, emotions, and will. Children's impulses seek immediate discharge and gratification. As impulses are mastered, as in toilet training, children begin the process of will development. If the will is carried too far, pathologic traits (e.g., stubbornness, disobedience, and inhibitions) may develop.

Wilhelm Reich (1897–1957)

Wilhelm Reich (Fig. 34-43), an Austrian psychoanalyst, made significant contributions to psychoanalysis in character formation and character types. The term *character armor* refers to the personality's defenses that serve as resistance to self-understanding and change. The four primary character types are as follows: the *hysterical character* is sexually seductive, anxious, and fixated at the phallic phase of libido development; the *compulsive character* is controlled, distrustful, indecisive, and fixated at the anal phase; the *narcissistic character* is fixated at the phallic stage of development, and if the

person is male, he has contempt for women; and the *masochistic character* is long-suffering, complaining, and self-deprecatory, with excessive demand for love.

The therapeutic process, called *will therapy*, emphasizes the relationship between patient and therapist; the goal of treatment is to help patients accept their separateness. A definite termination date for therapy is used to protect against excessive dependence on the therapist.

Carl Rogers (1902–1987)

Carl Rogers (Fig. 34-44) received his Ph.D. in psychology from Columbia University. After attending Union Theological Seminary in New York, Rogers studied for the ministry. His name is most clearly associated with the *person-centered theory* of personality and psychotherapy, in which the central concepts are self-actualization and self-direction. Specifically, persons are born with a capacity to direct themselves in the healthiest way toward a level of completeness called self-actualization. From his person-centered approach, Rogers viewed personality not as a static entity composed of traits and patterns but as a dynamic phenomenon involving ever-changing communications, relationships, and self-concepts.

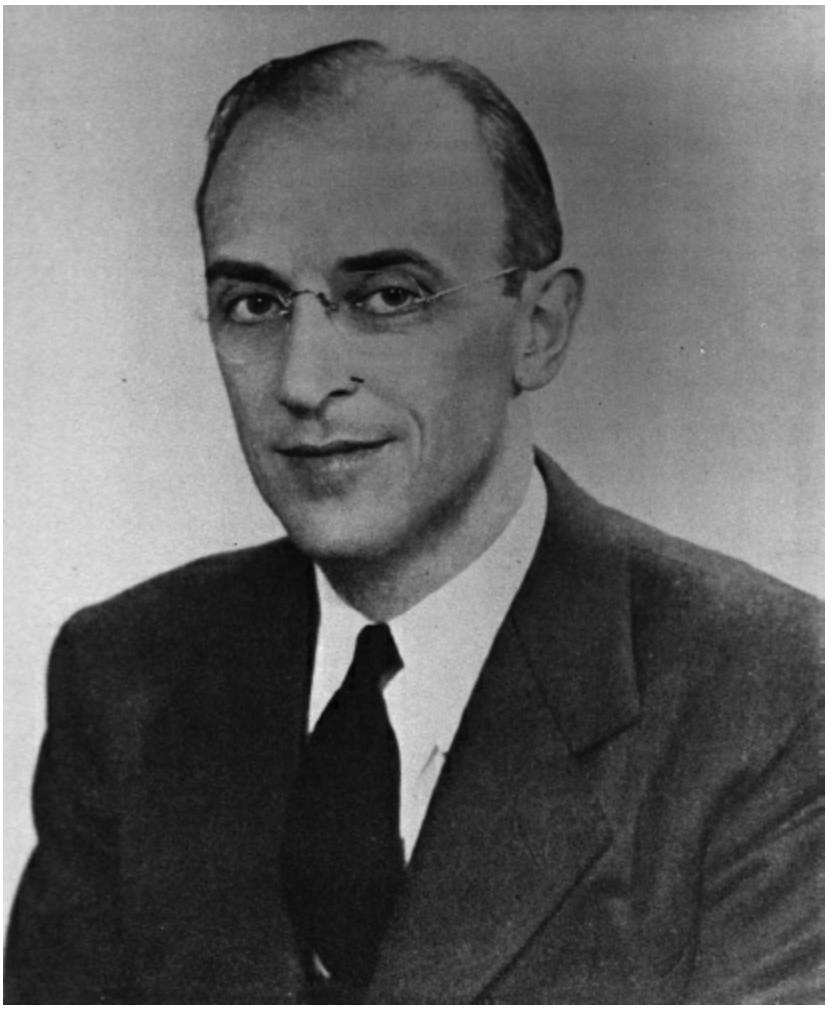

FIGURE 34-44
Carl Rogers. (Courtesy of the National Library of Medicine.)

Rogers developed a treatment program called *client-centered psychotherapy*. Therapists attempt to produce an atmosphere in which clients can reconstruct their strivings for self-actualization. Therapists hold clients in unconditional positive regard, which is the total nonjudgmental acceptance of clients. Other therapeutic practices include attention to the present, focus on clients' feelings, emphasis on process, trust in the potential and self-responsibility of clients, and a philosophy grounded in a positive attitude toward them, rather than a preconceived structure of treatment.

Jean-Paul Sartre (1905–1980)

Born in Paris, Jean-Paul Sartre wrote plays and novels before turning to psychology. He was a German prisoner of war from 1940 to 1941 during

World War II. Influenced by the ideas of Martin Heidegger, he developed what he called *existential psychoanalysis.* The reflective self was a crucial concept in Sartre's psychology. He recognized that humans alone could reflect on themselves as objects so that the experience of "being" in humans is unique in the natural world. This capacity to reflect leads humans to impose meaning on existence. For Sartre, this meaning allows a human being to create their essence.

Sartre denied the unconscious; he thought that human beings were condemned to be free and to face the fundamental existential dilemma—their aloneness without a god to provide meaning. As a result, each individual creates values and meanings. Neurosis is an escape from freedom, which is the key to maintaining psychological health. Sartre made no distinction between philosophy and psychology. Psychologists, as with philosophers, search for the truth about the world. Part of this truth, in Sartre's view, was the dialectic between consciousness and *being.* Consciousness introduces nothingness and is a negation of being-in-itself. Ideals are revealed in actions, not in professed beliefs.

FIGURE 34-45
B. F. Skinner. (Courtesy of New York Academy of Medicine, New York.)

B. F. Skinner (1904–1990)

Burrhus Frederic Skinner (Fig. 34-45), commonly known as B. F. Skinner, received his Ph.D. in psychology from Harvard University, where he taught for many years. Skinner's seminal work in operant learning laid much of the groundwork for many current methods of behavior modification, programmed instruction, and general education. His global beliefs about the nature of behavior have been applied more widely. It can be argued, than those of any other theorist, except, perhaps, Freud. His impact has been impressive in scope and magnitude.

Skinner's approach to personality was derived more from his fundamental beliefs about behavior than from a specific theory of personality per se. To Skinner, personality did not differ from other behaviors or sets of behaviors; it is acquired, maintained, and strengthened or weakened according to the

same rules of reward and punishment that alter any other behavior. *Behaviorism,* as Skinner's basic theory is most commonly known, is concerned only with observable, measurable behavior that can be operationalized. Many abstract and mentalistic hallmarks of other dominant personality theories have little place in Skinner's framework. Concepts such as self, ideas, and ego are considered unnecessary for understanding behavior. Through the process of operant conditioning and the application of basic principles of learning, persons are believed to develop sets of behavior that characterize their responses to the world of stimuli that they face in their lives. Such a set of responses is called *personality.*

Harry Stack Sullivan (1892–1949)

Harry Stack Sullivan (Fig. 34-46) is generally acknowledged as the most original and distinctive American-born theorist in dynamic psychiatry. When psychiatrists use the term *parataxic distortion,* apply the concept of self-esteem, consider the importance of preadolescent peer groups in development, or view a patient's behavior as an interpersonal manipulation, they are applying concepts Sullivan first proposed.

Sullivan described three modes of experiencing and thinking about the world. The *prototaxic mode* is undifferentiated thought that cannot separate the whole into parts or use symbols. It occurs in infancy and also appears in patients with schizophrenia. In the *parataxic mode,* events are causally related because of temporal or serial connections. Logical relationships, however, are not perceived. The *syntaxic mode* is the logical, rational, and most mature type of cognitive functioning of which a person is capable. These three types of thinking and experiencing occur side by side in all persons; it is the rare person who functions exclusively in the syntaxic mode.

FIGURE 34-46
Harry Stack Sullivan. (Courtesy of the National Library of Medicine.)

The total configuration of personality traits is known as the *self-system*, which develops in various stages and is the outgrowth of interpersonal experiences, rather than an unfolding of intrapsychic forces. During infancy, anxiety occurs for the first time when infants' primary needs are not satisfied. During childhood, from 2 to 5 years, a child's main tasks are to learn the requirements of the culture and how to deal with influential adults. As a juvenile, from 5 to 8 years, a child needs peers and must learn how to deal with them. In preadolescence, from 8 to 12 years, the capacity for love and collaboration with another person of the same sex develops. This so-called *chum period* is the prototype for a sense of intimacy. In the history of patients with schizophrenia, this experience of chums is often missing. During adolescence, significant tasks include the separation from the family, the

development of standards and values, and the transition to heterosexuality.

The therapy process requires the active participation of the therapist, who is known as a *participant-observer*. Modes of experience, particularly the parataxic, need to be clarified, and new patterns of behavior need to be implemented. Ultimately, persons need to see themselves as they are, instead of as they think they are or want others to think they are.

Sullivan is best known for his creative psychotherapeutic work with severely disturbed patients. He believed that even the most psychotic patients with schizophrenia could be reached through the human relationship of psychotherapy.

Donald W. Winnicott (1896–1971)

Donald W. Winnicott (Fig. 34-47) was one of the central figures in the British school of object relations theory. His theory of *multiple self-organization* included a *true self*, which develops in the context of a responsive *holding environment* provided by a *good-enough mother*. When infants experience a traumatic disruption of their developing sense of self, however, a false self emerges and monitors and adapts to the conscious and unconscious needs of the mother; it thus provides a protected exterior behind which the true self is afforded the privacy that it requires to maintain its integrity.

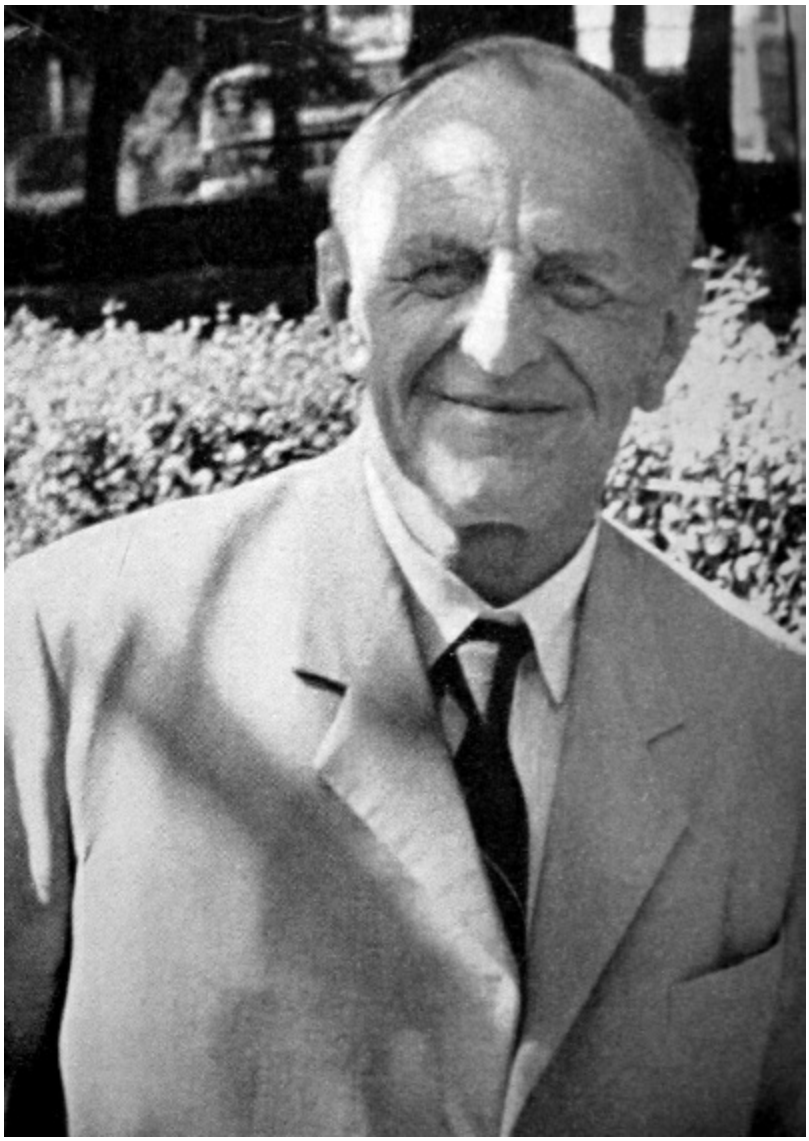

FIGURE 34-47
Donald Winnicott. (Courtesy of New York Academy of Medicine, New York.)

Winnicott also developed the notion of the *transitional object.* Ordinarily, a pacifier, blanket, or teddy bear, this object serves as a substitute for the mother during infants' efforts to separate and become independent. It provides a soothing sense of security in the absence of the mother.

The case history below illustrates how the different psychodynamic schools discussed in this chapter can be applied to the clinical observations.

Mr. A was a 26-year-old white man who had a history of bipolar I disorder. He was brought in for treatment after not completing the last

required course for his advanced degree and being arrested for disturbing the peace. He had consistently lied to his family about where he stood with his coursework and about having skipped an examination that would have qualified him to use his professional degree. He had also not told them that he had been using marijuana almost daily for several years and occasionally used hallucinogens. His arrest for disorderly conduct was for swimming naked in an apartment complex in the middle of the night while taking hallucinogens.

Mr. A's use of marijuana began early in college but became daily during graduate school. He was diagnosed as having bipolar I disorder early in his senior year at college after an apparent episode of mania. His mood disorder was well controlled on lithium (Eskalith). During graduate school, he was episodically compliant with medications, preferring to try to maintain a state of hypomania. He saw a psychiatrist every 3 to 6 months for medication checks. During his 4 years in graduate school, he had two clear episodes of depression and began taking sertraline (Zoloft), 100 mg/day, with questionable benefit. Mr. A believed that he could be a great writer. He spent most of his time reading and trying to write. He dreamed of going to New York and becoming part of a group of avant-garde writers that would parallel the Algonquin Club of the 1930s or the Beat poets of the late 1940s. This aspiration and his marijuana abuse predated his development of bipolar I disorder. He attended class episodically, nonetheless performing adequately. His last class had no final examination but required a paper. He planned to write this paper in the form of a play, involving a dialogue between two thinkers from different times and cultures. His professor was very excited about this idea, but Mr. A kept postponing the task until he was forced to extend his schooling by a year. His other significant interest during this time involved growing and photographing flowers.

Mr. A was born and raised in a large city. His father had been very successful in commercial real estate, and his mother, after raising the children, used the substantial real estate holdings she inherited from her father to set up a business to manage them. Most of the money was placed in trust for the patient and his siblings. His mother had total financial control of the trusts and doled out the proceeds to the children as they needed them. There was no family history of any psychiatric

disorders.

The patient described his mother as very loving and caring but intrusive and controlling. For example, the mother arranged the initial treatment but then was angry that the psychiatrist had not called her regularly to report on her adult son's progress. She was also critical of various aspects of the treatment, as reported to her by her son. The patient's two older siblings had attended prestigious colleges and graduate schools but had returned home to work in the mother's real estate management company. The 30-year-old sister was living in the parents' home. The 35-year-old brother had lived at home for a time but then moved out to a location a few blocks away. There was a younger brother, still in college, who also smoked marijuana excessively. He tried to minimize the patient's problems to the family and tried to protect the patient, who desperately had not wanted to return home. Of note is that none of the children were married, although the two older ones had a couple of serious relationships.

The children seemed to regard the mother with affectionate amusement and bemusement. The father was seen as a very caring but undemonstrative man who put much energy into keeping the mother from becoming too upset and encouraged them to do the same. The children often wanted to provoke the mother for her judgmental, detail-oriented intrusiveness. The father discouraged them but occasionally found their provocations amusing.

The family viewed itself as very close, with strong values oriented toward community service and family loyalty. The family belonged to a religious community but expressed their involvement primarily in social service and social action volunteer work, accompanied by generous financial contributions.

The patient had been a very successful debater in high school and recalled his development as very positive but provided few details. He tended to place himself in the role of the outsider, an observer of humanity, which he saw as consonant with the role of a writer. He was proud to have bipolar I disorder and tried to regulate his medications so that he would be hypomanic much of the time, seeing this as enhancing his creativity. He viewed his use of marijuana in the same vein. One of the most distressing aspects of his depressive episodes was that marijuana

no longer created a feeling of well-being but made him feel worse. His current depressive episode involved no neurovegetative symptoms. Instead, he presented as flat, numb, apathetic, ashamed, anhedonic, and anergic. He was notably ashamed of being back in his hometown and of living with his parents.

The patient ostensibly understood and accepted his illness well and had read much about it. However, the family had responded to the information "with proper treatment, bipolars can live normal lives," meaning that the information should be kept secret to be treated normally. Mr. A, on the other hand, was very open with friends at graduate school about his illness and his pride in it and the creativity he associated with it.

The patient had two long-standing recurrent dreams. One involved him flying. The narrative line varied, but the flying theme recurred. Often, he had other magical powers in his dreams, such as the ability to heal, not to be killed by bullets, to save the world or some group of people from mortal danger, and so on. The other recurrent dream was of a hotel lobby. These dreams regularly began with him entering a hotel lobby to meet a group of people, accompanied by a feeling of dread.

POSITIVE PSYCHOLOGY

Positive psychology is an umbrella term describing the scientific study of what makes life most worth living. Research findings from positive psychology are intended to provide a more complete and balanced scientific understanding of the human experience. The new field of positive psychology calls for as much focus on strength as on weakness, as much interest in building the best things in life as in repairing the worst, and as much concern with making the lives of normal people fulfilling as with healing pathology.

Positive psychology does not replace business-as-usual psychology, which often focuses on people's problems and how to remedy them. Instead, positive psychology intends to complement and extend problem-focused psychology. The attention of positive psychologists is increasingly turning to deliberate interventions that promote the well-being of individuals and groups, and again, these should be regarded as supplements to existing therapies.

Positive psychology studies what goes right in life, from birth to death. It is concerned with optimal experience—people being their best and doing their best. Everyone's life has peaks and valleys, and positive psychology does not deny the low points. Its signature premise is nuanced: What is good about life is as genuine as what is bad and deserves equal attention from psychologists. Positive psychology assumes that life entails more than avoiding or undoing problems and that explanations of the good life must do more than reverse accounts of distress and dysfunction.

Empirical Findings

Although still a young field, positive psychology already has a canon of established findings worth considering. Indeed, positive psychology is a bottom-up field, very much defined by its empirical results. Discussed below are some of the things that have been learned about positive experiences, positive traits, positive relationships, and positive institutions.

When psychologists study self-reported happiness and life satisfaction, usually under the rubric of subjective well-being, they administer numerical rating scales. The consistent and perhaps surprising result is that most people in most circumstances, most of the time, score above the scale midpoint, whether they are multimillionaires in the United States or pavement dwellers in Calcutta. This conclusion holds across demographic characteristics like age, sex, ethnicity, and education, each of which has a surprisingly small association with avowed happiness.

The significant correlates of happiness are social. In contrast to the modest demographic correlates of happiness and well-being, consider the following robust correlates:

- Number of friends
- Being married
- Being extroverted
- Being grateful
- Being religious
- Pursuing leisure activities
- Employment (not income)

In a study that compared happy people to very happy people, there was one

striking difference: good relationships with other people. Of the very happy people in the sample, all had close relationships with others. Psychology research documents very few necessary or sufficient conditions, but these data suggest that good social relationships may be a necessary condition for extreme happiness.

People who are successful in life's venues are, of course, happy, but the less obvious and more interesting finding from experimental and longitudinal research is that happiness foreshadows success in academic, vocational, and interpersonal realms.

Having good relationships with other people is the most critical contributor to a satisfying life and may even be a necessary condition for happiness. Having a "best friend" at work is a strong predictor of satisfaction and even productivity. A good relationship is one in which the amount of positive communication considerably outweighs negative communication.

Positive psychologists have taken a close look at the features of positive communication, describing four ways in which a person can respond to someone else when something happens, including good events such as a raise at work:

- Active-constructive responding—an enthusiastic response: "That's great; I bet you'll receive many more raises."
- Active-destructive responding—a response that points out the potential downside: "Are they going to expect more of you now?"
- Passive-constructive responding—a muted response: "That's nice, dear."
- Passive-destructive responding—a response that conveys disinterest: "It rained all day here."

Couples who use active-constructive responding have good marriages. The other responses, if they dominate, are associated with marital dissatisfaction. Although this research has only been done in the context of marriage, it may well generalize to other relationships.

Psychology and psychiatry have a long history of either ignoring religion or regarding it with suspicion. However, research findings have begun to accumulate, showing that religion has particular benefits in various psychological domains. Internalized religious beliefs may help a person to cope with problems and even avoid physical illness in the first place. Religiousness is robustly associated with longevity, happiness, and other

indices of a life lived well.

People who are so poor that they cannot meet their basic needs are unhappy, but above extreme poverty, increased income has a surprisingly small relationship with life satisfaction.

Despite the small contribution of income to well-being, whether or not someone is working is much more strongly related to happiness. People who are employed and engaged in what they do are happy, regardless of the status or compensation associated with their job. Happiness and engagement lead people to regard their work as a calling and be more productive at whatever they do, take fewer sick days, and even postpone their retirement.

According to Aristotle's notion of *eudaimonia*—being faithful to one's inner self (demon)—true happiness entails identifying one's virtues, cultivating them, and living by them. Contrast this notion with the equally venerable idea of *hedonism*—pursuing pleasure and avoiding pain—that is the foundation for *utilitarianism,* which in turn provides the underpinning of psychoanalysis and all but the most radical of the behaviorisms. Research shows that eudaimonia consistently trumps pleasure as a predictor of life satisfaction. Those who pursue eudaimonic goals and activities are more satisfied than those who pursue pleasure. This is not to say that hedonism is irrelevant to life satisfaction, just that all things being equal, hedonism contributes less to long-term happiness than does eudaimonia.

Although the study of positive institutions is in its infancy, there is an agreement that institutions that allow people to flourish—whether families, schools, workplaces, or even entire societies—share a core of common characteristics:

- Purpose—a shared vision of the moral goals of the institution, one reinforced by remembrances and celebrations
- Safety—protection against threat, danger, and exploitation
- Fairness—equitable rules governing reward and punishment and the means for consistently enforcing them
- Humanity—mutual care and concern
- Dignity—the treatment of all people in the institution as individuals regardless of their position

Psychologists, at least in the United States, have long believed that the human condition can be improved by the intelligent application of what they

have learned. Positive psychologists are no exception, and many have turned their attention to interventions that make people more happy, hopeful, virtuous, accomplished, and socially involved. In some cases, these applications are running in front of data that would support them, but in other cases, outcome research has been done. Even the most compelling research is not based on follow-up that extends beyond a few years, and the research participants are usually motivated and willing volunteers. How well these interventions will generalize—across diverse people and over time—is a research topic of high priority.

Positive Psychology and Clinical Work

When positive psychology was first described, its stated goal was not to move people from –5 to zero—the goal of conventional psychology and psychiatry—but rather from +2 to +5, within the upper right-hand quadrant of Figure 34-48. This emphasis on *promotion* instead of remediation is an essential feature of a positive psychology perspective, but it does not do justice to this new field and its potential role in clinical work.

Positive Psychology's Vision of Psychological Health. In its 1948 constitution, the World Health Organization (WHO) defined *health* as "a state of complete physical, mental, and social well-being and not merely the absence of disease or infirmity." In more recent years, this statement has been expanded to include the ability to lead a life that is socially and economically productive. This definition is an essential declaration that health entails more than the absence of illness, but it is circular since "well-being" is a synonym for "health." Work by positive psychologists makes this definition more concrete and useful as a guide for research and intervention.

If one can extrapolate from the sorts of topics that have been studied, positive psychology assumes that people are doing well when they experience more positive feelings than negative feelings, are satisfied with their lives as they have been lived, have identified what they do well, and use these talents and strengths on an ongoing basis, are highly engaged in what they do, are contributing members of a social community, and have a sense of meaning and purpose in their lives. Physical health and safety, of course, provide an essential context for psychological well-being. It is difficult to

imagine a cultural group in which these components of the good life are not valued. Respect for human diversity need not entail extreme cultural relativism.

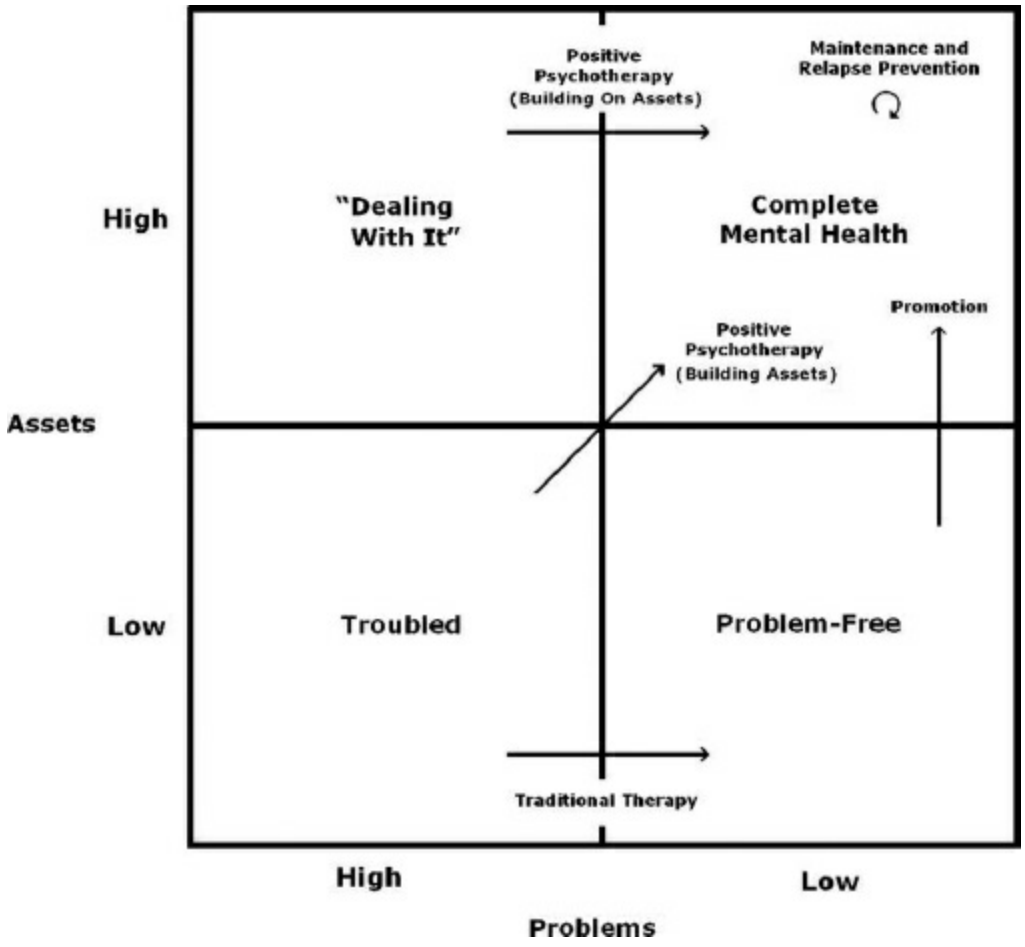

FIGURE 34-48
Mental health and mental illness. These are dimensions. Quadrants are shown for the purpose of illustration only. (From Sadock BJ, Sadock VA, Ruiz P, eds. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2009:2942, with permission.)

Note that this fuller characterization of health reflects the WHO definition and is drawn from research in all of the domains of concern to contemporary positive psychology. The relevant research cautions that health so defined is not unitary. No one can have it all, at least at the same time, given tradeoffs among the psychological states and traits that reflect doing well. Psychological health, therefore, needs to be described with a profile of features and not a single summary score. The fifth edition of the *Diagnostic*

and Statistical Manual of Mental Disorders (DSM-5) describes hundreds of psychological problems. However, there may be just as many different manifestations of the good life.

Theory of Psychopathology. As a perspective on topics that deserve scientific study, positive psychology has no single theory. Like much of contemporary psychology, it instead relies on midrange theories that draw on various broader perspectives, from evolutionary to behavioral to cognitive to sociocultural models, to make sense of specific phenomena. Different topics are explained with different theories. The eventual integration of psychology may be a worthy goal, but it has not yet been achieved.

At this early point in the development of positive psychology, the lack of a consensual or integrated theory is not a problem. The good psychological life is not yet understood, and positive psychologists are still grappling with the right vocabulary to describe it. Accordingly, championing a single theory at present would be premature, even counterproductive.

It has been argued that positive psychology is a descriptive endeavor, not a prescriptive one. If this means that positive psychology should be an empirical science—informed by replicable facts—then this claim is reasonable and a defining feature of the entire field. If this means that positive psychology is assumption-free or value-neutral, it becomes much more challenging to defend. After all, positive psychologists make the value judgment that the "good" life is indeed good—that is, desirable, morally and otherwise—and the metatheoretical assumption that the good life can be studied with the conventional methods of psychology. In any event, positive psychology seems no more prescriptive than clinical psychology or psychiatry. It may even be less so, given the theoretical diversity of positive psychology as it now exists.

Positive Psychology Assessment. The assessment has long been a staple of psychology, and much of it has been tilted—understandably—toward identifying weaknesses, deficiencies, and problems. The positive psychology perspective is that business-as-usual assessment should be expanded (not replaced) by attention to areas of strength and competence. Low life satisfaction can occur in the absence of psychopathology, but it is nonetheless related to psychological and social problems. Conversely, high

life satisfaction is linked to good functioning, even in the presence of symptoms.

Positive psychologists have developed an impressive set of measurement instruments that allow someone to break through the zero point of deficiency measures. For example, the healthiest that one can score on a typical measure of depression is zero, but this lumps together people who are blasé with those filled with zest and joy. The distinction seems well worth making, and the self-report surveys and interviews developed by positive psychologists allow it.

Most of the existing positive psychology measures were developed for research purposes, and they are most valid when aggregated to yield conclusions about groups of people. They can also be used ipsatively (i.e., forced to choose between two options), to describe the psychological characteristics of an individual and how they stay the same or change over time, but the cautious use of these descriptions is a point of discussion and a departure in treatment. None is a robust diagnostic test, and none should be treated as if it were. Such prudence is appropriate for all psychological assessments, but it is worth emphasizing in positive psychology measures.

Positive Psychology Techniques. Positive psychologists have demonstrated that brief interventions in the short term can increase happiness, satisfaction, and fulfillment. In some cases, there is also evidence that they can alleviate depression. For example, patients or clients can be asked to count their blessings:

Every night for 1 week, set aside 10 minutes before you go to bed. Use that time to write down three things that went really well on that day and why they went well. You may use a journal or your computer to write about the events, but you must have a physical record of your writing. It is not enough to do this exercise in your head. The three things you list can be relatively small in importance or relatively large in importance. Next to each positive event in your list, answer the question, “Why did this good thing happen?”

They can also be asked to use their strengths in novel ways. They take the Values in Action Inventory of Strengths (VIA-IS) questionnaire online and identify their most signature strengths of character. Then they are instructed to use these strengths in their daily life:

Every day for the next 7 days, use one of your top five strengths in a way that you have not before. You might use your strength in a new setting or with a new person. It is your choice.

Outcome research shows that various psychotherapies are effective in alleviating problems and usually equally so, despite the different forms they take. One interpretation of the equal effectiveness of different therapies is that nonspecific factors common to all treatments are responsible. Perhaps the types of strategies being studied by positive psychologists reflect these common factors and give names to them. Strategies like instilling hope and building strengths may be the critical factors in the effectiveness of any therapy.

Some qualifications are in order if these techniques are used in the context of treatment. First, the therapist must ascertain a client's readiness to change in the particular ways requested in the exercise and the client's capacity to make the change. Like any psychotherapeutic procedure, these techniques cannot be imposed on the unwilling or unable.

Second, none of these techniques is akin to a crash diet or an antibiotic. The degree to which they have lasting effects is related to how patients or clients integrate them into their regular behavioral routines. Counting blessings for a week will make a person happier for that week, but only if they become habitually grateful will there be a more enduring effect. Research finds—not surprisingly—that the people who showed lasting benefits were those who continued to use the exercise.

Third, these exercises are typically presented as one size fits all, but there is no reason to think that they are equally useful for all patients or clients. Nothing is known about the match of an exercise with a client's particular presenting problems or goals or with a client's age, sex, social class, or ethnicity.

Fourth, little is known about the parameters of these interventions. For example, how many blessings should one count, and how frequently should this be done? With college students, counting blessings three times a week may be more effective in increasing happiness than counting them more frequently. Is this a general phenomenon or one

specific to young adults attending college?

Fifth, all interventions run the risk of unintended harm, and although positive psychologists would like to believe that their techniques avoid iatrogenic effects, this assertion cannot be made with thorough confidence. For example, although optimism is related to mental and physical health, it would be simplistic and potentially hazardous to tell patients or clients that positive expectations will solve all their difficulties. Along these lines, if a positive psychology intervention overemphasizes a client's choice and responsibility, considerable damage could be done in cases of abuse and victimization, in which self-blame needs to be undone and certainly not encouraged. Interventions based on positive psychology should not preclude the use of existing therapeutic strategies when these are indicated.

Positive Psychotherapies. *Positive psychotherapies* are beginning to appear: therapeutic interventions based on the theories and findings of positive psychology. What distinguishes these emerging positive psychotherapies from conventional treatments is that their stated goal is not symptom reduction or relief but relatively enhanced happiness, life satisfaction fulfillment, productivity, and the like—one or more components of positive psychology's vision of the good life. These new therapies target people with psychological problems as well as those without them. In the latter case, positive psychotherapies make contact with life coaching.

The possible field of positive psychotherapies is so broad that it needs narrowing, and somewhat arbitrarily, the focus here is on approaches characterized by an explicit *therapeutic alliance* between the positive psychologist and the patient or client. This feature goes by many names and has been variously defined, but its recurring themes include collaboration between therapist and client, an affective bond between them, and an agreement on the goals and tasks of the intervention. Asking people to write about their goals or perform acts of kindness, despite beneficial consequences, may or may not be instances of positive psychotherapy—what matters is the relational context of the request.

TAKING STOCK. The unique and explicit goal of emerging positive psychotherapies is to enhance well-being and to promote the good life among

those with obvious psychological problems as well as those without them. They are also similar to more established therapies. Positive psychotherapies are short-term, structured interventions for individuals or small groups. Most can be placed in the cognitive-behavioral realm, although their techniques could be integrated easily into other treatment models. Most positive psychotherapies entail out-of-sessions exercises and homework assignments, the results of which are discussed in sessions. Several positive psychotherapies rely on journal-keeping, and many of these therapies rely on ongoing assessment.

Like other cognitive-behavioral interventions, positive psychotherapies take issue with assumptions of the medical model that people in treatment are ill and that their problems are best described as discrete (present-or-absent) entities as in DSM-5. According to positive psychology, people's weaknesses and strengths exist in degrees.

As emphasized, research support is still accumulating. Enough outcome studies have been conducted to conclude that positive psychotherapies are more than just promising, with effect sizes in the small to moderate range typical of psychological interventions. Not known in most cases is how positive psychotherapies fare in direct comparison with conventional treatments for anxiety or depression. Also, as already mentioned, the boundary conditions of effective positive psychotherapy are unknown.

Many positive psychologists would like to believe that a strengths-based approach to change is superior to one that focuses on the remediation of deficiencies, but this hypothesis has yet to be put to a serious test. The even-handed suspicion is that attention to both strengths and weaknesses is critical and that no useful purpose is served by regarding these as mutually exclusive therapeutic strategies.

A Brief History of Psychiatry

It is challenging to present a brief history of psychiatry that goes beyond cherry-picking individual moments as it is difficult to decide what advances in science are most relevant to the field. Equally significant are the contributions of related fields, including philosophy, theology, psychology, sociology, and other disciplines that have contributed to our understanding and attitudes about mental health.

Psychiatry was not considered a formal discipline of medicine until relatively recently. However, concern with the causes and treatment of various mental illnesses go back to antiquity. We can often see specific familiar themes and debates from different ages. For example, are mental illnesses truly aberrant, or merely variations of normal behavior. Is there some value in evolutionary fitness or to society, in mental illness? Are mental illnesses diseases of the "mind" or the "body," and what is the difference? Is the pathogen internal, such as a virus, a malfunctioning gene or a dysfunctional immune system, or external, such as a god, demon, industrial life, or a society in general? Who is best suited to treat the diseases—a medical doctor, or some other professional or nonprofessional healer? We see such debates emerge throughout society, and even when some no longer have scientific merit (i.e., mind vs. body debates), they often still linger in the lay understanding of the illnesses and affect how society treats individuals suffering from these disorders.

PSYCHIATRY BEFORE THE MODERN ERA

Many of us think of the roots of medicine beginning in Ancient Greece, and for the western world, that is, in part, true. However, the civilizations of

Ancient Asia tended to be more advanced in the medical sciences. For example, psychiatry was practiced as a discipline in Ancient India, and the pre-2nd century CE medical treatise, the Charaka Sam.hitaO or Compendium of Charaka, includes sections on psychiatric diseases (Fig. 35-1). Psychiatric hospitals existed in India even before that.

The Greeks tended to see psychiatric illnesses as supernatural disorders, although Hippocrates makes some mention of rudimentary anatomic research into the causes of psychiatric illness. In a broader sense, the Greeks were wrestling with what has become a significant theme in modern psychiatry: whether to view diseases as mere abnormalities or on a continuum with normal. Thus, the ongoing debate between whether we should see such disorders as depression on a continuum with normal sadness and grief, or as a fundamentally different phenomenon has its roots in antiquity. For example, Galen and Plato stressed a categorical approach to disease, whereas Hippocrates took a more dimensional approach, often seeing typical human attributes as being on a continuum with abnormal. This affected treatment approaches: Galen focused on treating the disease process, whereas Hippocrates emphasized treating the individual.

In the Middle Ages, Arab countries included psychiatric wards in their hospitals. The first was built in Baghdad around the early 9th century. Many of the great Islamic medical scholars, including Abu Ali al-Hussain ibn Abdallah ibn Sina (known in the West as Avicenna), wrote on mental disorder treatments.

Psychiatric hospitals appeared in medieval Europe around the 13th century. However, they did not provide treatment and were merely places for custodial care. The best known is probably the Bethlem Royal Hospital, usually shortened to Bethlem, or *Bedlam* (Fig. 35-2). It was founded in 1247 and was not a hospital in the modern sense but rather a place to collect alms for the care of the needy. Although the history is somewhat unclear, it may have taken in and cared for the insane as early as the later 14th century, and there is documentation of mentally ill inmates by the early 15th century. Little is known about the treatments that might have occurred. However, the hospital gradually transitioned from a general hospital to an asylum for the insane by the later 15th century.

PSYCHIATRY IN THE MODERN AGE

Early Modern Age

By the late 17th century, other “lunatic asylums” proliferated, most were privately run. The first building built specifically as an asylum for the insane was the Bethel Hospital Norwich, founded by Mary Chapman. Meanwhile, in France, Louis XIV created what was for Europe the first public mental health system, although again, there was little treatment.

One of the earliest Western treatises on mental illness was the *Anatomy of Melancholy, What it is: With all the Kinds, Causes, Symptomes, Prognostickes, and Several Cures of it. In Three Maine Partitions with their several Sections, Members, and Subsections. Philosophically, Medicinally, Historically, Opened and Cut Up* (usually just called *The Anatomy of Melancholy*) by Robert Burton, a mathematician, astrologer, and scholar at Oxford University (Fig. 35-3). Although going well beyond what we would consider a medical textbook, Burton’s book does discuss “melancholy,” which includes depressive illnesses, although it takes a much broader view and includes much of the human experience.

Although the medieval focus was theoretically on care, not punishment for the insane, often, the treatments were barbaric. These could include prolonged chained restraint and physical punishments. These practices began to change during the enlightenment, with a call for humanitarian reform. For example, in William Battie’s, Treatise on Madness, he criticized the treatments occurring at such hospitals as Bethlem and argued for good hygiene and nutrition as mainstays of treatment. Although many of the somatic treatments he recommended were likely counterproductive (bleeding, purgatives), he did raise psychiatry to the level of a respectable discipline and helped support the humane treatment of mentally ill patients.

Expanding on the concept, the York Retreat in England, founded by William Tuke and the Bicêtre Hospital and then Salpêtrière, in France, under Dr. Philippe Pinel, championed the concept of "moral treatment." These approaches emphasized avoiding restraint—Pinel is famous for removing the patients' chains (Fig. 35-4). His mentor, Jean-Baptiste Pussin, who, with his wife and colleague Marguerite, advocated for moral treatment and began banning chains at the Bicêtre Hospital, which greatly influenced the young Pinel. Pinel extensively elaborated this and took a scientific approach. He was one of the first to present a comprehensive categorization of psychiatric diseases, which reflected a functional view of mental illness emphasizing phenomenology over pathophysiology.

In Edinburgh, Scotland, the pseudoscience of phrenology gained influence in the 18th century under the leadership of William Browne and George and Andrew Combe. Although useless as medical science, it was an important conceptual and philosophical step in that it shifted the concept of mental illness from a moral or philosophical disorder to a material one originating in the physical matter of the brain.

The 19th and Early 20th Century

In the early 19th century, the state began playing a larger role in the Western treatment of mental illness. In 1808, Britain passed the Country Asylums Act, which established public mental asylums. In 1828 the Commissioners in Lunacy were appointed to oversee and license private asylums, partly in response to public concern over the abuses at Bethlem Hospital and similar private asylums. By then, “Bedlam” had become synonymous with “uproar” and “confusion,” owing to the mismanagement at the hospital, and scandalous practices, such as continuing to chain patients (Fig. 35-5), and allowing the public to visit the hospital and view patients for their entertainment.

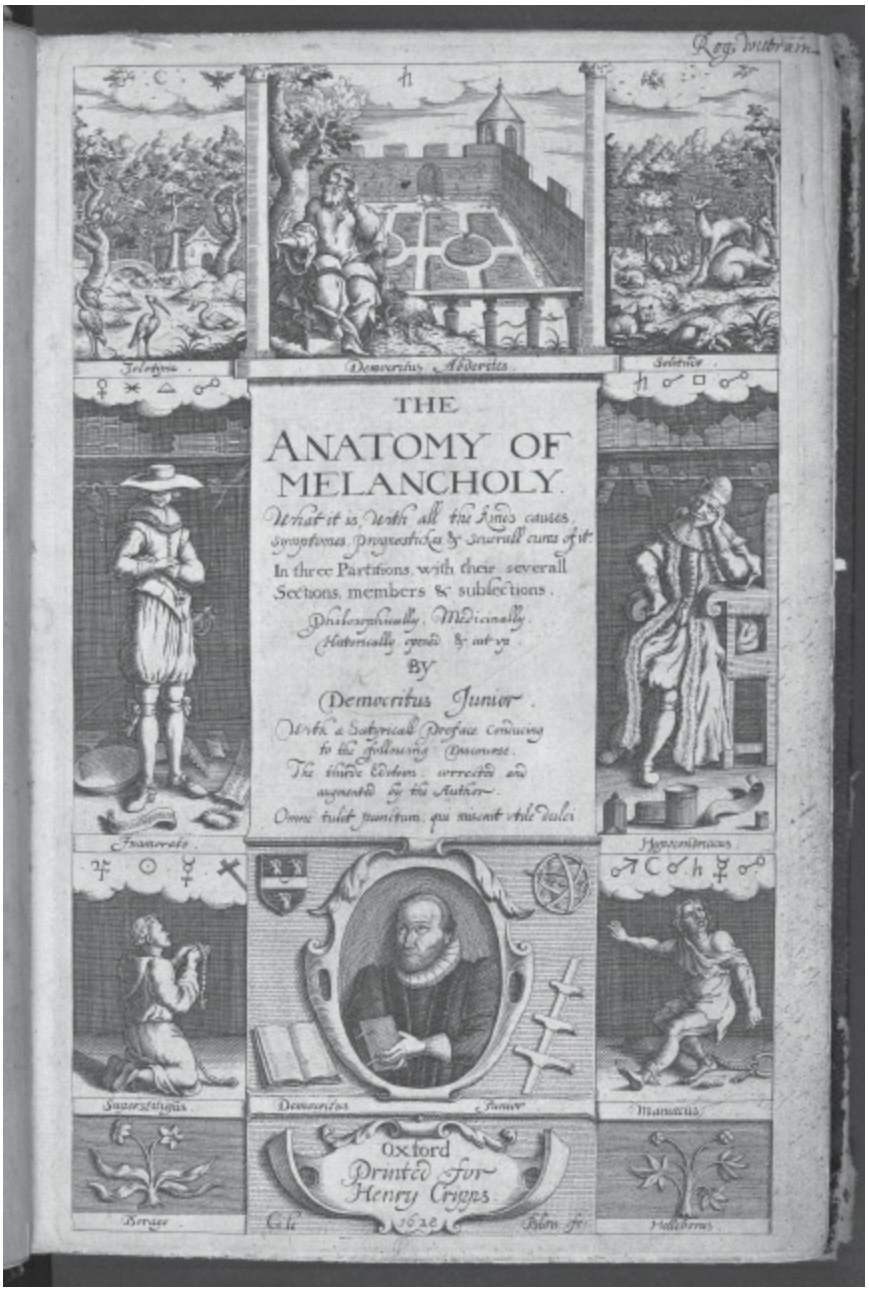

FIGURE 35-3
Robert Burton's The Anatomy of Melancholy, 1628. (Source: The British Library.)

In 1838, France enacted a law regulating asylum services across the country and built the first school for individuals with intellectual disabilities. Similarly, the 1845 Lunacy Act in Britain reclassified mentally ill people as patients requiring treatment. It mandated that asylums be built and required periodic inspections of these facilities.

In the United States, reformers such as Dorothea Dix (Fig. 35-6) helped advocate for the first law to establish a state asylum, which became the Utica State Hospital, founded in about 1850. Dix achieved this after conducting a statewide investigation of the mentally ill poor in Massachusetts, showing

that they were treated like prisoners in cages, often naked and physically abused. She later conducted similar investigations in other states, always advocating for moral care for the mentally ill.

The latter half of the 19th century and early 20th century saw the rise of scientific approaches to mental disorders, which advances in the classification of psychiatric disorders and beginning insights into the pathophysiology and etiology of disorders.

The first medical case report formally describing a schizophrenic psychosis was most likely that of Benedict Morel (1809–1873) in 1852, a French psychiatrist, who used the term *démence précoce* to describe deteriorated patients whose illnesses began in adolescence. Subsequent cases describing what was likely schizophrenia include those reported by Greisinger in 1867, Hecker in 1871, and Kahlbaum in 1874. Kalbaum's case was notable as one of the first medical case reports of catatonia.

For much of the 19th and early 20th century in Europe, most psychiatric disorders were thought to derive from either congenital or degenerative diseases. Jules Falret in 1854 described bipolar disorder (*folie circulaire*), and 1882, the German psychiatrist Karl Kahlbaum used the term cyclothymia, describing mania and depression as stages of the same illness.

FIGURE 35-6
Dorothea Dix. (Source: United States Library of Congress's Prints and Photographs division (Public domain).)

Emil Kraepelin, building on the work of these predecessors, pioneered the scientific classification of psychiatric disease (Fig. 35-7). Kraepelin declared that all psychiatric disorders were biologic. As etiologic classification was not feasible, he based his classification on a careful study of disease phenomenology in different patients, in which he noted the similarities and differences in the symptomatology between different diseases.

FIGURE 35-7
Emil Kraepelin in 1926. (Source: Wikipedia, original: Münchener Medizinische Wochenschrift], unknown photographer.)

Kraepelin translated Morel's *démence précoce* into *dementia praecox*, a term that emphasized the change in cognition (dementia) and early onset (praecox) of the disorder. Patients with dementia praecox were described as having a long-term deteriorating course and the clinical symptoms of hallucinations and delusions. Kraepelin distinguished these patients from those who underwent distinct episodes of illness alternating with periods of normal functioning, which he classified as having manic-depressive

psychosis. Persistent persecutory delusions characterized another separate condition called paranoia. These patients lacked the deteriorating course of dementia praecox and intermittent symptoms of manic-depressive psychosis.

Eugene Bleuler coined the term schizophrenia, which replaced dementia praecox in the literature. Deriving it from the Ancient Greek words “schizo” (“I split”) and “phren” (“mind”), he chose the term to express the presence of schisms among thought, emotion, and behavior in patients with the disorder. This term is often misconstrued, especially by laypeople, to mean split personality, a concept that would be closer to that of the dissociative disorders. Bleuler also stressed that, unlike Kraepelin’s concept of dementia praecox, schizophrenia need not have a deteriorating course.

Bleuler identified specific fundamental (or primary) symptoms of schizophrenia to develop his theory about the internal mental schisms of patients. These symptoms included associational disturbances of thought, especially looseness, affective disturbances, autism, and ambivalence, summarized as “the four As”: associations, affect, autism, and ambivalence. Bleuler also identified accessory (secondary) symptoms, including the symptoms significant to Kraepelin, such as hallucinations and delusions.

Sigmund Freud (Fig. 35-8) initially also sought a biologic explanation for mental disease. However, realizing that the contemporary scientific tools were not up to the task, he instead developed a psychoanalytic approach based on his experiences with his private patients as he sought to understand the unconscious meanings behind their thoughts, behaviors, and desires. Although Freud was a neurologist and arguably working in psychology, his work was soon adopted by psychiatrists. The psychoanalytic approach became transcendent in the middle of the 20th century, and many psychiatric illnesses were explained in psychoanalytic terms; that is, in terms of conflicts and drives, particularly sexual drives, and stemming from early life experiences. Like many philosophical movements, psychoanalysis may have suffered from its overwhelming popularity, and at times it overreached as it tried to treat illnesses for which it was not suited, or tried to explain many human behaviors and achievements through the lens of psychoanalytic theory. In the latter half of the 20th century, as effective biologic treatments were discovered, many psychiatrists became disenchanted with psychoanalysis’s lack of empirical data and seeming resistance to scientific testing. It began to lose influence as a primary approach to understanding and

treating psychiatric disease.

The Latter 20th Century

The approach to mental illness, including the specific patients treated, shifted around World War II, as psychiatrists moved out of the asylum to confront very different patients, moving from the treatment of the “insane” to people who were “like us.” No longer confined to just the asylum, psychiatrists proved their usefulness in the military arena, treating both patients traumatized by combat and those found unfit to serve in the military for psychological reasons.

Greater importance was attached to the role of the environment on mental illness. This change drew from the work of Adolph Meyer (Fig. 35-9).

Meyer, the founder of psychobiology, saw mental disorders as reactions to life stresses. It was a maladaptation that was understandable in terms of the patient's life experiences.

FIGURE 35-9
Adolf Meyer. (Courtesy of National Library of Medicine, Bethesda, M.D.)

FIGURE 35-10
Otto Loewi. (Source: Creative Commons Attribution 4.0 International.)

Building on Meyer's social perspective and Freud's emphasis on early life experiences, Walter Menninger and others developed the *psychosocial model* of mental illness. Depression was seen not as a neurologic illness but as a failure to adapt. Menninger went as far as to suggest that all psychiatric disorders could be reduced to "one basic psychosocial process: the failure of the suffering individual to adapt to his or her environment."

The second half of the 20th century saw a gradual transition from a psychoanalytic and sociologic understanding of mental illness to a biologic one. Many discoveries helped propel this shift in approach.

Biologic models had existed before. For example, in the 1930s, Papez theorized that emotions were caused by a circuit connecting the limbic lobe, amygdala, septal region, and hippocampus. Electroconvulsive therapy was also developed in the 1930s and used to treat depression as early as the 1940s.

An early influence on biologic explanations for etiology was Otto Loewi's discovery of acetylcholine's role as a neurotransmitter. In proving this, Loewi (Fig. 35-10) employed a now-famous experiment, published in 1921, in which he used the saline solution from one frog heart to stimulate the rate in a second denervated heart, thus proving that a chemical must control the heart rate. He later showed that this chemical was acetylcholine. This was the first experiment that showed that a chemical could cause a response absent of electrical stimulation, thus discovering the critical role of neurotransmitters.

Loewi's experiment is famous, not only for its scientific value but also that the idea for the experiment came in a dream. Although he wrote down the dream when briefly waking from it, he could not make sense of his scribbles the next morning. Fortunately, he went on to have the same dream the next night, and when awakening from that, he rushed to his laboratory to perform what would become Nobel Prize-winning research.

The practical beginning of biologic psychiatry occurred with the serendipitous discovery of several drugs that could treat mental disorders, including chlorpromazine for schizophrenia, imipramine and iproniazid for depression, and lithium carbonate for bipolar disorder. In each case, the initial importance of the drug was not appreciated. For example, chlorpromazine was synthesized from promethazine, an antihistamine, in a search for more stable antihistamine sedatives. It was initially used as an anesthetic adjunct, and its antipsychotic properties were only later recognized after psychiatrists began administering it to manic and psychotic patients, again originally as a sedative.

Imipramine was also first synthesized as an antihistamine, and, following in the footsteps of chlorpromazine, tried as an antipsychotic before some case reports convinced the manufacturers to investigate its role as an antidepressant. Supporting these findings was the discovery that certain

drugs, such as reserpine, which irreversibly blocks monoamine transporters, could cause depression through the depletion of monoamines. Not only did it help the development of the first biologic theory for depression, the monoamine theory, but it also lent what was considered the first reproducible example of a chemical causing a mental disorder.

Lithium had been used as a medication since the 19th century, initially for gout. However, the doses needed to, for example, dissolve urate in the body were toxic. It was later used as a salt substitute for hypertensive patients but was largely banned after the toxicity became apparent. Lithium was used for mania in the late 1800s, but this was related to some theories that mood disorders were a type of “brain gout.” As that theory waned in popularity, lithium was largely abandoned as a psychotherapeutic. In the late 1940s, John Cade, an Australian physician, rediscovered lithium’s value for mania. Because of toxicity concerns, however, it took many decades and much research before it was adopted in the United States and other countries.

Neuroimaging started being used as an investigatory tool in the 1980s, following the discovery by Johnstone and others that patients with schizophrenia had enlarged cerebral ventricles. Pioneers such as Nancy Andreasen conducted the first MRI studies of schizophrenia and developed many of the techniques used by other investigators of the disease.

Genetic explorations also yielded interesting findings, such as the high heritability of certain disorders such as schizophrenia, autism spectrum disorder, and bipolar disorder. Although actual genetic associations have been elusive, the research in genetics lent additional support to the drug research and neuroimaging research which, when combined, created a growing body of research which moved the understanding of the etiology of many mental disorders from childhood parenting and other experiences or social causes to disorders that are, at least in part, inherited.

DEINSTITUTIONALIZATION

The 20th century also saw a shift from the asylum to the office and the community as the center of psychiatric treatment. The influence of the psychoanalytic and psychosocial movements also influenced psychiatry’s belief that most psychiatric diseases had at least potential treatments. In 1963, President Kennedy introduced legislation that delegated the NIH to

administer community mental health centers, thus beginning the community health movement in the United States (Fig. 35-11). It outlined a plan to discharge patients, including severely mentally ill patients, from institutions and instead treat them in the community. Although a laudable goal, it has been most successful at deinstitutionalization, whereas community centers have been poorly funded and supported. Thus, although most psychiatric patients no longer live in asylums, they may be homeless, living in dangerous environments, or be confined in jails, and in each case, receive little treatment.

THE CLASSIFICATION OF PSYCHIATRIC DISORDERS

Clinical treatment and classification dragged somewhat behind the science. Before the 1960s, many institutions and asylums developed their unique classification systems, and the result was a significant variation in both diagnostic terminology and how those diagnoses were applied. For example, in 1953, the American Psychiatric Association held a conference to develop a research program to evaluate psychiatry therapies. However, the members concluded that such research would be meaningless without a standardized approach diagnosis, which did not then exist.

This problem was further exposed in the United States–United Kingdom study conducted in the 1960s, which showed that many patients diagnosed with schizophrenia would be diagnosed with bipolar disorder in the United Kingdom. This variation results from an overemphasis in the United States on psychotic symptoms as a diagnostic criterion for schizophrenia. Another telling study was the Rosenhan experiment, in which experimenters feigned hallucinations to enter psychiatric hospitals, but usually acted normally once admitted. They were diagnosed with psychiatric disorders and even given antipsychotic drugs (which they flushed down toilets).

The problem was also apparent in such studies as the Baltimore Morbidity Study, which used DSM-I criteria and found inconsistent and unreliable results. The situation was such that in the 1970s, the President's Commission on Mental Health, informally called the Carter Commission, concluded that they could not form meaningful goals for mental health treatment until they understood the disorders better.

This problem led to an attempt to develop more reliable diagnostic systems. In the United States, this coalesced into the Diagnostic and Statistical Manual of Mental Disorders (DSM), developed by the American Psychiatric Association (APA). The first two editions are mostly preliminary works, reflecting the prevalent approaches among psychiatrists. For example, the second edition of the DSM (1968) distinguished between psychotic (defined more broadly than today) and neurotic forms of depression. This division developed into an endogenous/exogenous distinction—virtually depression due to a disease of the brain versus depression that is a reaction to stress, be it current or developmental. Although lacking any empirical validity, the distinction was a convenient way to divide biologic and

psychodynamic concepts of depression. This division often drove treatment during much of the 1970s, in which it was thought some forms of depression were better treated with psychotherapy, whereas others should be addressed with medication.

The introduction of the DSM-III in 1980, and its subsequent revisions up to and including DSM-5, represented a significant paradigm change in diagnosis, which was borne of research designed to create more reliable criteria for mental disorders (Fig. 35-12).

Feighner and colleagues at Washington University developed the Feighner, or St. Louis criteria, criteria for 15 major psychiatric categories. This approach represented the first systematic approach that relied entirely on numbers and types of symptoms to diagnose psychiatric disorders. While this was taking place, Robert Spitzer, Jean Endicott, and other researchers at the New York State Psychiatric Institute were developing methods to increase the reliability of psychiatric diagnoses. These groups and other researchers were brought together by the National Institute of Mental Health in the 1970s, where they developed the Research Diagnostic Criteria (RDC), which were essentially an elaboration and expansion of the Feighner criteria.

The RDC prepared the way for the DSM-III, which resulted from the work of the Task Force on Nomenclature and Statistics, headed by Dr. Spitzer, formed by the APA in the early 1970s. The DSM-III eliminated the endogenous/exogenous dichotomy previously inherent in many diagnoses, and eliminated assumptions of cause from the criteria, taking a strictly phenomenal approach. For example, major depression was defined by symptomatic criteria. It also divided the mood disorders, with major depression and bipolar disorder being treated as distinct disorders. Although acknowledging more minor forms of depression, DSM-III's categorical approach created a rigid divide between those with major depressive disorder and those not meeting the criteria for the disorder, a difference that survives to this day. This divide risks neglecting some individuals who do not fit into one of the DSM categories and yet suffer from depression; although DSM includes ways to categorize them, it is likely that in clinical practice, many such patients are treated as if they had no disorder.

However, the benefits of this categorical approach have been that it has created more reliable diagnoses, allowing for research on more homogeneous populations. This strategy bore significant fruit, and there was a

pharmaceutical revolution in the 1980s and 1990s, in which researchers developed and introduced new classes of medications, such as the SSRIs and the atypical antipsychotics. Although arguably not more efficacious than the original antidepressants and antipsychotics, the drugs were considered more tolerable, and the result was a considerable increase in the number of patients taking, and benefitting from, psychopharmacological agents. Some have pointed out that this phenomenon also caused abuses and overuse of the drugs for conditions that could be more considered part of the human condition, and there was a predictable backlash in which critics questioned both the safety and efficacy of many psychiatric drugs. Organized psychiatry often found itself on the defensive as it had to make a case for the drugs and contend with critiques that went beyond scientific questions into the effect of the drugs on culture and society.

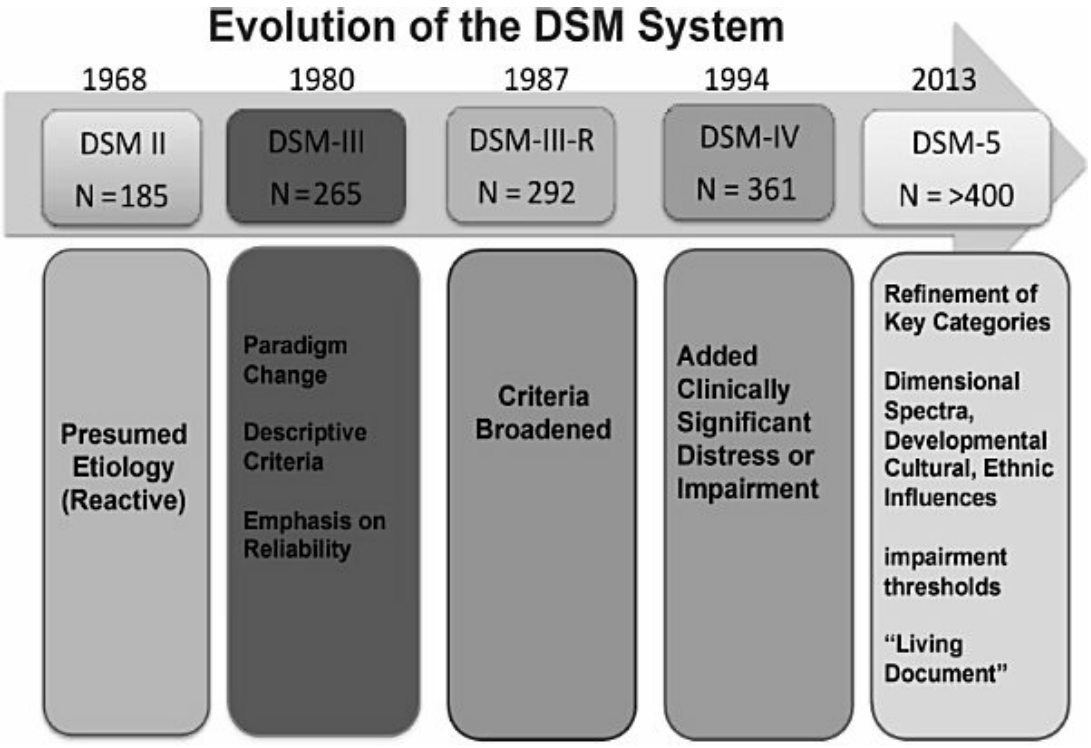

FIGURE 35-12
DSM system. Key issues and number of categories.

The DSM-III and its role in contributing to the remedicalization of psychiatry also affected psychological treatments. Although the more reliable criteria made it easier to design studies and enroll suitable populations for treatment studies, it also helped encourage a bias toward psychological

treatments that lent themselves to scientific research—ones that were easily manualized and reproducible in a consistent way. Hence, such therapies as cognitive-behavioral therapies, behavioral therapies, and interpersonal therapies gained predominance as treatments for major psychiatric disorders. In contrast, psychoanalytic treatments, whose depth and complexity made them inherently harder to study consistently, became more marginalized and considered "boutique treatments" reserved for those who could pay the sometimes considerable out-of-pocket costs for these therapies.

LOOKING TO THE FUTURE

The combination of new technologies, such as high-resolution functional imagining (Fig. 35-13) and total gene mapping, combined with the ever-increasing ability of computers to manipulate vast amounts of data, has resulted in a remarkable explosion in research on such disorders as schizophrenia, autism, obsessive-compulsive disorder, and major depression during the past decade, and we have made great strides toward understanding the genetics and pathophysiology of these disorders. However, there remains a frustrating gap between basic and clinical research.

In genetics, the limitations of clinical diagnoses for research purposes are clear, and the search for valid biomarkers has been disappointing. It may be that a focus on meaningful endophenotypes may be an essential step. However, the predictive power of many of the proposed endophenotypes remains to be proven.

Pharmacologic research into treating the disorder, after several fruitful decades, has stalled. Clozapine, arguably the most effective antipsychotic, was discovered in the 1960s, the SSRIs became available in the 1980s and 90s, and the subsequent efforts to refine pharmacologic treatment have, so far, fallen short of hopes. Barriers to translational research include the lack of a valid animal model for many of the disorders, and efforts are being made in improving how animal testing is performed. In the meantime, new approaches are being attempted that deemphasize the importance of single receptors and emphasize a multi-target approach to psychopharmacology—essentially using "dirty drugs," which had previously been discouraged due to concerns over side effects, as well as moving beyond monoamine targets to include other receptors, including glutamatergic targets and G-protein–

coupled receptors.

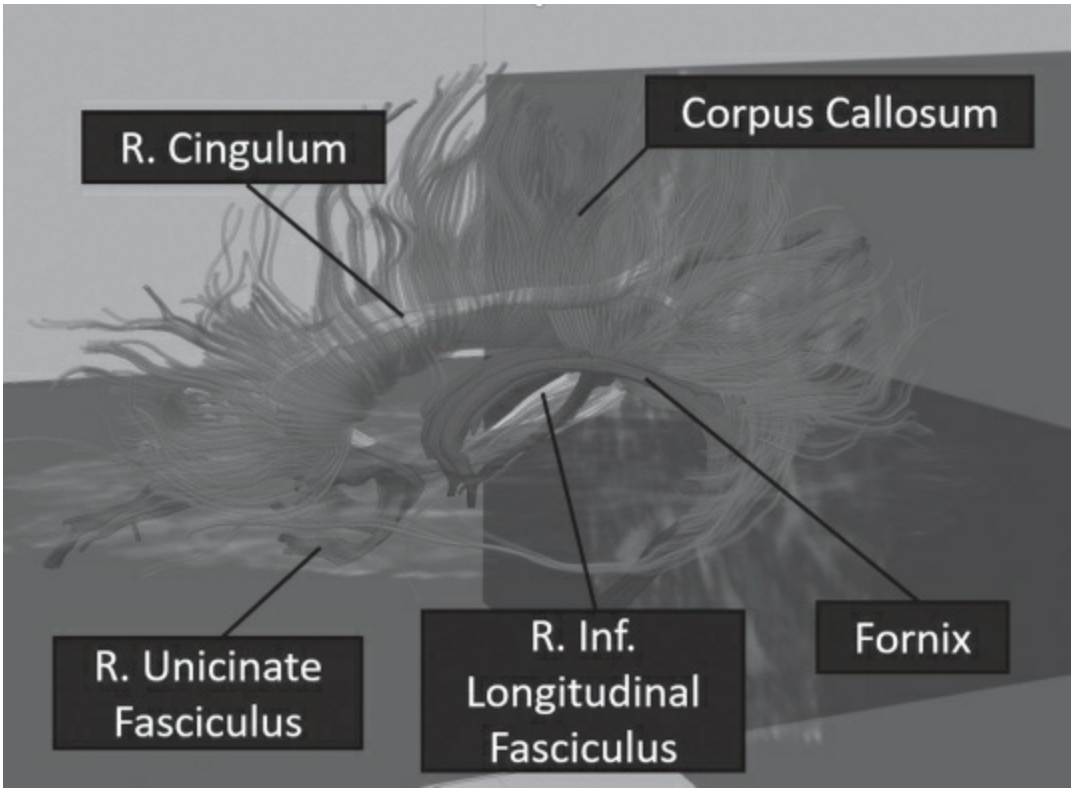

FIGURE 35-13
This image is an example of the high level of detail that neuroimaging technologies can produce to aid investigators. Three-dimensional image reconstructed based on diffusion data acquired on a 3-T General Electric scanner, Brigham and Women's Hospital, Harvard Medical School, Boston, MA, which shows several major white matter fiber bundles (generally differing in colors, converted to grayscale for this book) identified through diffusion tensor imaging.

What is clear, however, is that most psychiatric disorders are very complex disorders that require multifaceted solutions. These solutions include attention to psychosocial treatments as well as pharmacologic. The change from conceptualizing many of the disorders as neurodevelopmental rather than neurodegenerative disorders also highlights the importance of early identification of disorders in the hopes that early interventions can alter the course at a more promising stage.

Glossary of Terms Relating to Signs and Symptoms

abreaction: A process by which repressed material, particularly a painful experience or conflict, is brought back to consciousness; in this process, the person not only recalls but also relives the repressed material, which is accompanied by the appropriate affective response.

abstract thinking: Thinking characterized by the ability to grasp the essentials of a whole, to break a whole into its parts, and to discern common properties. To think symbolically.

abulia: Reduced impulse to act and to think, associated with indifference about consequences of action. Occurs as a result of neurologic deficit, depression, and schizophrenia.

acalculia: Loss of ability to do calculations; not caused by anxiety or impairment in concentration. Occurs with neurologic deficit and learning disorder.

acataphasia: Disordered speech in which statements are incorrectly formulated. Patients may express themselves with words that sound like the ones intended but are not appropriate to the thoughts, or they may use totally inappropriate expressions.

acathexis: Lack of feeling associated with an ordinarily emotionally charged subject; in psychoanalysis, it denotes the patient's detaching or transferring of emotion from thoughts and ideas. Also called *decathexis.* Occurs in anxiety, dissociative, schizophrenic, and bipolar disorders.

acenesthesia: Loss of sensation of physical existence.

acrophobia: Dread of high places.

acting out: Behavioral response to an unconscious drive or impulse that

brings about temporary partial relief of inner tension; relief is attained by reacting to a present situation as if it were the situation that originally gave rise to the drive or impulse. Common in borderline states.

aculalia: Nonsense speech associated with marked impairment of comprehension. Occurs in mania, schizophrenia, and neurologic deficit.

addiction: Psychological or physical dependence on a drug. Sometimes more broadly used to describe dependence on any potentially pleasurable experience (gambling, sexual activity).

adiadochokinesia: Inability to perform rapid alternating movements. Occurs with neurologic deficit and cerebellar lesions.

adynamia: Weakness and fatigability, characteristic of neurasthenia and depression.

aerophagia: Excessive swallowing of air. Seen in anxiety disorder.

affect: The subjective and immediate experience of emotion attached to ideas or mental representations of objects. Affect has outward manifestations that may be classified as restricted, blunted, flattened, broad, labile, appropriate, or inappropriate. *See also* **mood**.

ageusia: Lack or impairment of the sense of taste. Seen in depression and neurologic deficit.

aggression: Forceful, goal-directed action that may be verbal or physical; the motor counterpart of the affect of rage, anger, or hostility. Seen in neurologic deficit, temporal lobe disorder, impulse-control disorders, mania, and schizophrenia.

agitation: Severe anxiety associated with motor restlessness.

agnosia: Inability to understand the import or significance of sensory stimuli; cannot be explained by a defect in sensory pathways or cerebral lesion; the term has also been used to refer to the selective loss or disuse of knowledge of specific objects because of emotional circumstances, as seen in certain schizophrenic, anxious, and depressed patients. Occurs with neurologic deficit. For types of agnosia, see the specific term.

agoraphobia: Morbid fear of open places or leaving the familiar setting of the home. May be present with or without panic attacks.

agrammatism: Speech in which the patient forms words into a sentence without regard for grammatical rules. Seen in Alzheimer and Pick diseases.

agraphia: Loss or impairment of a previously possessed ability to write.

ailurophobia: Dread of cats.

akataphasia: A form of disordered speech in which thoughts cannot be expressed directly but are expressed indirectly such as by making a similar sound (displacement paralogia) or by being derailed into another thought (derailment paralogia). *See also* **derailment**.

akathisia: Subjective feeling of motor restlessness manifested by a compelling need to be in constant movement; may be seen as an extrapyramidal adverse effect of antipsychotic medication. May be mistaken for psychotic agitation.

akinesia: Lack of physical movement, as in the extreme immobility of catatonic schizophrenia; may also occur as an extrapyramidal effect of antipsychotic medication.

akinetic mutism: Absence of voluntary motor movement or speech in a patient who is apparently alert (as evidenced by eye movements). Seen in psychotic depression and catatonic states.

alexia: Loss of a previously possessed reading facility; not explained by defective visual acuity. *Compare with* **dyslexia**.

alexithymia: Inability or difficulty in describing or being aware of one's emotions or moods.

algophobia: Dread of pain.

alogia: Inability to speak because of a mental deficiency or an episode of dementia.

ambivalence: Coexistence of two opposing impulses toward the same thing in the same person at the same time. Seen in schizophrenia, borderline states, and obsessive-compulsive disorders (OCDs).

amimia: Lack of the ability to make gestures or to comprehend those made by others.

amnesia: Partial or total inability to recall past experiences; may be organic (*amnestic disorder*) or emotional (*dissociative amnesia*) in origin.

amnesic aphasia: Disturbed capacity to name objects, even though they are known to the patient. Also called *anomic aphasia, dysnomia, nominal aphasia, and amnestic aphasia.*

anaclitic: Depending on others, especially as the infant on the mother; analytic depression in children results from an absence of mothering.

analgesia: State in which one feels little or no pain. Can occur under hypnosis and in dissociative disorder.

anancasm: Repetitious or stereotyped behavior or thought usually used as a

tension-relieving device; used as a synonym for obsession and seen in obsessive-compulsive (anankastic) personality.

androgyny: Combination of culturally determined female and male characteristics in one person.

anergia: Lack of energy.

anhedonia: Loss of interest in and withdrawal from all regular and pleasurable activities. Often associated with depression.

anomia: Inability to recall the names of objects.

anorexia: Loss or decrease in appetite. In *anorexia nervosa*, appetite may be preserved, but the patient refuses to eat.

anosognosia: Inability to recognize a physical deficit in oneself (e.g., patient denies paralyzed limb).

anterograde amnesia: Loss of memory for events subsequent to the onset of the amnesia; common after trauma. *Compare with* **retrograde amnesia**.

anxiety: Feeling of apprehension caused by anticipation of danger, which may be internal or external.

apathy: Dulled emotional tone associated with detachment or indifference; observed in certain types of schizophrenia and depression.

aphasia: Any disturbance in the comprehension or expression of language caused by a brain lesion. For types of aphasia, see the specific term.

aphonia: Loss of voice. Seen in conversion disorder.

apperception: Awareness of the meaning and significance of a particular sensory stimulus as modified by one's own experiences, knowledge, thoughts, and emotions. *See also* **perception**.

appropriate affect: Emotional tone in harmony with the accompanying idea, thought, or speech.

apraxia: Inability to perform a voluntary purposeful motor activity; cannot be explained by paralysis or other motor or sensory impairment. In *constructional apraxia*, a patient cannot draw two- or three-dimensional forms.

asomatopagnosia: Inability to recognize a part of one's body as one's own (also called *ignorance of the body* and *autotopagnosia*).

astasia abasia: Inability to stand or to walk in a normal manner, even though normal leg movements can be performed in a sitting or lying down position. Seen in conversion disorder.

astereognosis: Inability to identify familiar objects by touch. Seen with

neurologic deficit. *See also* **neurologic amnesia**.

asthenia: Weakness or debility.

asyndesis: Disorder of language in which the patient combines unconnected ideas and images. Commonly seen in schizophrenia.

ataxia: Lack of coordination, physical or mental. (1) In neurology, refers to loss of muscular coordination. (2) In psychiatry, the term *intrapsychic ataxia* refers to lack of coordination between feelings and thoughts; seen in schizophrenia and in severe OCD.

atonia: Lack of muscle tone. *See* **waxy flexibility**.

attention: Concentration; the aspect of consciousness that relates to the amount of effort exerted in focusing on certain aspects of an experience, activity, or task. Usually impaired in anxiety and depressive disorders.

auditory hallucination: False perception of sound, usually voices, but also other noises, such as music. Most common hallucination in psychiatric disorders.

audible thoughts: A form of auditory hallucination in which everything the patient thinks or speaks is repeated by the voices. Also known as thought echoing.

aura: (1) Warning sensations, such as automatisms, fullness in the stomach, blushing, and changes in respiration, cognitive sensations, and mood states usually experienced before a seizure. (2) A sensory prodrome that precedes a classic migraine headache.

autistic thinking: Thinking in which the thoughts are largely narcissistic and egocentric, with emphasis on subjectivity rather than objectivity, and without regard for reality; used interchangeably with autism and dereism. Seen in schizophrenia and autistic disorder.

automatic obedience: Strict obedience of command without critical judgment. The person may respond to an inner voice, as in schizophrenia, or to another person's command, as in hypnosis.

automatism: Activity carried out without conscious knowledge.

autoscopy: Seeing oneself or a double as part of a brief hallucinatory experience.

behavior: Sum total of the psyche that includes impulses, motivations, wishes, drives, instincts, and cravings, as expressed by a person's actions or motor activity. Also called *conation*.

bereavement: Feeling of grief or desolation, especially at the death or loss of

a loved one.

bizarre delusion: False belief that is patently absurd or fantastic (e.g., invaders from space have implanted electrodes in a person's brain). Common in schizophrenia. In nonbizarre delusion, content is usually within the range of possibility.

blackout: Amnesia experienced by alcoholics about behavior during drinking bouts; usually indicates reversible brain damage.

blocking: Abrupt interruption in train of thinking before a thought or idea is finished; after a brief pause, the person indicates no recall of what was being said or was going to be said (also known as *thought deprivation* or *increased thought latency*). Common in schizophrenia and severe anxiety.

blunted affect: Disturbance of affect manifested by a severe reduction in the intensity of externalized feeling tone; one of the fundamental symptoms of schizophrenia, as outlined by Eugen Bleuler.

bradykinesia: Slowness of motor activity, with a decrease in normal spontaneous movement.

bradylalia: Abnormally slow speech. Common in depression.

bradylexia: Inability to read at normal speed.

bruxism: Grinding or gnashing of the teeth, typically occurring during sleep. Seen in anxiety disorder.

carebaria: Sensation of discomfort or pressure in the head.

catalepsy: Condition in which persons maintain the body position into which they are placed; observed in severe cases of catatonic schizophrenia. Compare with *waxy flexibility* and *cerea flexibilitas. See also* **command automatism**.

cataplexy: Temporary sudden loss of muscle tone, causing weakness and immobilization; can be precipitated by a variety of emotional states and is often followed by sleep. Commonly seen in narcolepsy.

catastrophic reaction: Extreme emotional state characterized by restlessness, irritability, crying, anxiety, and uncooperativeness. Seen in patients who have had a stroke.

catatonic excitement: Excited, uncontrolled motor activity seen in catatonic schizophrenia. Patients in catatonic state may suddenly erupt into an excited state and may be violent.

catatonic posturing: Voluntary assumption of an inappropriate or bizarre posture, generally maintained for long periods of time. May switch

unexpectedly with catatonic excitement.

catatonic rigidity: Fixed and sustained motoric position that is resistant to change.

catatonic stupor: Stupor in which patients ordinarily are well aware of their surroundings.

cathexis: In psychoanalysis, a conscious or unconscious investment of psychic energy in an idea, concept, object, or person. *Compare with* **acathexis**.

cenesthesia: The general awareness of being alive coming from stimuli arising from the functioning of various bodily organs.

cephalagia: Headache.

cerea flexibilitas: Condition of a person who can be molded into a position that is then maintained; when an examiner moves the person's limb, the limb feels as if it were made of wax. Also called *waxy flexibility*. Seen in schizophrenia.

chorea: Movement disorder characterized by random and involuntary quick, jerky, purposeless movements. Seen in Huntington disease.

circumstantiality: Disturbance in the associative thought and speech processes in which a patient digresses into unnecessary details and inappropriate thoughts before communicating the central idea. Observed in schizophrenia, obsessional disturbances, and certain cases of dementia. *See also* **tangentiality**.

clang association: Association or speech directed by the sound of a word rather than by its meaning; words have no logical connection; punning and rhyming may dominate the verbal behavior. Seen most frequently in schizophrenia or mania.

claustrophobia: Abnormal fear of closed or confining spaces.

clonic convulsion: An involuntary, violent muscular contraction or spasm in which the muscles alternately contract and relax. Characteristic phase in grand mal epileptic seizure.

clouding of consciousness: Any disturbance of consciousness in which the person is not fully awake, alert, and oriented. Occurs in delirium, dementia, and cognitive disorder.

cluttering: Disturbance of fluency involving an abnormally rapid rate and erratic rhythm of speech that impedes intelligibility; the affected individual is usually unaware of communicative impairment.

cognition: Mental process of knowing and becoming aware; function is closely associated with judgment.

coma: State of profound unconsciousness from which a person cannot be roused, with minimal or no detectable responsiveness to stimuli; seen in injury or disease of the brain, in systemic conditions such as diabetic ketoacidosis and uremia, and in intoxications with alcohol and other drugs. Coma may also occur in severe catatonic states and in conversion disorder.

coma vigil: Coma in which a patient appears to be asleep and cannot be aroused. A persistent vegetative state.

command automatism: Condition in which suggestions are followed automatically.

command hallucination: False perception of orders that a person may feel obliged to obey or unable to resist.

complex partial seizure: A seizure characterized by alterations in consciousness that may be accompanied by complex hallucinations (sometimes olfactory) or illusions. During the seizure, a state of impaired consciousness resembling a dreamlike state may occur, and the patient may exhibit repetitive, automatic, or semipurposeful behavior.

compulsion: Pathologic need to act on an impulse that, if resisted, produces anxiety; repetitive behavior in response to an obsession or performed according to certain rules, with no true end in itself other than to prevent something from occurring in the future.

conation: That part of a person's mental life concerned with cravings, strivings, motivations, drives, and wishes as expressed through behavior or motor activity.

concrete thinking: Thinking characterized by actual things, events, and immediate experience rather than by abstractions; seen in young children, in those who have lost or never developed the ability to generalize (as in certain cognitive mental disorders), and in schizophrenic persons. *Compare with* **abstract thinking**.

condensation: Mental process in which one symbol stands for a number of components.

confabulation: Unconscious filling of gaps in memory by imagining experiences or events that have no basis in fact, commonly seen in amnestic syndromes; should be differentiated from lying. *See also* **paramnesia**.

confusion: Disturbances of consciousness manifested by a disordered orientation in relation to time, place, or person.

consciousness: State of awareness, with response to external stimuli.

constricted affect: Reduction in intensity of feeling tone that is less severe than that of blunted affect.

constructional apraxia: Inability to copy a drawing, such as a cube, clock, or pentagon, as a result of a brain lesion.

conversion phenomena: The development of symbolic physical symptoms and distortions involving the voluntary muscles or special sense organs; not under voluntary control and not explained by any physical disorder. Most common in conversion disorder but also seen in a variety of mental disorders.

convulsion: An involuntary, violent muscular contraction or spasm. *See also* **clonic convulsion** and **tonic convulsion**.

coprolalia: Involuntary use of vulgar or obscene language. Observed in some cases of schizophrenia and in Tourette syndrome.

coprophagia: Eating of filth or feces.

cryptographia: A private written language.

cryptolalia: A private spoken language.

cycloplegia: Paralysis of the muscles of accommodation in the eye; observed, at times, as an autonomic adverse effect (anticholinergic effect) of antipsychotic or antidepressant medication.

decompensation: Deterioration of psychic functioning caused by a breakdown of defense mechanisms. Seen in psychotic states.

déjà entendu: Illusion that what one is hearing one has been heard previously. *See also* **paramnesia**.

déjà pensé: Condition in which a thought never entertained before is incorrectly regarded as a repetition of a previous thought. *See also* **paramnesia**.

déjà vu: Illusion of visual recognition in which a new situation is incorrectly regarded as a repetition of a previous experience. *See also* **paramnesia**.

delirium: Acute reversible mental disorder characterized by confusion and some impairment of consciousness; generally associated with emotional lability, hallucinations or illusions, and inappropriate, impulsive, irrational, or violent behavior.

delirium tremens: Acute and sometimes fatal reaction to withdrawal from

alcohol, usually occurring 72 to 96 hours after the cessation of heavy drinking; distinctive characteristics are marked autonomic hyperactivity (tachycardia, fever, hyperhidrosis, and dilated pupils), usually accompanied by tremulousness, hallucinations, illusions, and delusions. Called *alcohol withdrawal with perceptual disturbance in DSM-5*. *See also* **formication**.

delusion: False belief, based on incorrect inference about external reality, that is firmly held despite objective and obvious contradictory proof or evidence and despite the fact that other members of the culture do not share the belief.

delusion of control: False belief that a person's will, thoughts, or feelings are being controlled by external forces.

delusion of grandeur: Exaggerated conception of one's importance, power, or identity.

delusion of infidelity: False belief that one's lover is unfaithful. Sometimes called *pathologic jealousy*.

delusion of persecution: False belief of being harassed or persecuted; often found in litigious patients who have a pathologic tendency to take legal action because of imagined mistreatment. Most common delusion.

delusion of poverty: False belief that one is bereft or will be deprived of all material possessions.

delusion of reference: False belief that the behavior of others refers to oneself or that events, objects, or other people have a particular and unusual significance, usually of a negative nature; derived from idea of reference, in which persons falsely feel that others are talking about them (e.g., belief that people on television or radio are talking to or about the person). *See also* **thought broadcasting**.

delusion of self-accusation: False feeling of remorse and guilt. Seen in depression with psychotic features.

dementia: Mental disorder characterized by general impairment in intellectual functioning without clouding of consciousness; characterized by failing memory, difficulty with calculations, distractibility, alterations in mood and affect, impaired judgment and abstraction, reduced facility with language, and disturbance of orientation. Although irreversible because of underlying progressive degenerative brain disease, dementia may be reversible if the cause can be treated. Also known as major

neurocognitive disorder in **DSM-5**.

denial: Defense mechanism in which the existence of unpleasant realities is disavowed; refers to keeping out of conscious awareness any aspects of external reality that, if acknowledged, would produce anxiety.

depersonalization: Sensation of unreality concerning oneself. Experiencing one's own behavior, thoughts, or feelings as if they were outside oneself, or as in a dream.

depression: Mental state characterized by feelings of sadness, loneliness, despair, low self-esteem, and self-reproach; accompanying signs include psychomotor retardation or, at times, agitation, withdrawal from interpersonal contact, and vegetative symptoms, such as insomnia and anorexia. The term refers to a mood that is so characterized or a mood disorder.

derailment: Gradual or sudden deviation in train of thought without blocking; sometimes used synonymously with *loosening of association.*

derealization: Sensation of changed reality or feeling detached from one's surroundings.

dereism: Mental activity that follows a totally subjective and idiosyncratic system of logic and fails to take the facts of reality or experience into consideration. Characteristic of schizophrenia. *See also* **autistic thinking**.

detachment: Characterized by distant interpersonal relationships and lack of emotional involvement.

devaluation: Defense mechanism in which a person attributes excessively negative qualities to self or others. Seen in depression and paranoid personality disorder.

diminished libido: Decreased sexual interest and drive. (Increased libido is often associated with mania.)

dipsomania: Compulsion to drink alcoholic beverages.

disinhibition: (1) Removal of an inhibitory effect, as in the reduction of the inhibitory function of the cerebral cortex by alcohol. (2) In psychiatry, a greater freedom to act in accordance with inner drives or feelings and with less regard for restraints dictated by cultural norms or one's superego.

disorientation: Confusion; impairment of awareness of time, place, and person (the position of the self in relation to other persons). Characteristic of cognitive disorders.

displacement: Unconscious defense mechanism by which the emotional

component of an unacceptable idea or object is transferred to a more acceptable one. Seen in phobias.

dissociation: Unconscious defense mechanism involving the segregation of any group of mental or behavioral processes from the rest of the person's psychic activity; may entail the separation of an idea from its accompanying emotional tone, as seen in dissociative and conversion disorders.

distractibility: Inability to focus one's attention; the patient does not respond to the task at hand but attends to irrelevant phenomena in the environment.

dread: Massive or pervasive anxiety, usually related to a specific danger.

dreamy state: Altered state of consciousness, the semiconscious state associated with an epileptic attack, particularly from medial temporal epilepsy.

drowsiness: State of impaired awareness associated with a desire or inclination to sleep.

dysarthria: Difficulty in articulation, the motor activity of shaping phonated sounds into speech, not in word finding or in grammar.

dyscalculia: Difficulty in performing calculations.

dysgeusia: Impaired sense of taste.

dysgraphia: Difficulty in writing.

dyskinesia: Uncontrolled, involuntary muscle movement. Seen in extrapyramidal disorders.

dyslalia: Faulty articulation caused by structural abnormalities of the articulatory organs or impaired hearing.

dyslexia: Specific learning disability syndrome involving an impairment of the ability to read; unrelated to the person's intelligence. *Compare with* **alexia**.

dysmegalopsia: A distortion in which the size and shape of objects is misperceived, sometimes called the "Alice in Wonderland" effect. *See also* **illusion**.

dysmetria: Impaired ability to gauge distance relative to movements. Seen in neurologic deficit.

dysmnesia: Impaired memory.

dyspareunia: Physical pain in sexual intercourse, which may be emotionally caused and more commonly experienced by women; may also result from cystitis, urethritis, or other medical conditions.

dysphagia: Difficulty in swallowing.

dysphasia: Difficulty in comprehending oral language (*reception dysphasia*) or in trying to express verbal language (*expressive dysphasia*).

dysphonia: Difficulty in speaking or singing.

dysphoria: Feeling of unpleasantness or discomfort; a mood of general dissatisfaction and restlessness. Occurs in depression and anxiety.

dysprosody: Loss of normal speech melody (*prosody*). Common in depression.

dystonia: Extrapyramidal motor disturbance consisting of slow, sustained contractions of the axial or appendicular musculature; one movement often predominates, leading to relatively sustained postural deviations; acute dystonic reactions (facial grimacing and torticollis) are occasionally seen with the initiation of antipsychotic drug therapy.

echolalia: Psychopathological repeating of words or phrases of one person by another; tends to be repetitive and persistent. Seen in certain kinds of schizophrenia, particularly the catatonic types.

echopraxia: Similar to echolalia, however this represents the repeating or mimicking of the movements of another person.

ego-alien: Denoting aspects of a person's personality that are viewed as repugnant, unacceptable, or inconsistent with the rest of the personality. Also called *ego-dystonia. Compare with* **ego-syntonic**.

egocentric: Self-centered; selfishly preoccupied with one's own needs; lacking interest in others.

ego-dystonic: *See* **ego-alien**.

egomania: Morbid self-preoccupation or self-centeredness. *See also* **narcissism**.

ego-syntonic: Denoting aspects of a personality that are viewed as acceptable and consistent with that person's total personality. Personality traits are usually ego-syntonic. *Compare with* **ego-alien**.

eidetic image: Unusually vivid or exact mental image of objects previously seen or imagined.

elation: Mood consisting of feelings of joy, euphoria, triumph, and intense self-satisfaction or optimism. Occurs in mania when not grounded in reality.

elevated mood: Air of confidence and enjoyment; a mood more cheerful than normal but not necessarily pathologic.

emotion: Complex feeling state with psychic, somatic, and behavioral components; external manifestation of emotion is *affect.*

emotional insight: A level of understanding or awareness that one has emotional problems. It facilitates positive changes in personality and behavior when present.

emotional lability: Excessive emotional responsiveness characterized by unstable and rapidly changing emotions.

encopresis: Involuntary passage of feces, usually occurring at night or during sleep.

enuresis: Incontinence of urine, often during sleep.

erotomania: Delusional belief, more common in women than in men, that someone is deeply in love with them (also known as *de Clérambault syndrome*).

erythrophobia: Abnormal fear of blushing.

euphoria: Exaggerated feeling of well-being that is inappropriate to real events. Can occur with drugs such as opiates, amphetamines, and alcohol.

euthymia: Normal range of mood, implying absence of depressed or elevated mood.

evasion: Act of not facing up to, or strategically eluding, something; consists of suppressing an idea that is next in a thought series and replacing it with another idea closely related to it. Also called *paralogia* and *perverted logic.*

exaltation: Feeling of intense elation and grandeur.

excited: Agitated, purposeless motor activity uninfluenced by external stimuli.

expansive mood: Expression of feelings without restraint, frequently with an overestimation of their significance or importance. Seen in mania and grandiose delusional disorder.

expressive aphasia: Disturbance of speech in which understanding remains, but ability to speak is grossly impaired; halting, laborious, and inaccurate speech (also known as *Broca's*, *nonfluent*, and *motor aphasias*).

expressive dysphasia: Difficulty in expressing verbal language; the ability to understand language is intact.

externalization: More general term than *projection* that refers to the tendency to perceive in the external world and in external objects elements of one's own personality, including instinctual impulses, conflicts, moods,

attitudes, and styles of thinking.

extroversion: State of one's energies being directed outside oneself. *Compare with* **introversion**.

false memory: A person's recollection and belief of an event that did not actually occur. In *false memory syndrome*, persons erroneously believe that they sustained an emotional or physical (e.g., sexual) trauma in early life.

fantasy: Daydream; fabricated mental picture of a situation or chain of events. A normal form of thinking dominated by unconscious material that seeks wish fulfillment and solutions to conflicts; may serve as the matrix for creativity. The content of the fantasy may indicate mental illness.

fatigue: A feeling of weariness, sleepiness, or irritability after a period of mental or bodily activity. Seen in depression, anxiety, neurasthenia, and somatoform disorders.

fausse reconnaissance: False recognition, a feature of paramnesia. Can occur in delusional disorders.

fear: Unpleasurable emotional state consisting of psychophysiological changes in response to a realistic threat or danger. *Compare with* **anxiety**.

flat affect: Absence or near absence of any signs of affective expression.

flight of ideas: Rapid succession of fragmentary thoughts or speech in which content changes abruptly and speech may be incoherent. Seen in mania.

floccillation: Aimless plucking or picking, usually at bedclothes or clothing, commonly seen in dementia and delirium.

fluent aphasia: Aphasia characterized by inability to understand the spoken word; fluent but incoherent speech is present. Also called *Wernicke's*, *sensory* and *receptive aphasias.*

folie à deux: Mental illness shared by two persons, usually involving a common delusional system; if it involves three persons, it is referred to as *folie à trois*, etc. Also called *shared psychotic disorder.*

formal thought disorder: Disturbance in the form of thought rather than the content of thought; thinking characterized by loosened associations, neologisms, and illogic constructs; thought process is disordered, and the person is defined as psychotic. Characteristic of schizophrenia.

formication: Tactile hallucination involving the sensation that tiny insects are crawling over the skin. Seen in cocaine addiction and delirium tremens.

free-floating anxiety: Severe, pervasive, generalized anxiety that is not attached to any particular idea, object, or event. Observed particularly in

anxiety disorders, although it may be seen in some cases of schizophrenia.

fugue: Dissociative disorder characterized by a period of almost complete amnesia, during which a person actually flees from an immediate life situation and begins a different life pattern; apart from the amnesia, mental faculties and skills are usually unimpaired.

galactorrhea: Abnormal discharge of milk from the breast; may result from the endocrine influence (e.g., prolactin) of dopamine receptor antagonists, such as phenothiazines.

generalized tonic–clonic seizure: Generalized onset of tonic–clonic movements of the limbs, tongue biting, and incontinence followed by slow, gradual recovery of consciousness and cognition; also called *grand mal seizure*.

global aphasia: Combination of grossly nonfluent aphasia and severe fluent aphasia.

glossolalia: Unintelligible jargon that has meaning to the speaker but not to the listener. Occurs in schizophrenia.

grandiosity: Exaggerated feelings of one's importance, power, knowledge, or identity. Occurs in delusional disorder and manic states.

grief: Alteration in mood and affect consisting of sadness appropriate to a real loss; normally, it is self-limited. *See also* **depression** and **mourning**.

guilt: Emotional state associated with self-reproach and the need for punishment. In psychoanalysis, refers to a feeling of culpability that stems from a conflict between the ego and the superego (conscience). Guilt has normal psychological and social functions, but special intensity or absence of guilt characterizes many mental disorders, such as depression and antisocial personality disorder, respectively. Psychiatrists distinguish shame as a less internalized form of guilt that relates more to others than to the self. *See also* **shame**.

gustatory hallucination: Hallucination primarily involving taste.

gynecomastia: Female-like development of the male breasts; may occur as an adverse effect of antipsychotic and antidepressant drugs because of increased prolactin levels or anabolic–androgenic steroid abuse.

hallucination: False sensory perception occurring in the absence of any relevant external stimulation of the sensory modality involved. For types of hallucinations, see the specific term.

hallucinosis: State in which a person experiences hallucinations without any

impairment of consciousness.

haptic hallucination: Hallucination of touch.

hebephrenia: Complex of symptoms, considered a form of schizophrenia, characterized by wild or silly behavior or mannerisms, inappropriate affect, and delusions and hallucinations that are transient and unsystematized. Hebephrenic schizophrenia is now called *disorganized schizophrenia.*

holophrastic: Using a single word to express a combination of ideas. Seen in schizophrenia.

hyperactivity: Increased muscular activity. The term is commonly used to describe a disturbance found in children that is manifested by constant restlessness, overactivity, distractibility, and difficulties in learning. Seen in *attention-deficit/hyperactivity disorder* (ADHD).

hyperacusis: Extreme sensitivity to sounds.

hyperalgesia: Excessive sensitivity to pain. Seen in somatoform disorder.

hyperesthesia: Increased sensitivity to any sense. It can affect one or more senses.

hypermnesia: Exaggerated degree of retention and recall. It can be elicited by hypnosis and may be seen in certain prodigies; also may be a feature of OCD, some cases of schizophrenia, and manic episodes of bipolar I disorder.

hyperphagia: Increase in appetite and intake of food.

hyperpragia: Excessive thinking and mental activity. Generally associated with manic episodes of bipolar I disorder.

hypersomnia: Excessive time spent asleep. May be associated with underlying medical or psychiatric disorder or narcolepsy, may be part of the Kleine–Levin syndrome, or may be primary.

hyperventilation: Excessive breathing, generally associated with anxiety, which can reduce blood carbon dioxide concentration and can produce lightheadedness, palpitations, numbness, tingling periorally and in the extremities, and, occasionally, syncope.

hypervigilance: Excessive attention to and focus on all internal and external stimuli; usually seen in delusional or paranoid states.

hypesthesia: Diminished sensitivity to tactile stimulation.

hypnagogic hallucination: Hallucination occurring while falling asleep, not ordinarily considered pathologic.

hypnopompic hallucination: Hallucination occurring while awakening from

sleep, not ordinarily considered pathologic.

hypnosis: Artificially induced alteration of consciousness characterized by increased suggestibility and receptivity to direction.

hypoactivity: Decreased motor and cognitive activity, as in psychomotor retardation; visible slowing of thought, speech, and movements. Also called *hypokinesis.*

hypochondria: Exaggerated concern about health that is based not on real medical pathology but on unrealistic interpretations of physical signs or sensations as abnormal.

hypomania: Mood abnormality with the qualitative characteristics of mania but somewhat less intense. Seen in cyclothymic disorder.

idea of reference: Misinterpretation of incidents and events in the outside world as having direct personal reference to oneself; occasionally observed in normal persons, but frequently seen in paranoid patients. If present with sufficient frequency or intensity or if organized and systematized, they constitute delusions of reference.

illogic thinking: Thinking containing erroneous conclusions or internal contradictions; psychopathological only when it is marked and not caused by cultural values or intellectual deficit.

illusion: Perceptual misinterpretation of a real external stimulus. *Compare with* **hallucination**.

immediate memory: Reproduction, recognition, or recall of perceived material within seconds after presentation. *Compare with* **long-term memory** and **short-term memory**.

impaired insight: Diminished ability to understand the objective reality of a situation.

impaired judgment: Diminished ability to understand a situation correctly and to act appropriately.

impulse control: Ability to resist an impulse, drive, or temptation to perform some action.

inappropriate affect: Emotional tone out of harmony with the idea, thought, or speech accompanying it. Seen in schizophrenia.

incoherence: Communication that is disconnected, disorganized, or incomprehensible. *See also* **word salad**.

incorporation: Primitive unconscious defense mechanism in which the psychic representation of another person or aspects of another person are

assimilated into oneself through a figurative process of symbolic oral ingestion; represents a special form of introjection and is the earliest mechanism of identification.

increased libido: Increase in sexual interest and drive.

ineffability: Ecstatic state in which persons insist that their experience is inexpressible and indescribable and that it is impossible to convey what it is like to one who never experienced it.

initial insomnia: Falling asleep with difficulty; usually seen in anxiety disorder. *Compare with* **middle insomnia** and **terminal insomnia**.

insight: Conscious recognition of one's own condition. In psychiatry, it refers to the conscious awareness and understanding of one's own psychodynamics and symptoms of maladaptive behavior; highly important in effecting changes in the personality and behavior of a person.

insomnia: Difficulty in falling asleep or difficulty in staying asleep. It can be related to a mental disorder, can be related to a physical disorder or an adverse effect of medication, or can be primary (not related to a known medical factor or another mental disorder). *See also* **initial insomnia**, **middle insomnia**, and **terminal insomnia**.

intellectual disability: Limitations in intellectual functioning and adaptive behavior, beginning before age 18 years. Below average intelligence.

intellectual insight: Knowledge of the reality of a situation without the ability to use that knowledge successfully to effect an adaptive change in behavior or to master the situation. *Compare with* **true insight**.

intelligence: Capacity for learning and ability to recall, to integrate constructively, and to apply what one has learned; the capacity to understand and to think rationally.

intoxication: Mental disorder caused by recent ingestion or presence in the body of an exogenous substance producing maladaptive behavior by virtue of its effects on the central nervous system (CNS). The most common psychiatric changes involve disturbances of perception, wakefulness, attention, thinking, judgment, emotional control, and psychomotor behavior; the specific clinical picture depends on the substance ingested.

intropunitive: Turning anger inward toward oneself. Commonly observed in depressed patients.

introspection: Contemplating one's own mental processes to achieve insight.

introversion: State in which a person's energies are directed inward toward

the self, with little or no interest in the external world.

irrelevant answer: Answer that is not responsive to the question.

irritability: Abnormal or excessive excitability, with easily triggered anger, annoyance, or impatience.

irritable mood: State in which one is easily annoyed and provoked to anger. *See also* **irritability**.

jamais vu: Paramnestic phenomenon characterized by a false feeling of unfamiliarity with a real situation that one has previously experienced.

jargon aphasia: Aphasia in which the words produced are neologistic; that is, nonsense words created by the patient.

judgment: Mental act of comparing or evaluating choices within the framework of a given set of values for the purpose of electing a course of action. If the course of action chosen is consonant with reality or with mature adult standards of behavior, then judgment is said to be *intact* or *normal*; judgment is said to be *impaired* if the chosen course of action is frankly maladaptive, results from impulsive decisions based on the need for immediate gratification, or is otherwise not consistent with reality as measured by mature adult standards.

kleptomania: Pathologic compulsion to steal.

la belle indifférence: Inappropriate attitude of calm or lack of concern about one's disability. May be seen in patients with conversion disorder.

labile affect: Affective expression characterized by rapid and abrupt changes, unrelated to external stimuli.

labile mood: Oscillations in mood between euphoria and depression or anxiety.

laconic speech: Condition characterized by a reduction in the quantity of spontaneous speech; replies to questions are brief and unelaborated, and little or no unprompted additional information is provided. Occurs in major depression, schizophrenia, and organic mental disorders. Also called *poverty of speech.*

lethologica: Momentary forgetting of a name or proper noun. *See* **blocking**.

lilliputian hallucination: Visual sensation that persons or objects are reduced in size; more properly regarded as an illusion. *See also* **micropsia**.

localized amnesia: Partial loss of memory; amnesia restricted to specific or isolated experiences. Also called *lacunar amnesia* and *patch amnesia.*

logoclonia: Repeated use of the same word. See perseveration.

logorrhea: Copious, pressured, coherent speech; uncontrollable, excessive talking; observed in manic episodes of bipolar disorder. Also called *tachylogia*, *verbomania*, and *volubility*.

long-term memory: Reproduction, recognition, or recall of experiences or information that was experienced in the distant past. Also called *remote memory*. *Compare with* **immediate memory** and **short-term memory**.

loosening of associations: Characteristic schizophrenic thinking or speech disturbance involving a disorder in the logical progression of thoughts, manifested as a failure to communicate verbally adequately; unrelated and unconnected ideas shift from one subject to another. *See also* **tangentiality**.

macropsia: False perception that objects are larger than they really are. *Compare with* **micropsia**.

magical thinking: A form of dereistic thought; thinking similar to that of the preoperational phase in children (Jean Piaget), in which thoughts, words, or actions assume power (e.g., to cause or to prevent events).

malingering: Feigning disease to achieve a specific goal, for example, to avoid an unpleasant responsibility.

mania: Mood state characterized by elation, agitation, hyperactivity, hypersexuality, and accelerated thinking and speaking (flight of ideas). Seen in bipolar I disorder. *See also* **hypomania**.

manipulation: Maneuvering by patients to get their own way, characteristic of antisocial personalities.

mannerism: Ingrained, habitual involuntary movement.

melancholia: Severe depressive state. Used in the term *involutional melancholia* as a descriptive term and also in reference to a distinct diagnostic entity.

memory: Process whereby what is experienced or learned is established as a record in the CNS (registration), where it persists with a variable degree of permanence (retention) and can be recollected or retrieved from storage at will (recall). For types of memory, see **immediate memory**, **long-term memory**, and **short-term memory**.

mental disorder: Psychiatric illness or disease whose manifestations are characterized primarily by behavioral or psychological impairment of function, measured in terms of deviation from some normative concept; associated with distress or disease, not just an expected response to a

particular event or limited to relations between a person and society.

mental retardation: Obsolete term, please see **intellectual disability**.

metonymy: Speech disturbance common in schizophrenia in which the affected person uses a word or phrase that is related to the proper one but is not the one ordinarily used; for example, the patient speaks of consuming a *menu* rather than a *meal* or refers to losing the *piece of string* of the conversation rather than the *thread* of the conversation. *See also* **paraphasia** and **word approximation**.

microcephaly: Condition in which the head is unusually small as a result of defective brain development and premature ossification of the skull.

micropsia: False perception that objects are smaller than they really are. Sometimes called *lilliputian hallucination. Compare with* **macropsia**.

middle insomnia: Waking up after falling asleep without difficulty and then having difficulty in falling asleep again. *Compare with* **initial insomnia** and **terminal insomnia**.

mimicry: Simple, imitative motion activity of childhood.

monomania: Mental state characterized by preoccupation with one subject.

mood: Pervasive and sustained feeling tone that is experienced internally and that, in the extreme, can markedly influence virtually all aspects of a person's behavior and perception of the world. Distinguished from affect, the external expression of the internal feeling tone. For types of mood, see the specific term.

mood-congruent delusion: Delusion with content that is mood appropriate (e.g., depressed patients who believe that they are responsible for the destruction of the world).

mood-congruent hallucination: Hallucination with content that is consistent with a depressed or manic mood (e.g., depressed patients hearing voices telling them that they are bad persons and manic patients hearing voices telling them that they have inflated worth, power, or knowledge).

mood-incongruent delusion: Delusion based on incorrect reference about external reality, with content that has no association to mood or is mood inappropriate (e.g., depressed patients who believe that they are the new Messiah).

mood-incongruent hallucination: Hallucination not associated with real external stimuli, with content that is not consistent with depressed or manic mood (e.g., in depression, hallucinations not involving such themes as

guilt, deserved punishment, or inadequacy; in mania, not involving such themes as inflated worth or power).

mood swings: Oscillation of a person's emotional feeling tone between periods of elation and periods of depression.

motor aphasia: Aphasia in which understanding is intact, but the ability to speak is lost. Also called *Broca's*, *expressive*, or *nonfluent aphasias.*

mourning: Syndrome following loss of a loved one, consisting of preoccupation with the lost individual, weeping, sadness, and repeated reliving of memories. *See also* **bereavement** and **grief**.

muscle rigidity: State in which the muscles remain immovable; seen in schizophrenia.

mutism: Organic or functional absence of the faculty of speech. *See also* **stupor**.

mydriasis: Dilation of the pupil; sometimes occurs as an autonomic (anticholinergic) or atropine-like adverse effect of some antipsychotic and antidepressant drugs.

narcissism: In psychoanalytic theory, divided into primary and secondary types: primary narcissism, the early infantile phase of object relationship development, when the child has not differentiated the self from the outside world, and all sources of pleasure are unrealistically recognized as coming from within the self, giving the child a false sense of omnipotence; secondary narcissism, when the libido, once attached to external love objects, is redirected back to the self. *See also* **autistic thinking**.

needle phobia: The persistent, intense, pathologic fear of receiving an injection.

negative signs: In schizophrenia: flat affect, alogia, abulia, and apathy.

negativism: Verbal or nonverbal opposition or resistance to outside suggestions and advice; commonly seen in catatonic schizophrenia in which the patient resists any effort to be moved or does the opposite of what is asked.

neologism: New word or phrase whose derivation cannot be understood; often seen in schizophrenia. It has also been used to mean a word that has been incorrectly constructed but whose origins are nonetheless understandable (e.g., *head shoe* to mean *hat*), but such constructions are more properly referred to as *word approximations.*

neurologic amnesia: (1) Auditory amnesia: loss of ability to comprehend

sounds or speech. (2) Tactile amnesia: loss of ability to judge the shape of objects by touch. *See also* **astereognosis**. (3) Verbal amnesia: loss of ability to remember words. (4) Visual amnesia: loss of ability to recall or to recognize familiar objects or printed words.

nihilism: Delusion of the nonexistence of the self or part of the self; also refers to an attitude of total rejection of established values or extreme skepticism regarding moral and value judgments.

nihilistic delusion: Depressive delusion that the world and everything related to it have ceased to exist.

noesis: The functioning of the intellectual or cognitive processes.

nominal aphasia: Aphasia characterized by difficulty in giving the correct name of an object. *See also* **anomia** and **amnesic aphasia**.

nymphomania: Abnormal, excessive, insatiable desire in a woman for sexual intercourse. *Compare with* **satyriasis**.

obsession: Persistent and recurrent idea, thought, or impulse that cannot be eliminated from consciousness by logic or reasoning; obsessions are involuntary and ego-dystonic. *See also* **compulsion**.

olfactory hallucination: Hallucination primarily involving smell or odors; most common in medical disorders, especially in the temporal lobe.

orientation: State of awareness of oneself and one's surroundings in terms of time, place, and person.

overactivity: Abnormality in motor behavior that can manifest itself as psychomotor agitation, hyperactivity (hyperkinesis), tics, sleepwalking, or compulsions.

overvalued idea: False or unreasonable belief or idea that is sustained beyond the bounds of reason. It is held with less intensity or duration than a delusion but is usually associated with mental illness.

panic: Acute, intense attack of anxiety associated with personality disorganization; the anxiety is overwhelming and accompanied by feelings of impending doom.

panphobia: Overwhelming fear of everything.

pantomime: Gesticulation; psychodrama without the use of words.

paramnesia: Disturbance of memory in which reality and fantasy are confused. It is observed in dreams and in certain types of schizophrenia and organic mental disorders; it includes phenomena such as *déjà vu* and *déjà entendu*, which may occur occasionally in normal persons.

paranoia: Unreasonable false beliefs, characterized by delusions of persecution, unwarranted jealousy, or exaggerated self-importance, typically elaborated into an organized system.

paranoid delusions: Includes persecutory delusions and delusions of reference, control, and grandeur.

paranoid ideation: Thinking dominated by suspicious, persecutory, or grandiose content of less than delusional proportions.

paraphasia: Abnormal speech in which one word is substituted for another, the irrelevant word generally resembling the required one in morphology, meaning, or phonetic composition; the inappropriate word may be a legitimate one used incorrectly, such as *clover* instead of *hand*, or a bizarre nonsense expression, such as *treen* instead of *train*. Paraphasic speech may be seen in organic aphasias and in mental disorders such as schizophrenia. *See also* **metonymy** and **word approximation**.

parapraxis: Faulty act, such as a slip of the tongue or the misplacement of an article. Freud ascribed parapraxes to unconscious motives.

paresis: Weakness or partial paralysis of organic origin.

paresthesia: Abnormal spontaneous tactile sensation, such as a burning, tingling, or pins-and-needles sensation.

perception: Conscious awareness of elements in the environment by the mental processing of sensory stimuli; sometimes used in a broader sense to refer to the mental process by which all kinds of data, intellectual, emotional, and sensory, are meaningfully organized. *See also* **apperception**.

perseveration: (1) Pathologic repetition of the same response to different stimuli, as in a repetition of the same verbal response to different questions. (2) Persistent repetition of specific words or concepts in the process of speaking. Seen in cognitive disorders, schizophrenia, and other mental illness. *See also* **verbigeration**.

phantom limb: False sensation that an extremity that has been lost is, in fact, present.

phobia: Persistent, pathologic, unrealistic, intense fear of an object or situation; the phobic person may realize that the fear is irrational but, nonetheless, cannot dispel it. For types of phobias, see the specific term.

pica: Craving and eating of nonfood substances, such as paint and clay.

polyphagia: Pathologic overeating.

positive signs: In schizophrenia: hallucinations, delusions, and thought disorder.

posturing: Strange, fixed, and bizarre bodily positions held by a patient for an extended time. *See also* **catatonic posturing**.

poverty of content of speech: Speech that is adequate in amount but conveys little information because of vagueness, emptiness, or stereotyped phrases.

poverty of speech: Restriction in the amount of speech used; replies may be monosyllabic. *See also* **laconic speech**.

preoccupation of thought: Centering of thought content on a particular idea, associated with a strong affective tone, such as a paranoid trend or a suicidal or homicidal preoccupation.

pressured speech: Increase in the amount of spontaneous speech; rapid, loud, accelerated speech, as occurs in mania, schizophrenia, and cognitive disorders.

primary process thinking: In psychoanalysis, the mental activity related directly to the functions of the id and characteristic of unconscious mental processes; marked by primitive, prelogical thinking and by the tendency to seek immediate discharge and gratification of instinctual demands. Includes thinking that is dereistic, illogic, magical; normally found in dreams, abnormally in psychosis. *Compare with* **secondary process thinking**.

projection: Unconscious defense mechanism in which persons attribute to another those generally unconscious ideas, thoughts, feelings, and impulses that are in themselves undesirable or unacceptable as a form of protection from anxiety arising from an inner conflict; by externalizing whatever is unacceptable, they deal with it as a situation apart from themselves.

prosopagnosia: Inability to recognize familiar faces that is not due to impaired visual acuity or level of consciousness.

pseudocyesis: Rare condition in which a nonpregnant patient has the signs and symptoms of pregnancy, such as abdominal distention, breast enlargement, pigmentation, cessation of menses, and morning sickness.

pseudodementia: (1) Dementia-like disorder that can be reversed by appropriate treatment and is not caused by organic brain disease. (2) Condition in which patients show exaggerated indifference to their surroundings in the absence of a mental disorder; also occurs in depression

and factitious disorders.

pseudologia fantastica: Disorder characterized by uncontrollable lying in which patients elaborate extensive fantasies that they freely communicate and act on.

psychomotor agitation: Physical and mental overactivity that is usually nonproductive and is associated with a feeling of inner turmoil, as seen in agitated depression.

psychosis: Mental disorder in which the thoughts, affective response, ability to recognize reality, and ability to communicate and relate to others are sufficiently impaired to interfere grossly with the capacity to deal with reality; the classical characteristics of psychosis are impaired reality testing, hallucinations, delusions, and illusions.

psychotic: (1) Person experiencing psychosis. (2) Denoting or characteristic of psychosis.

rationalization: An unconscious defense mechanism in which irrational or unacceptable behavior, motives, or feelings are logically justified or made consciously tolerable by plausible means.

reaction formation: Unconscious defense mechanism in which a person develops a socialized attitude or interest that is the direct antithesis of some infantile wish or impulse that is harbored consciously or unconsciously. One of the earliest and most unstable defense mechanisms, closely related to repression; both are defenses against impulses or urges that are unacceptable to the ego.

reality testing: Fundamental ego function that consists of tentative actions that test and objectively evaluate the nature and limits of the environment; includes the ability to differentiate between the external world and the internal world and to accurately judge the relation between the self and the environment.

recall: Process of bringing stored memories into consciousness. *See also* **memory**.

recent memory: Recall of events over the past few days.

recent past memory: Recall of events over the past few months.

receptive aphasia: Organic loss of ability to comprehend the meaning of words; fluid and spontaneous, but incoherent and nonsensical, speech. *See also* **fluent aphasia** and **sensory aphasia**.

receptive dysphasia: Difficulty in comprehending oral language; the

impairment involves comprehension and production of language.

regression: Unconscious defense mechanism in which a person undergoes a partial or total return to earlier patterns of adaptation; observed in many psychiatric conditions, particularly schizophrenia.

remote memory: Recall of events in the distant past.

repression: Freud's term for an unconscious defense mechanism in which unacceptable mental contents are banished or kept out of consciousness; important in normal psychological development and in neurotic and psychotic symptom formation. Freud recognized two kinds of repression: (1) repression proper, in which the repressed material was once in the conscious domain, and (2) primal repression, in which the repressed material was never in the conscious realm. *Compare with* **suppression**.

restricted affect: Reduction in intensity of feeling tone that is less severe than in blunted affect but clearly reduced. *See also* **constricted affect**.

retrograde amnesia: Loss of memory for events preceding the onset of the amnesia. *Compare with* **anterograde amnesia**.

retrospective falsification: Memory becomes unintentionally (unconsciously) distorted by being filtered through a person's present emotional, cognitive, and experiential state.

rigidity: In psychiatry, a person's resistance to change, a personality trait.

ritual: (1) Formalized activity practiced by a person to reduce anxiety, as in OCD. (2) Ceremonial activity of cultural origin.

rumination: Constant preoccupation with thinking about a single idea or theme, as in OCD.

satyriasis: Morbid, insatiable sexual need or desire in a man. *Compare with* **nymphomania**.

scotoma: (1) In psychiatry, a figurative blind spot in a person's psychological awareness. (2) In neurology, a localized visual field defect.

secondary process thinking: In psychoanalysis, the form of thinking that is logical, organized, reality oriented, and influenced by the demands of the environment; characterizes the mental activity of the ego. *Compare with* **primary process thinking**.

seizure: An attack or sudden onset of certain symptoms, such as convulsions, loss of consciousness, and psychic or sensory disturbances; seen in epilepsy and can be substance induced. For types of seizures, see the specific term.

sensorium: Perceptual awareness or the sensory apparatus considered as a whole. Sometimes used interchangeably with *consciousness.*

sensory aphasia: Organic loss of ability to comprehend the meaning of words; fluid and spontaneous, but incoherent and nonsensical, speech. *See also* **fluent aphasia** and **receptive aphasia**.

sensory extinction: Neurologic sign operationally defined as failure to report one of two simultaneously presented sensory stimuli, despite the fact that either stimulus alone is correctly reported. Also called *sensory inattention.*

shame: Failure to live up to self-expectations; often associated with fantasy of how person will be seen by others. *See also* **guilt**.

short-term memory: Reproduction, recognition, or recall of perceived material within minutes after the initial presentation. *Compare with* **immediate memory** *and* **long-term memory**.

simultanagnosia: Impairment in the perception or integration of visual stimuli appearing simultaneously.

somatic delusion: Delusion pertaining to the functioning of one's body.

somatic hallucination: Hallucination involving the perception of a physical experience localized within the body.

somnolence: Pathologic sleepiness or drowsiness from which one can be aroused to a normal state of consciousness.

spatial agnosia: Inability to recognize spatial relations.

speaking in tongues: Expression of a revelatory message through unintelligible words; not considered a disorder of thought if associated with practices of specific Pentecostal religions. *See also* **glossolalia**.

stereotypy: Continuous mechanical repetition of speech or physical activities; observed in catatonic schizophrenia.

stupor: (1) State of decreased reactivity to stimuli and less than full awareness of one's surroundings; as a disturbance of consciousness, it indicates a condition of partial coma or semicoma. (2) In psychiatry, used synonymously with *mutism* and does not necessarily imply a disturbance of consciousness; in *catatonic stupor*, patients are ordinarily aware of their surroundings.

stuttering: Frequent repetition or prolongation of a sound or syllable, leading to markedly impaired speech fluency.

sublimation: Unconscious defense mechanism in which the energy associated with unacceptable impulses or drives is diverted into personally

and socially acceptable channels; unlike other defense mechanisms, it offers some minimal gratification of the instinctual drive or impulse.

substitution: Unconscious defense mechanism in which a person replaces an unacceptable wish, drive, emotion, or goal with one that is more acceptable.

suggestibility: State of uncritical compliance with influence or of uncritical acceptance of an idea, belief, or attitude; commonly observed among persons with hysterical traits.

suicidal ideation: Thoughts or act of taking one's own life.

suppression: Conscious act of controlling and inhibiting an unacceptable impulse, emotion, or idea; differentiated from repression in that repression is an unconscious process.

symbolization: Unconscious defense mechanism in which one idea or object comes to stand for another because of some common aspect or quality in both; based on similarity and association; the symbols formed protect the person from the anxiety that may be attached to the original idea or object.

synesthesia: Condition in which the stimulation of one sensory modality is perceived as sensation in a different modality, as when a sound produces a sensation of color.

syntactical aphasia: Aphasia characterized by the fluent production of words, however the inability to form normal grammatical constructions.

systematized delusion: Group of elaborate delusions related to a single event or theme.

tactile hallucination: Hallucination primarily involving the sense of touch. Also called *haptic hallucination.*

tangentiality: Oblique, digressive, or even irrelevant manner of speech in which the central idea is not communicated.

tension: Physiologic or psychic arousal, uneasiness, or pressure toward action; an unpleasurable alteration in mental or physical state that seeks relief through action.

terminal insomnia: Early morning awakening or waking up at least 2 hours before planning to wake up. *Compare with* **initial insomnia** and **middle insomnia**.

thought broadcasting: Feeling that one's thoughts are being broadcast or projected into the environment. *See also* **thought withdrawal**.

thought disorder: Any disturbance of thinking that affects language,

communication, or thought content; the hallmark feature of schizophrenia. Manifestations range from simple blocking and mild circumstantiality to profound loosening of associations, incoherence, and delusions; characterized by a failure to follow semantic and syntactic rules that is inconsistent with the person's education, intelligence, or cultural background.

thought insertion: Delusion that thoughts are being implanted in one's mind by other people or forces.

thought latency: The period of time between a thought and its verbal expression. Increased in schizophrenia (*see* **blocking**) and decreased in mania (*see* **pressured speech**).

thought withdrawal: Delusion that one's thoughts are being removed from one's mind by other people or forces. *See also* **thought broadcasting**.

tic disorders: Predominantly psychogenic disorders characterized by involuntary, spasmodic, stereotyped movement of small groups of muscles; seen most predominantly in moments of stress or anxiety, rarely as a result of organic disease.

tinnitus: Noises in one or both ears, such as ringing, buzzing, or clicking; an adverse effect of some psychotropic drugs.

tonic convulsion: Convulsion in which the muscle contraction is sustained.

trailing phenomenon: Perceptual abnormality associated with hallucinogenic drugs in which moving objects are seen as a series of discrete and discontinuous images.

trance: Sleeplike state of reduced consciousness and activity.

tremor: Rhythmical alteration in movement, which is usually faster than one beat a second; typically, tremors decrease during periods of relaxation and sleep and increase during periods of anger and increased tension.

true insight: Understanding of the objective reality of a situation coupled with the motivational and emotional impetus to master the situation or change behavior.

twilight state: Disturbed consciousness with hallucinations.

twirling: Sign present in autistic children who continually rotate in the direction in which their head is turned.

unconscious: (1) One of three divisions of Freud's topographic theory of the mind (the others being the conscious and the preconscious) in which the psychic material is not readily accessible to conscious awareness by

ordinary means; its existence may be manifest in symptom formation, in dreams, or under the influence of drugs. (2) In popular (but more ambiguous) usage, any mental material not in the immediate field of awareness. (3) Denoting a state of unawareness, with lack of response to external stimuli, as in a coma.

undoing: Unconscious primitive defense mechanism, repetitive in nature, by which a person symbolically acts out in reverse something unacceptable that has already been done or against which the ego must defend itself; a form of magical expiatory action, commonly observed in OCD.

unio mystica: Feeling of mystic unity with an infinite power. Although this can be a religious phenomenon, it can also be a type of delusion.

vegetative signs: In depression, denoting characteristic symptoms such as sleep disturbance (especially early morning awakening), decreased appetite, constipation, weight loss, and loss of sexual response.

verbigeration: Meaningless and stereotyped repetition of words or phrases, as seen in schizophrenia. Also called *cataphasia*. *See also* **perseveration**.

vertigo: Sensation that one or the world around one is spinning or revolving; a hallmark of vestibular dysfunction, not to be confused with dizziness.

visual agnosia: Inability to recognize objects or persons.

visual amnesia: Inability to remember the appearance of objects or to recognize familiar words

visual hallucination: Hallucination primarily involving the sense of sight.

waxy flexibility: Condition in which a person maintains the body position into which they are placed with slight resistance to movement giving it a waxy feel. See also **cerea flexibilitas**.

word approximation: Use of conventional words in an unconventional or inappropriate way (metonymy or of new words that are developed by conventional rules of word formation) (e.g., *hand shoes* for *gloves* and *time measure* for *clock*); distinguished from a *neologism*, which is a new word whose derivation cannot be understood. *See also* **paraphasia**.

word salad: Incoherent, essentially incomprehensible, mixture of words and phrases commonly seen in far-advanced cases of schizophrenia. *See also* **incoherence**.

xenophobia: Abnormal fear of strangers.

zoophobia: Abnormal fear of animals.
