the diagnostic approaches to RLS.

Table 15-15
Medications and Drugs Causing or Worsening Certain Parasomnias

REM Sleep Behavior Disorder
Biperiden
Caffeine
Monoamine oxidase inhibitors (MAOIs)
Selegiline
Serotonin agonists
Tricyclic antidepressants
Venlafaxine
Withdrawal syndromes
Alcohol
Meprobamate
Pentazocine
Nitrazepam
Nightmares
Alcohol abuse or withdrawal
Drug-induced REM sleep rebound (e.g., withdrawal from REM-suppressing drugs such as methamphetamine)
l-DOPA
β-Blockers

A variety of medical conditions can cause secondary RLS, and we list these in Table 15-17. A detailed history and physical examination are essential parts of the RLS workup. Also, we should check a ferritin level in every patient with symptoms consistent with RLS.

Periodic Limb Movement Disorder. Periodic limb movement disorder (PLMD), previously called *nocturnal myoclonus,* involves brief, stereotypic, repetitive, nonepileptiform movements of the limbs, usually the legs. It

occurs primarily in NREM sleep and involves an extension of the big toe. A partial flexion of the ankle, knee, and hip may also occur. These movements range from 0.5 to 5 seconds in duration and occur every 20 to 40 seconds. The leg movements are frequently associated with brief arousals from sleep and, as a result, can (but do not always) disturb sleep architecture. The prevalence of PLMD increases with aging and can occur in association with folate deficiency, renal disease, anemia, and the use of antidepressants.

Sleep-Related Leg Cramps. Nocturnal leg cramps are much like leg cramps that occur during wakefulness. They usually affect the calf and are painful muscle contractions. The pain awakens the sleeper and thereby disrupts sleep. Metabolic disorders, mineral deficiencies, electrolytic imbalances, diabetes, and pregnancy are known precipitators. The reason that some individuals have repeated leg cramps during sleep and not during the day is not known.

Sleep-Related Bruxism. Sleep-related bruxism occurs when an individual grinds or clenches the teeth during sleep. Formerly classified as a parasomnia, sleep bruxism can produce abnormal wear and damage to teeth, provoke tooth and jaw pain, or make loud, unpleasant sounds that disturb the bed partner. Sometimes atypical facial pain and headache also result. More than 85 percent of the population may brux at one time or another; however, it is clinically significant in only about 5 percent. Teeth grinding occurs in any sleep stage but is most common at the transition to sleep, in stage 2 sleep, and during REM sleep. Some evidence indicates that teeth grinding during REM sleep is more commonly associated with dental wear or damage. Sleep bruxism does not appear to be exacerbated by dental malocclusion. It worsens during periods of stress. Researchers studying sleep bruxism have found that many patients seem to have less frequent teeth grinding when sleeping in the laboratory; therefore, we may need repeat studies to document the disorder. By contrast, bruxism frequently appears on polysomnographic recordings made for other purposes. Sleep bruxism may occur secondary to sleep-related breathing disorders, the use of psychostimulants (e.g., amphetamine, cocaine), alcohol ingestion, and treatment with some SSRIs. Sleep bruxism can infrequently occur (monthly), regularly (weekly), or frequently (nightly). We judge the severity by considering the degree of sleep

disruption, consequent pain, and dental damage.

Table 15-16
Restless Legs Syndrome

	DSM-5	ICSD-3	ICD-10
Name	Restless legs syndrome	Restless legs syndrome	Other specified extrapyramida and movement disorders **Restless legs syndrome**
Duration	≥3×/wk for ≥3 mo		
Symptoms	Urge to move legs Worse at night Urge relieved by movement	Urge to move legs Uncomfortable sensations occurring during rest/inactivity At least partially relieved by movement Tend to have circadian pattern (occurring primarily at night)	Experiencing a strong urge to move legs to relieve discomfort often occurs while lying down or sitting and tends to be worse at night
# Symptoms needed	All the above	All the above	

Exclusion (not the result of):	Akathisia Effects of a substance or medication Another mental disorder or medical condition Behavioral condition (i.e., habitual movements)	
Psychosocial impact	Marked distress and/or impairment in areas of functioning present	Marked distress and/or impairment in areas of functioning present

Sleep-Related Rhythmic Movement Disorder. This sleep disorder consists of repetitive, rhythmic movements, usually involving the head and neck. Most often occurring at the transition from wakefulness to sleep, this movement disorder may also continue during light sleep. Formerly classified as a parasomnia, sleep-related rhythmic movement disorder has many names, including *jactatio capitis nocturna,* headbanging, head rolling, body rocking, and *rhythmie du sommeil.* Most infants body rock. Some clinicians believe that body rocking develops from the soothing effect of vestibular stimulation. If the rhythmic movement persists into childhood, the risk of injury increases. This is particularly true if the movement includes headbanging. The male to female ratio is 4:1. Severity ranges from less than one episode weekly to nightly episodes producing injury.

Table 15-17
Medical Disorders That Can Cause Secondary Restless Legs Syndrome

COPD
Diabetes
Fibromyalgia
Iron and folic acid deficiency anemias
Neuropathies
Rheumatoid arthritis
Thyroid diseases
Uremia

Benign Sleep Myoclonus of Infancy. Previously called benign neonatal sleep myoclonus, this disorder is characterized by asynchronous jerking of limbs and trunk during quiet sleep in neonates. This benign, apparently rare, parasomnia usually begins within the first week of life and may last a few days or several months. It does not require any treatment and should resolve with time.

Propriospinal Myoclonus at Sleep Onset. Propriospinal myoclonus at sleep onset is a spinal cord–mediated movement disorder, sometimes associated with spinal cord lesions. Movements appear during times of wakeful relaxation and may interfere with sleep onset. They start in the abdominal and truncal muscles and then progress to the neck and proximal muscles of the limbs.

Sleep-Related Movement Disorder due to Medication or Substance Use and Sleep-Related Movement Disorder due to Medical Condition. A variety of medications, substances, and comorbid conditions can produce or exacerbate sleep-related movement disorders. Table 15-18 lists some example medications. Neurologic diseases that are associated with daytime movement disorders can also be associated with sleep-related movement disorders. Stress, anxiety, and sleep deprivation may contribute to bruxism.

Table 15-18
Medications Causing Sleep-Related Movement Disorders

Antidepressants (including most tricyclics and SSRIs)
Antiemetics
Antihistamines
Antipsychotics (restless legs symptoms, periodic limb movement disorder)
Calcium channel blockers
Lithium
Stimulants (rhythmic movement disorders, bruxism)

Isolated Symptoms and Normal Variants

Sleep Talking. As the name implies, sleep talking in classic form involves unconscious speech during sleep. Unless it annoys the bed partner, it is seldom recognized. Fever, stress, or talking with the sleeper can all induce the behavior. Somniloquy may accompany sleep terror, sleepwalking, confusional arousals, OSAs, and RBD.

Sleep Starts (Hypnic Jerks). Sleep starts are sudden, brief muscle contractions that occur at the transition between wakefulness and sleep in 60 to 70 percent of adults. The contractions commonly involve the legs; however, sometimes there is movement in the arms and head. Sometimes called a “hypnic jerk,” it is usually benign. The sleep start, however, can interfere with the ability to fall asleep and may be accompanied by sensations of falling, a hallucinated flash of light, or a loud crackling sound. In severe cases, the sleep start produces profound sleep-onset insomnia.

CLINICAL TOOLS IN SLEEP MEDICINE

Clinical Interview

A careful and thorough clinical interview is one of the most informative parts of a workup for sleep disorders. The habitual bedtime and arising times for both weekdays and weekends, the frequency, duration, and restorative nature

of naps, and overall level of sleepiness are good places to begin. Specific sleep problems relating to difficulty initiating and maintaining sleep are informative, including whether there is rumination at bedtime, fear of not being able to sleep, or excessive worry when attempting to sleep. We should assess for movements, including leg movement, leg sensations, leg cramps, teeth grinding, and dream enactments (with or without injury). We should also review for morning headaches, morning dry mouth, nocturnal reflux, hyperhidrosis (excess sweating), nocturia, enuresis, nocturnal tongue biting, nightmares, sleep terrors, and other sleep-related problems. In some cases, it can be crucial to ask about the presence of family pets and whether they sleep in the bedroom (or bed). A sleep history questionnaire is often helpful in diagnosing a patient's sleep disorder (Table 15-19).

Clinical Tests

Polysomnography. Polysomnography is the continuous, attended, comprehensive recording of the physiologic changes that occur during sleep. A polysomnogram is typically recorded at night and lasts between 6 and 8 hours. Brain wave activity, eye movements, submentalis electromyography activity, nasal–oral airflow, nasal pressure, respiratory effort, oxyhemoglobin saturation, heart rhythm, and leg movements during sleep are measured. Usually, the laboratory records body position and snoring sounds. Brain wave activity, eye movements, and submentalis electromyogram are essential for identifying sleep stages and CNS arousals. Muscle tension and movements subside with deeper sleep and can also be useful in the diagnosis of PLMD and RLS. Nasal airflow, respiratory effort, and oxyhemoglobin saturation are instrumental in diagnosing sleep apnea and other sleep-related breathing disorders.

Table 15-20 lists the most common reasons for ordering polysomnography. A sleep study is not needed to diagnose RLS.

Table 15-21 lists standard polysomnographic measures.

Home Sleep Testing. Home sleep testing involves recording a limited number of cardiopulmonary parameters to assess patients for sleep-related breathing disorders. Home sleep testing is much less expensive than polysomnography. The test can record airflow, respiratory effort, heart

rhythm, snoring sounds, and oximetry. Several devices are commercially available that are capable of detecting sleep apnea in patients with moderate to severe pathophysiology. Negative studies are problematic because home sleep testing is less sensitive than full laboratory polysomnography. Patients with negative tests, notwithstanding obvious symptoms or comorbidity, should be scheduled for laboratory polysomnography. Also, home sleep testing does not check for the full spectrum of sleep disorders; therefore, the presence of residual symptoms after a breathing disorder is diagnosed in this manner and treated indicates a need for careful follow-up.

Multiple Sleep Latency Test. The multiple sleep latency test (MSLT) is essential for the workup of narcolepsy. Every 2 hours, beginning 2 hours after morning awakening, the patient is provided with 20-minute nap opportunities and instructed not to resist falling asleep. During sleep, the laboratory records electroencephalographic, electrooculographic, and submentalis electromyography activity to determine the sleep stage. The latency to sleep helps assess hypersomnolence, and the appearance of REM sleep on two or more nap opportunities confirms narcolepsy (or on one nap if the previous night's polysomnography revealed REM sleep within 15 minutes of sleep onset). If the patient falls asleep on a given nap opportunity, the laboratory will wake the patient 15 minutes after initial sleep onset. If the patient does not fall asleep after 20 minutes, the laboratory will terminate the session. The laboratory gives the patient five nap opportunities during 2-hour intervals across the day.

Maintenance of Wakefulness Test. Similar to the MSLT, the maintenance of wakefulness test (MWT) provides 40-minute test sessions at 2-hour intervals across the day. However, in this test, the laboratory instructs the patient to try to remain awake. This technique is used to assess treatment outcomes and is sometimes part of "fit for duty" testing. Patients are recorded in a darkened room while sitting in a comfortable chair or a bed with a bolster pillow. The first epoch of stage 2, 3, or 4 sleep or REM or three consecutive epochs of stage 1 mark unequivocal sleep onset. Falling asleep on MWT indicates some level of sleepiness. Any sleep latency of fewer than 8 minutes is abnormal. Sleep latency ranging from 8 to 40 minutes is of unknown significance.

Actigraphy. An actigraph is a device that measures and records movement. It is usually worn on the wrist (like a watch) and is a rough measure of the sleep–wake cycle. Depending on the model and the settings, it can make continuous recordings for days or weeks. It can be especially useful for assessing insomnia, circadian rhythm disorders, movement disorders, and an assortment of rare events.

Common Test Findings in Sleep–Wake Disorders

Hypersomnolence Disorder. The EEG sleep pattern is essentially the same as that found in healthy individuals who are sleep deprived (Fig. 15-2). Unlike a sleep-deprived individual, the sleep pattern continues in this profile even after several nights of extended sleep. Also, we may see elevated slow-wave sleep.

Narcolepsy. When the diagnosis is not clinically apparent, a nighttime polysomnographic recording reveals a characteristic sleep-onset REM period (Fig. 15-3). A test of daytime MSLT shows rapid sleep onset and usually one or more sleep-onset REM periods.

Table 15-19
Example Sleep History Questionnaire

Patient name _____	
Date _____	
Please check the appropriate box or give short answers for the followi	
	Ye
1. Do you feel sleepy or have sleep attacks during the day?	☐
2. Do you nap during the day?	☐
3. Do you have trouble concentrating during the day?	☐
4. Do you have trouble falling asleep when you first go to bed?	☐

5. Do you awaken during the night? ☐

6. Do you awaken more than once? ☐

7. Do you awaken too early in the morning? ☐

8. How long have you had trouble sleeping? ☐

What do you think precipitated the problem?

9. How would you describe your usual night's sleep (hours of sleep, quality of sleep, etc.)?

10. Does your schedule for sleep and rising on the weekend differ from what it is during the week? ☐

11. Do others live at home who interrupt your sleep? ☐

12. Are you regularly awakened at night by pain or the need to use the bathroom? ☐

13. Does your job require shift changes or travel? ☐

14. Do you drink caffeinated beverages (coffee, tea, or soft drinks)? ☐

15. Apart from difficulty in sleeping, what, if any, other medical problems do you have?

16. What sleep medications, prescription or nonprescription, do you take? (Please include the dosage, how often you take it, and for how many months or years you have taken it.)

17. What other prescription and over-the-counter medications do you regularly use? (Again, please include the dosage, the frequency, and the duration.)

_____
_____
_____

18. Have you ever suffered from depression, anxiety, or similar problems? ☐

19. Do you snore? ☐

Questions for the Sleep Partner

1. Does your sleep partner snore? ☐

2. Does your sleep partner seem to stop breathing repeatedly during the night? ☐

3. Does your sleep partner jerk his or her legs or kick you while he or she is sleeping? ☐

4. Have you ever experienced trouble sleeping? Please explain. ☐

_____
_____

Table 15-20
Indications for Polysomnography

Common Reasons

Diagnosis of sleep-related breathing disorders

Positive airway pressure (PAP) titration and assessment of treatment efficacy

Evaluation of sleep-related behaviors that are violent or may potentially harm the patient or bed partner

Differentiating narcolepsy from other hypersomnolence disorders

Differentiating parasomnias from nocturnal seizures

Other Possible Uses

Diagnose atypical parasomnias
Sleep-related problems secondary to neuromuscular disorders
Periodic limb movement disorder
Arousals secondary to seizure disorder
Excessive daytime sleepiness
Waking up gasping or choking
Narcolepsy (to assess sleep quality and quantity prior to a multiple sleep latency test)

Obstructive Sleep Apnea. On the polysomnogram, episodes of OSA appear as multiple periods of at least 10 seconds' duration in which nasal and oral airflow ceases either wholly or partially. Meanwhile, the abdominal and chest expansion leads indicate the continuing efforts of the diaphragm and accessory muscles of respiration to move air through the obstruction (Fig. 15-4). The arterial oxygen saturation drops, and often we see bradycardia, along with possible arrhythmias, such as premature ventricular contractions. In the end, an arousal reflex takes place, seen as a waking signal, and possibly as a motor artifact on the EEG channels. At this moment, sometimes called the *breakthrough,* the patient can make brief restless movements in bed.

Table 15-21
Common Polysomnographic Measures

Sleep latency: Period of time from turning out the lights until the appearance of stage 2 sleep

Early morning awakening: Time of being continuously awake from the last stage of the sleep until the end of the sleep record (usually at 7 am)

Sleep efficiency: Total sleep time or total time of the sleep record × 100

Apnea index: Number of apneas longer than 10 s/h of sleep

Nocturnal myoclonus index: Number of periodic leg movements per hour

Rapid eye movement (REM) latency: Period of time from the onset of sleep until the first REM period of the night

Sleep-onset REM period: REM sleep within the first 10 min of sleep

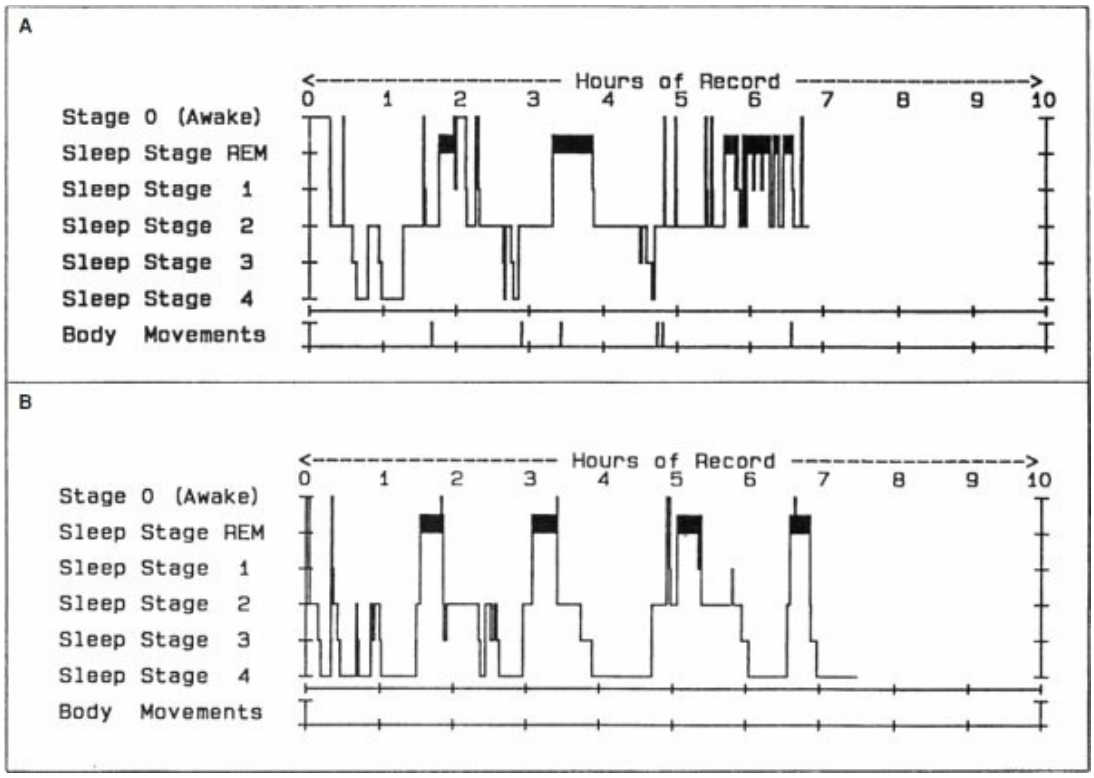

FIGURE 15-2
Sleep stage histograms comparing a normal sleep profile with that of a patient with hypersomnolence. **Panel A** illustrates the sleep pattern recorded in a healthy young adult. His sleep was interrupted several times by awakenings associated with other concurrent laboratory procedures; however, all parameters were within normal limits. **Panel B** depicts the sleep pattern of a patient with severe daytime sleepiness. The patient did not have narcolepsy or apnea. In the laboratory, sleep onset was rapid, sleep continued virtually without interruption, and he was extremely difficult to arouse. This recording was terminated after 7.5 hours to begin daytime testing; however, the patient's sleep revealed little indication of progressing toward a lighter state. In contrast to the normal sleep pattern, slow-wave sleep duration was elevated and it continued to emerge in alternation with REM sleep throughout the night. The patient awoke feeling unrefreshed and not satisfied with his sleep.

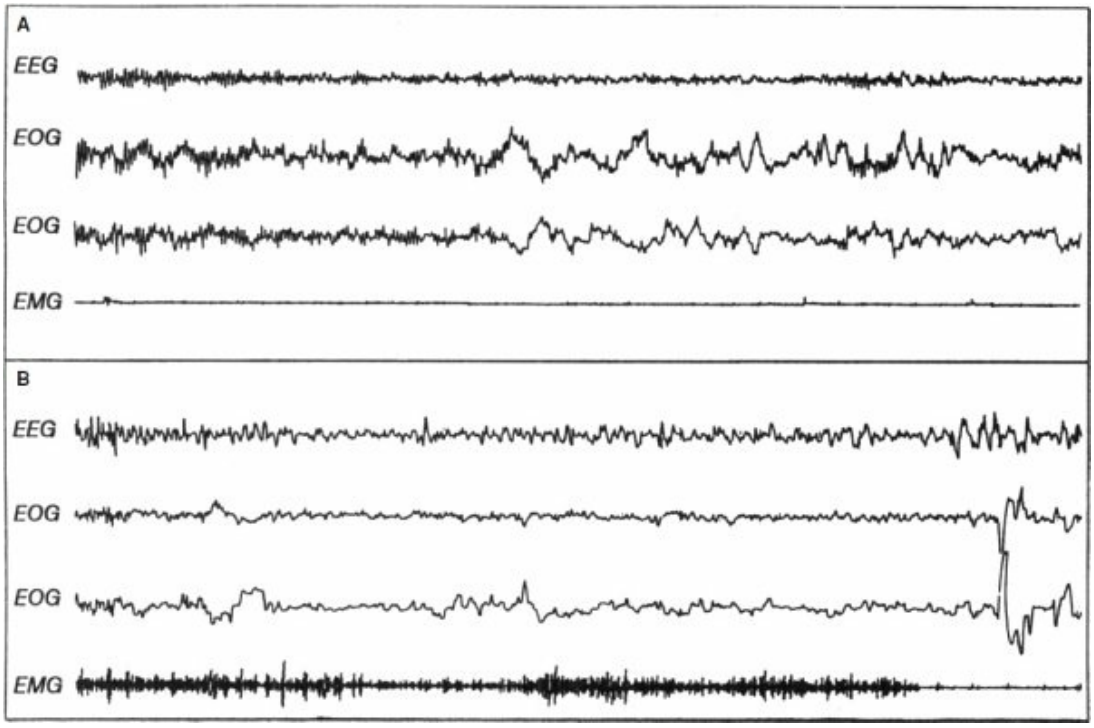

FIGURE 15-3
Polysomnographic tracing comparing normal sleep onset with that of a patient with narcolepsy. Each panel illustrates approximately 30 seconds of polysomnographic recording beginning with relaxed wakefulness. **Panel A** (normal sleep progression) shows a reduction of EEG α activity and development of slow rolling eye movements. **Panel B** shows the normally expected abatement of EEG α activity associated with increased θ activity and the appearance of a few slow eye movements. However, within 25 seconds (far right of figure) a swift loss of muscle tone occurs accompanied by rapid eye movements. This appearance of sleep-onset REM sleep (SOREM) characterizes narcolepsy and is part of the diagnostic criteria.

Central Sleep Apnea. The polysomnographic features of CSA are similar to those of OSA. However, during the periods of apnea, cessation of respiratory effort is seen in the abdominal and chest expansion leads. In Cheyne–Stokes breathing, polysomnography reveals five or more central apnea and hypopnea episodes per hour of sleep. In CSA, due to a medical disorder without Cheyne–Stokes breathing, diagnostic criteria require a polysomnographically verified rate of 5 or more central apneas and hypopneas per hour of sleep. Also, CSA due to medication or substance requires five or more central apneas per hour.

Sleep-Related Hypoventilation. Polysomnography demonstrates either episodes with elevated CO_2 levels and decreased respirations or, if not

monitoring CO_2, episodes of persistently low oxyhemoglobin levels that are not provoked by apnea or hypopnea.

Parasomnias. Sleep studies help to develop a differential diagnosis and rule out that the unusual behavior is secondary to a seizure, sleep-related breathing disorder, or another sleep disorder. Figures 15-5 to 15-7 give examples of polysomnograms for sleep terrors, RLS, and sleep-related bruxism.

DIFFERENTIAL DIAGNOSIS

In general, the differential diagnosis of sleep–wake disorders should include other individual sleep–wake disorders, psychiatric disorders, medical conditions, medications and substance use, and normal variants.

Insomnia Disorder

Many psychiatric disorders can cause a person to experience insomnia. For example, MDD, bipolar disorder, and PTSD can all present with sleep disruption. Many medications and substances also affect sleep, some of which we listed in Table 15-7. Other sleep–wake disorders should also be considered, including circadian rhythm sleep–wake disorder, RLS, sleep-related breathing disorders, narcolepsy, and parasomnias. Finally, one should consider whether the sleep pattern is a normal variant in the population (e.g., a “short sleeper”) or is occurring in the context of an acute stressor.

Hypersomnolence Disorder

Psychiatric disorders associated with increased sleep or fatigue, such as MDD or bipolar depression, should be considered part of the differential diagnosis. Certain medications or substances can also cause sedation, such as sedative–hypnotics and opioids. Other sleep–wake disorders should be considered, including circadian rhythm sleep–wake disorder, sleep-related breathing disorders, and parasomnias. Also, poor sleep quality can lead to excessive daytime sleepiness, and there are some persons for whom it is a normal variant to require more sleep (e.g., “long sleepers”).

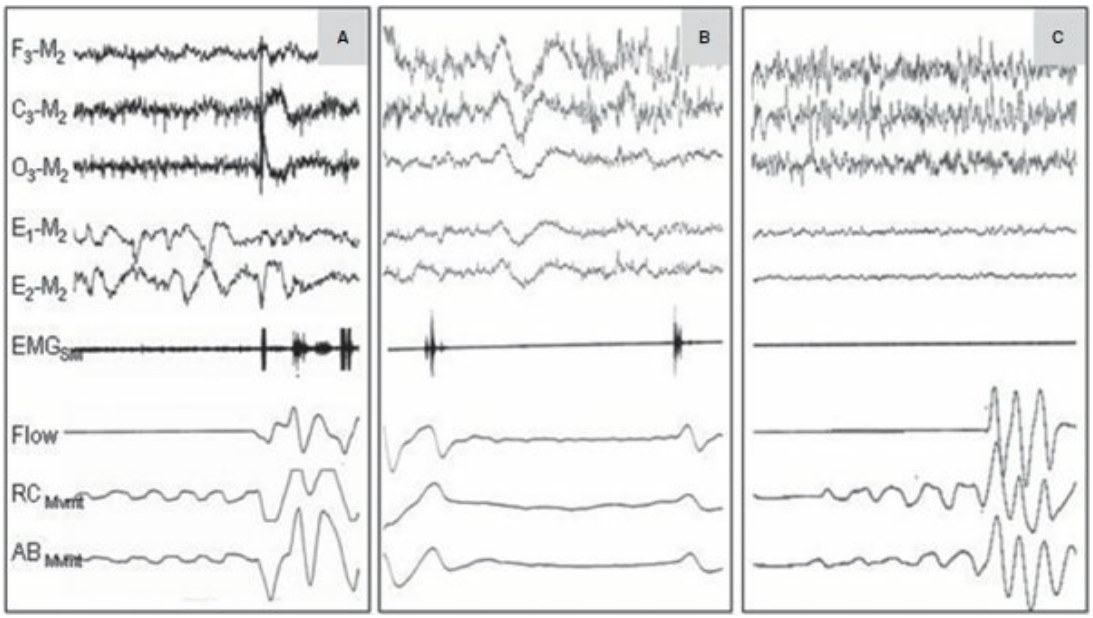

FIGURE 15-4

Polysomnographic tracings illustrating sleep apnea episodes. **Panel A** illustrates an obstructive sleep apnea, **Panel B** shows a central sleep apnea, and **Panel C** depicts a mixed sleep apnea. Note the presence of respiratory effort (rib cage and abdominal movement), notwithstanding cessation of airflow, throughout the obstructive apnea and during the latter portion of the mixed apnea. By contrast, respiratory effort is absent during the flow cessation throughout the central apnea and during the early portion of the mixed apnea. Notation: F_3 (left frontal scalp derivation); M_2 (right mastoid electrode location); C_3 (left central scalp derivation); O_3 (left occipital scalp derivation); E_1 (left outer canthus eye electrode location); E_2 (right outer canthus eye electrode location); EMG_{SM} (surface electrode electromyogram from submentalis muscle); Flow (airflow measured with nasal–nasal–oral thermistors); RC Mvmt (rib cage movement measured with inductive plethysmography); AB Mvmt (abdominal movement measured with inductive plethysmography). (From Hirshkowitz M, Sharafkhaneh A. Diagnostic assessment methods in adults. In: Kryger MH, Avidan AY, Berry RB, eds. *Atlas of Clinical Sleep Medicine*. 2nd ed. Elsevier Saunders: Philadelphia, PA; 2014:378.)

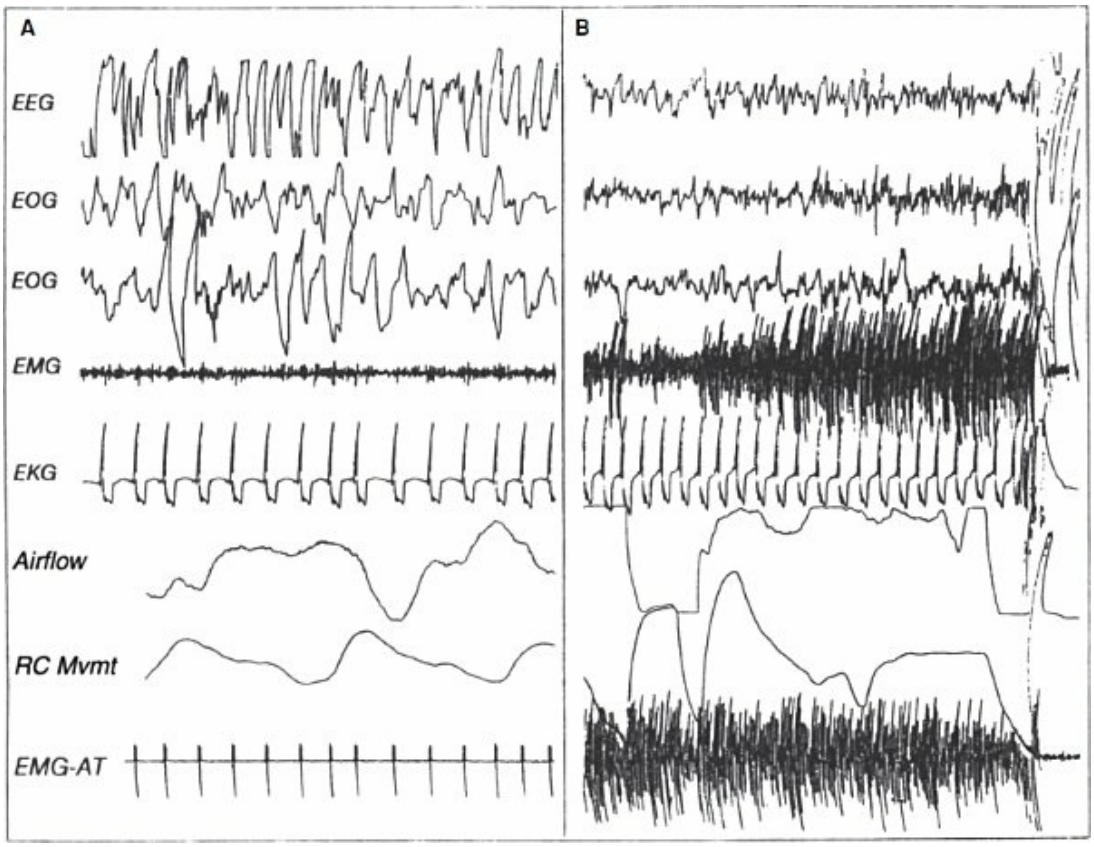

FIGURE 15-5

Polysomnographic tracing illustrating a sleep terror. **Panel A** shows approximately 14 seconds of tracing occurring immediately before the sleep terror. Prominent EEG slow-wave activity and other characteristics of stage 4 sleep are seen. **Panel B** shows the awakening, accompanied by tachycardia and movement. EEG activity is ambiguous and the patient eventually disconnected his electrodes as he thrashed about in bed (visible at far right of figure). Although the patient was screaming and greatly agitated, there was no report of dreaming. In the morning, there was little recollection of anything having occurred during the night.

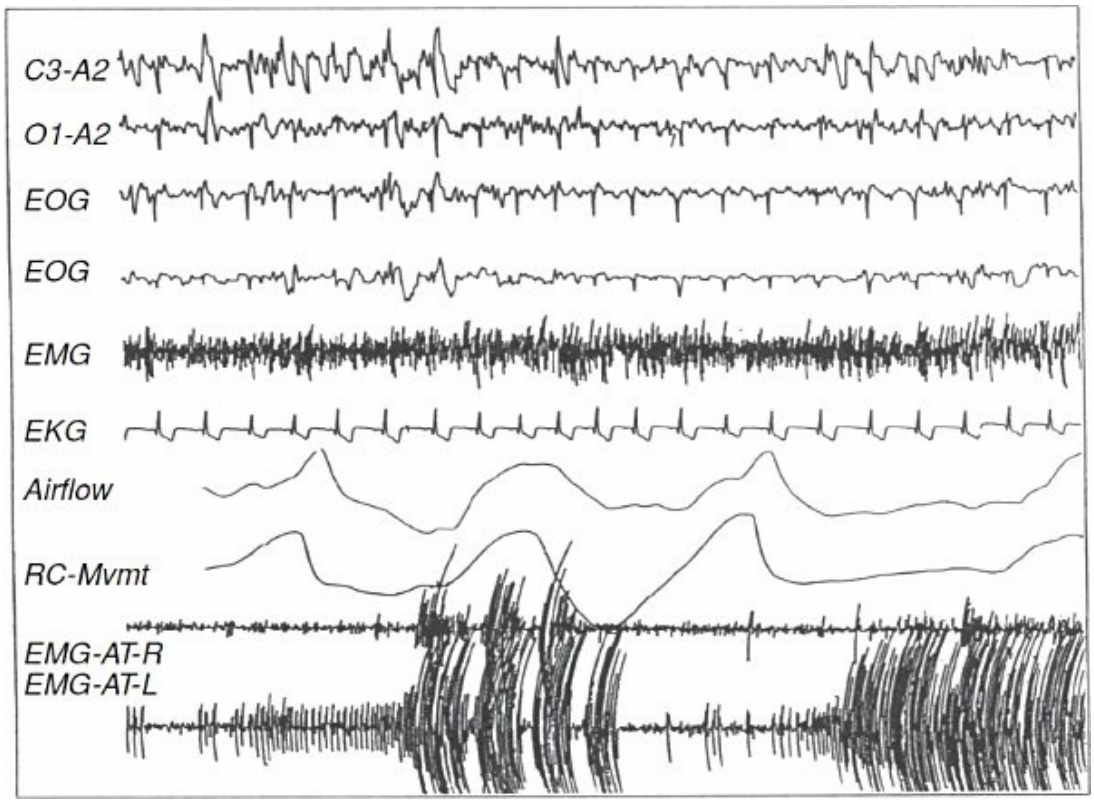

FIGURE 15-6

Restless legs syndrome. This patient presented with complaints of uncomfortable, crawling sensations in the legs when trying to fall asleep. Patients commonly report an urge to move the leg in order to dispel the sensation. This figure shows a bilateral pattern of leg EMG activity; however, the discharge is more pronounced in the left anterior tibialis (EMG-AT-L) than the right (EMG-AT-R). This pattern continued for more than an hour as the patient attempted to fall asleep; note that the sharp activity in central and occipital EEG (C3-A2 and O1-A2, respectively) and EOG is EKG artifact and not an EEG abnormality.

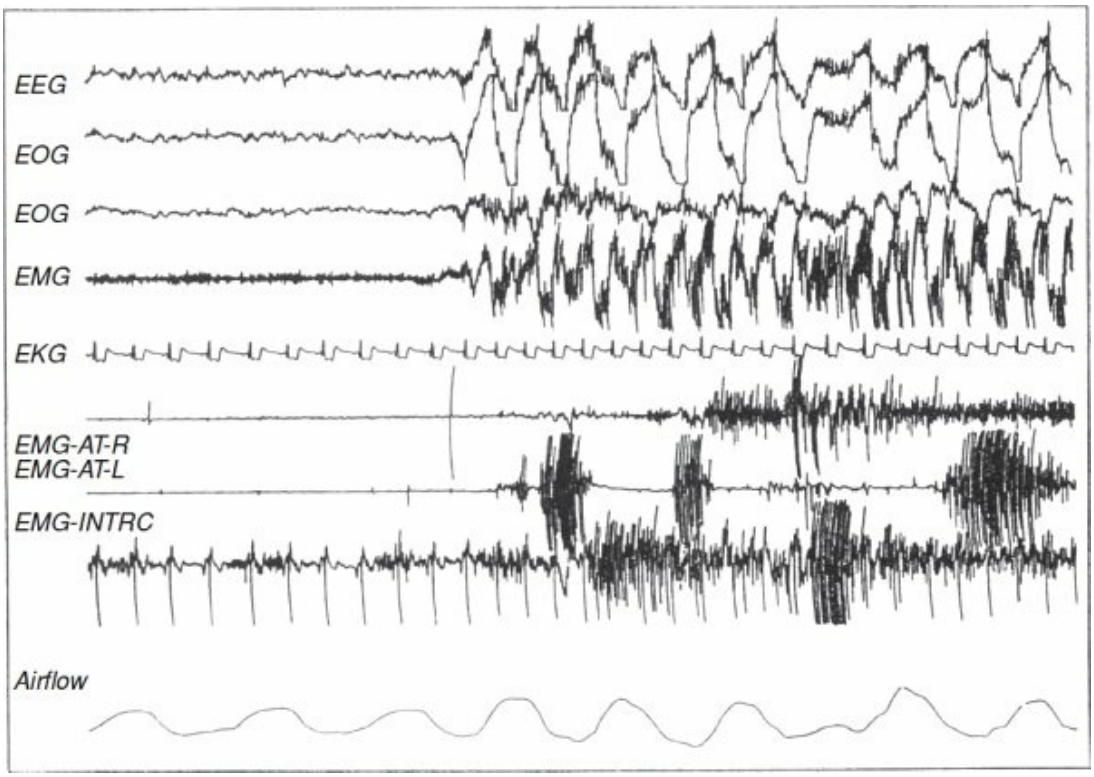

FIGURE 15-7
Polysomnographic tracing showing sleep-related bruxism. This figure showing approximately 25 seconds of tracing was obtained from a patient during an episode of bruxism. Bruxism can occur during any stage of sleep or wakefulness. The interference pattern of EEG-EOG-EMG channels is typical and reflects the rhythmic jaw movement and grinding of the teeth. This patient had many such episodes, some that caused awakening. Readily observable tooth damage and jaw pain were noted.

Table 15-22
Medical Disorders Causing Cataplexy

Disorders affecting the hypothalamus
Tumors
Sarcoidosis
Multiple sclerosis plaques
Paraneoplastic syndrome
Neimann–Pick type C disease
Coffin–Lowry syndrome

Narcolepsy

The differential diagnosis of narcolepsy includes many of the same disorders as the differential diagnosis of hypersomnolence disorder. Also, cataplexy can be confused for seizures or neurologic movement disorders (e.g., chorea). Many disorders can precipitate cataplexy, and we list some of the more common in Table 15-22. All of these disorders would preclude a diagnosis of narcolepsy. Cataplexy is usually absent in narcolepsy associated with multiple sclerosis, myotonic dystrophy, Prader–Willi syndrome, Parkinson disease, and multisystem atrophy.

Sleep-Related Breathing Disorders

The differential diagnosis of sleep-related breathing disorders includes many of the same disorders as the differential diagnosis of insomnia and hypersomnolence disorders, given the clinical presentation of fatigue and daytime sleepiness. Other possible conditions include panic attacks and attention-deficit/hyperactivity disorder (as repeated apneic episodes may lead to problems with focus, attention, and school- or job-related performance).

Circadian Rhythm Sleep–Wake Disorders

The differential diagnosis of circadian rhythm sleep–wake disorders includes insomnia disorder, other sleep–wake disorders, and mood disorders. One should also consider the possibility that the sleep pattern represents a normal variant.

Parasomnias and Sleep-Related Movement Disorders

The differential diagnosis of parasomnias can be complicated and should include other individual parasomnias, sleep-related breathing disorders, nocturnal seizures, panic attacks, other sleep–wake disorders, amnestic and dissociative syndromes, and numerous medical conditions. The differential diagnosis of RLS includes multiple medical conditions, such as arthritis, neuropathy, positional ischemia, and peripheral artery disease, to name a few, while the differential diagnosis of sleep-related bruxism should include nocturnal seizures.

COMORBIDITY

Insomnia Disorder

Several psychiatric disorders are often comorbid with insomnia. We list some common ones in Table 15-23. Nearly 90 percent of patients with MDD have insomnia. Of the most significant concern, insomnia is an independent risk factor for suicide in patients with MDD. Insomnia also predicts who will develop posttraumatic stress disorder following a trauma. For bipolar patients, lack of sleep may precipitate a manic episode. Patients with schizophrenia may deny having slept despite objective measures showing normal sleep.

Hypersomnolence Disorder

Many disorders also occur with hypersomnolence disorder, and we list some of these in Table 15-23. Medication use disorders are also common, particularly the stimulants, as the individual attempts to stay awake.

Narcolepsy

Narcolepsy is associated with psychiatric disorders in general, as well as many medical disorders. We list some of these in Table 15-23.

Sleep-Related Breathing Disorders

Table 15-23 lists several disorders associated with sleep-related breathing disorders. The section on diagnosis discusses conditions associated with central sleep apnea and sleep-related hypoventilation.

Circadian Rhythm Sleep–Wake Disorders

The circadian rhythm sleep–wake disorders can be associated with psychiatric and medical comorbidities; we list some of these in Table 15-23. The shift work type is especially associated with many psychiatric and medical disorders.

Parasomnias and Sleep-Related Movement Disorders

Each parasomnia has its own set of common comorbid diagnoses, and we list some examples in Table 15-23. Many individuals who present with RBD will go on to develop a neurodegenerative disorder.

TREATMENT APPROACH

Insomnia

Pharmacologic Treatment. For many years, benzodiazepines were the most commonly prescribed sedative–hypnotic medications for treating insomnia. Other benzodiazepine-receptor agonists (e.g., zolpidem and similar drugs) then emerged as an option to treat insomnia. The subsequent development of a low-dose antihistamine (doxepin), a melatonin receptor agonist (ramelteon), and an orexin antagonist (suvorexant) have more recently augmented the armamentarium of medications approved for treating insomnia. However, unapproved off-label (and not recommended) use of sedating antidepressants is commonplace. Additionally, a variety of over-the-counter (OTC) sleep aids is available. Nonprescription formulas include sedating antihistamines, protein precursors, and other substances. L-tryptophan was trendy and readily available at health food stores until an outbreak of eosinophilia led to pulling it off the shelves. However, the cause was a single manufacturer, and L-tryptophan subsequently became available OTC again. Melatonin is the leader among self-administered food additives believed by some to alleviate sleeplessness. Low-dose melatonin can improve sleep when used to align or reentrain the circadian rhythm with the desired sleep–wake schedule.

Table 15-23
Disorders That Are Commonly Comorbid with Various Sleep Disorders

Insomnia Disorder
Bipolar disorder
Generalized anxiety disorder
Major depressive disorder
Posttraumatic stress disorder
Schizophrenia

REM sleep behavior disorder
Narcolepsy
Neurodegenerative disorders
Restless legs syndrome
Depression
Anxiety
Attentional disorders
Iron deficiency

Drug manufacturers must rigorously test prescription medications in clinical trials; therefore, they hold an advantage over the virtually untested OTCs. Medication must be proven safe and effective to become FDA approved.

Most hypnotic medications are approved for short-, not long-term use. Exceptions include zolpidem-modified release, eszopiclone, and ramelteon, which the FDA approved for long-term therapy. When properly used, hypnotics can provide immediate and adequate relief from sleeplessness.

Insomnia, however, usually returns upon discontinuation of dosing.

The clinical practice guideline from the American Academy of Sleep Medicine recommends the use of suvorexant, eszopiclone, zaleplon, zolpidem, triazolam, temazepam, ramelteon, and doxepin for the treatment of insomnia (with specific agents having different indications for sleep-onset or sleep-maintenance insomnia). They recommend against the use of trazodone, tiagabine, diphenhydramine, melatonin, tryptophan, and valerian for insomnia treatment.

Cognitive-Behavioral Therapy for Insomnia. Cognitive-behavioral therapy for insomnia (CBTi), as a treatment modality, uses a combination of behavioral and cognitive techniques to overcome dysfunctional sleep behaviors, misperceptions, and distorted, disruptive thoughts about sleep. Behavioral techniques include universal sleep hygiene, stimulus control therapy, sleep restriction therapy, relaxation therapies, and biofeedback.

Studies repeatedly show significant, sustained improvement in sleep symptoms, including number and duration of awakenings and sleep latency, from CBTi. Short-term benefits are similar to that of medication, but CBTi tends to have lasting benefits, even 36 months after treatment. With the cessation of the medication, insomnia frequently returns and is sometimes accompanied by rebound insomnia. CBTi has no apparent adverse effects. There are no established “best practice” guidelines for length or quantity of sessions. CBTi, however, is not without limitations. Most data do not compare the efficacy of the individual components of CBTi. However, sleep hygiene education alone produces an insignificant effect on sleep. Intuitively, the multicomponent approach addresses many of the variables contributing to insomnia. Other limitations of CBTi include lack of or unavailability of trained specialists, cost of sessions, and noncoverage by insurance carriers.

The effects of CBTi take longer to emerge than the effects of medications. Usually, when patients finally come for treatment of their insomnia, they are desperate. It is challenging to convince them to try a therapy that may take several weeks before it will provide relief. Furthermore, patients do not assume a passive role in this type of therapy; they must be active participants. Many individuals not only want a “quick fix,” but they also want to undergo a procedure or have something administered rather than be involved in the therapeutic process. For optimal CBTi, patients must commit to come to

multiple sessions and also be open to the idea that modifying thoughts and behaviors about sleep can improve the symptoms of insomnia.

Although firmly focused on cognitive and behavioral issues, it helps to extend CBT just slightly into the psychodynamic sphere. For some patients with long-standing difficulty sleeping, being an insomniac becomes an essential part of their identity. There may be primary or secondary gain to such identification. It is the negative emotional response (i.e., anger at the inability to control one's sleep, feeling like a failure because one cannot sleep) to insomnia that contributes to its chronicity. In general, these individuals tend to internalize rather than express emotion, feel a heightened need for control, experience interpersonal difficulties and have significant discontent with past events. For this subset of people, neglecting the emotional response can limit the response to treatment and cause a relapse. The clinician will be better able to intercept barriers to treatment when they attune themselves to a patient's tendency to view something as a failure rather than a challenge.

Universal Sleep Hygiene. A patient's lifestyle can lead to a sleep disturbance. We usually call this *inadequate sleep hygiene*, referring to a problem in following generally accepted practices to aid sleep. These include, for instance, keeping regular hours of bedtime and arousal, avoiding excessive caffeine, not eating heavy meals before bedtime, and getting adequate exercise. Many behaviors can interfere with sleep and may do so by increasing nervous system arousal near bedtime or by altering circadian rhythms.

The focus of universal sleep hygiene is on modifiable environmental and lifestyle components that may interfere with sleep, as well as behaviors that may improve sleep. Because some of these behaviors are difficult to change, we should concentrate on only one or two items, chosen in collaboration with the patient, to address. The patient then has the best chance at a successful intervention. We list some sleep-enhancing directives in Table 15-24. Often a few simple alterations in a patient's habits or sleep environment are useful. The clinician, however, needs to spend time reviewing both the patient's routine and its irregularity. In some respects, the essence of insomnia is its variability. The day-to-day changes in behavior and the changing severity of sleeplessness can obscure the factors responsible for the problem. A carefully

explained program of sleep hygiene, with follow-up, represents a reasonably inexpensive intervention. Furthermore, improving sleep habits can enhance sleep, even when the primary cause of insomnia is physical. However, sleep hygiene education does not appear to be as effective as CBTi.

Stimulus Control Therapy. Stimulus control therapy is a deconditioning paradigm that aims to break the cycle of problems commonly associated with difficulty initiating sleep. By attempting to undo conditioning that undermines sleep, stimulus control therapy helps reduce both primary and reactive factors involved in insomnia. The rules attempt to enhance stimulus cues for sleeping and diminish associations with sleeplessness. The instructions are simple; however, the patient must consistently follow them. We list an example of these instructions in Table 15-25. Stimulus control therapy does work; however, we might not see results for weeks or even a month. If continually practiced, the bouts of insomnia lessen in both frequency and severity.

Sleep Restriction Therapy. Sleep restriction therapy is a strategy designed to increase sleep efficiency by decreasing the amount of time spent awake while lying in bed. This therapy targets explicitly those patients who lie awake in bed, unable to sleep. Restricting time in bed can help to consolidate sleep. If the patient reports sleeping only 5 hours of an 8-hour scheduled time in bed, reduce the time in bed. It is advised, however, not to reduce bedtime to less than 4 hours per night and to warn the patient about the hazards of daytime sleepiness. Sleep at other times during the day must be avoided, except in the elderly, who may take a 30-minute nap. The clinician then monitors sleep efficiency (time asleep as a percentage of the time in bed). When sleep efficiency reaches 85 percent (averaged over five nights), we should increase the time in bed by 15 minutes. Sleep restriction therapy produces a gradual and steady decline in nocturnal wakefulness.

Table 15-24
Do's and Don'ts for Good Sleep Hygiene

	DO	DON'T
Maintain regular hours of bedtime and arising	✓	

If you are hungry, have a light snack before bedtime	✓	
Maintain a regular exercise schedule	✓	
Give yourself approximately an hour to wind down before going to bed	✓	
If you are preoccupied or worried about something at bedtime, write it down and deal with it in the morning	✓	
Keep the bedroom cool	✓	
Keep the bedroom dark	✓	
Keep the bedroom quiet	✓	
Take naps		✓
Watch the clock so you know how bad your insomnia actually is		✓
Exercise right before going to bed in order wear yourself out		✓
Watch television in bed when you cannot sleep		✓
Eat a heavy meal before bedtime to help you sleep		✓
Drink coffee in the afternoon and evening		✓
If you cannot sleep, smoke a cigarette		✓
Use alcohol to help in going to sleep		✓
Read in bed when you cannot sleep		✓
Eat in bed		✓
Exercise in bed		✓
Talk on the phone in bed		✓

Relaxation Therapy and Biofeedback. The most critical aspect of relaxation therapy is to perform it properly. Self-hypnosis, progressive

relaxation, guided imagery, and deep breathing exercises are all useful if they produce relaxation. The goal is to find the optimal technique for each patient, but not all patients need help in relaxing. *Progressive muscle relaxation* is especially useful for patients who experience muscle tension. The patients should purposefully tense (5 to 6 seconds) and then relax (20 to 30 seconds) muscle groups, beginning at the head and ending at the feet. The patient should appreciate the difference between tension and relaxation. *Guided imagery* has the patient visualize a pleasant, restful scene, engaging all of his or her senses.

Table 15-25
Stimulus Control Instructions

1. Go to bed only when sleepy to maximize success.
2. Use the bed only for sleeping. Do not watch television in bed, do not read, do not eat, and do not talk on the telephone while in bed.
3. Do not lie in bed and become frustrated if unable to sleep. After a few minutes (do not watch the clock), get up, go to another room, and do something nonarousing until sleepiness returns. Repeat as often as needed.
4. Awaken at the same time every morning (regardless of bedtime, total sleep time, or day of week) and totally avoid napping.

Table 15-26
Abdominal Breathing

1. In the supine position, the patient should breathe normally through his or her mouth or nose, whichever is more comfortable, and attend to his or her breathing pattern.
2. While maintaining that rhythm, the patient should begin to breathe more with his or her abdomen and less with his or her chest.
3. The patient should pause for a half second after each breath cycle (in and out) and evaluate the breath. How did it feel? Was it

smooth? Eventually each breath will become uniform and smooth.
4. The patient should find a place where he or she can best feel the air move in and out. Concentrate on that spot and on the air moving in and out.
5. The patient should visualize intrusive thoughts as floating away; if there are too many thoughts, stop practicing and try again later.

Breathing exercises should be practiced for at least 20 min/day for 2 weeks. Once mastered, the technique should be used once at bedtime for 30 minutes. If it does not work, the patient should try a different night again. It is essential that the technique not become associated with failure to fall asleep. Table 15-26 gives example instructions for *abdominal breathing,* an important technique. The patient should become comfortable with each step before moving on to the next.

Biofeedback provides stimulus cues for physiologic markers of relaxation and can increase self-awareness. Muscle tension in the forehead or finger temperature is measured. Finger temperature rises when a person becomes more relaxed. Patients require thorough and adequate training; merely giving them an instruction tape is not especially helpful. Techniques are ideally mastered during the day for several weeks before application to the sleep problem; the patient preferably does this outside of the bed. By the time the patient uses the techniques in bed, the skill should be automatic. Relaxation techniques readily lend themselves to being combined with sleep hygiene and stimulus control therapies. Sometimes they make for good distractions from thinking about the inability to sleep. The ruminations fuel insomnia, and if the ruminator can be distracted, then the person may sleep better.

Cognitive Therapy. This practical, validated treatment for a variety of psychiatric conditions, including major depression and generalized anxiety, has been adapted for use with insomnia. The cognitive aspect of insomnia treatment targets the negative emotional response to an appraisal of a sleep-related situation. The negative emotional response produces emotional arousal, which in turn contributes to or perpetuates insomnia. People who have maladaptive cognitions tend to exaggerate the negative consequences of insomnia: “There must be something wrong with me if I cannot fall asleep in

40 minutes." They also tend to have unrealistic expectations about their sleep requirements: "If I do not sleep 8 hours a night, then my whole day will be ruined." The first step is to identify these cognitions, then challenge their validity, and finally, substitute them with more adaptive cognitions.

DH was a 42-year-old man with a 5-year history of insomnia. He identified losing his job and the birth of a colicky baby as precipitating factors in his inability to sleep. However, even after he found a new position with better hours and pay and with the child sleeping through the night, DH continued to experience difficulty falling and staying asleep. Perpetuating factors included low back pain and a spouse with periodic limb movement disorder. He reported spending 8 to 9 hours in bed each night and sleeping only 4 to 5 hours intermittently. He watched 1 hour of television in bed before turning out the light for bedtime. He spent hours watching the minutes tick away. He did not wake feeling rested, and when his alarm went off, he was frequently already awake and had thoughts such as, "I hardly slept at all last night. I should be able to get more sleep. There must be something wrong. Great, I'll be too tired to concentrate on anything today."

Examples of maladaptive thoughts: *"I should be able to get more sleep."* This is a faulty appraisal of sleeping ability and may relate to a need for control over sleep. This need for control interferes with having a more laissez-faire attitude about a few missed hours of rest. Such thoughts can also lead to feelings of frustration and anger. *"Great, I'll be too tired to concentrate on anything today."* This is a misattribution of daytime impairment due to poor sleep. DH was also magnifying the negative and discounting the positive with his black-and-white or all-or-nothing thinking. Could DH be too tired to concentrate on some things, but not all things? Might his inability to concentrate be due to a myriad of other factors? "*There must be something wrong with me (if I can't get enough sleep).*" This is catastrophizing and emotional reasoning: just because a person had a feeling does not mean that the thought or feeling is valid. A firmly held belief that sleeplessness negatively affects physical and mental health can set off catastrophizing. (Courtesy of Max Hirshkowitz, Ph.D., Rhoda G. Seplowitz-Hafkin, M.D., and Amir

Sharafkhaneh, M.D., Ph.D.)

Paradoxical Intention. This is a cognitive technique with conflicting evidence regarding its efficacy. In clinical practice, compliance is often a barrier, but it does work for a limited number of patients. The theory is that performance anxiety interferes with sleep onset. Thus, when the patient tries to stay awake for as long as possible rather than trying to fall asleep, performance anxiety will be reduced, and sleep latency will improve.

Hypersomnolence Disorder

We usually treat hypersomnolence disorder with medication. Although there are no medications approved for its treatment, physicians commonly use stimulants, with varying degrees of success. The wake-promoting substance modafinil or traditional psychostimulants (amphetamines and their derivatives) sometimes help manage the sleepiness. In addition to drug therapies, the overall therapeutic approach usually includes lifestyle adjustment, psychological counseling, drug holidays to reduce tolerance (if using stimulants), and careful monitoring of refills, general health, and cardiac status.

Narcolepsy

Currently, we cannot cure narcolepsy; however, the symptoms can be managed with either the wake-promoting substances modafinil or armodafinil, or traditional psychostimulants like amphetamines and their derivatives. The FDA has approved two medications for the treatment of narcolepsy as wake-promoting agents: pitolisant, which is a selective H_3 receptor antagonist/inverse agonist, and solriamfetol, a selective norepinephrine–dopamine reuptake inhibitor. For managing cataplexy, clinicians often administer REM sleep–suppressing drugs (e.g., many antidepressants). This approach capitalizes on the REM sleep-suppressant properties of these drugs. Because cataplexy is presumably an intrusion of REM sleep phenomena into the awake state, the rationale is clear. Many reports indicate that imipramine and protriptyline are quite effective in reducing or eliminating cataplexy. Selective serotonin reuptake inhibitors

have gained popularity because they are associated with fewer side effects than the tricyclic antidepressants. Sodium oxybate has proven extremely useful for reducing cataplexy, even in cases where clinicians thought that the cataplexy was intractable. Studies also suggest that sodium oxybate helps improve sleep and relieves some of the sleepiness associated with narcolepsy. Although drug therapy is the treatment of choice, the overall therapeutic approach should include scheduled naps, lifestyle adjustment, psychological counseling, drug holidays to reduce tolerance, and careful monitoring of drug refills, general health, and cardiac status.

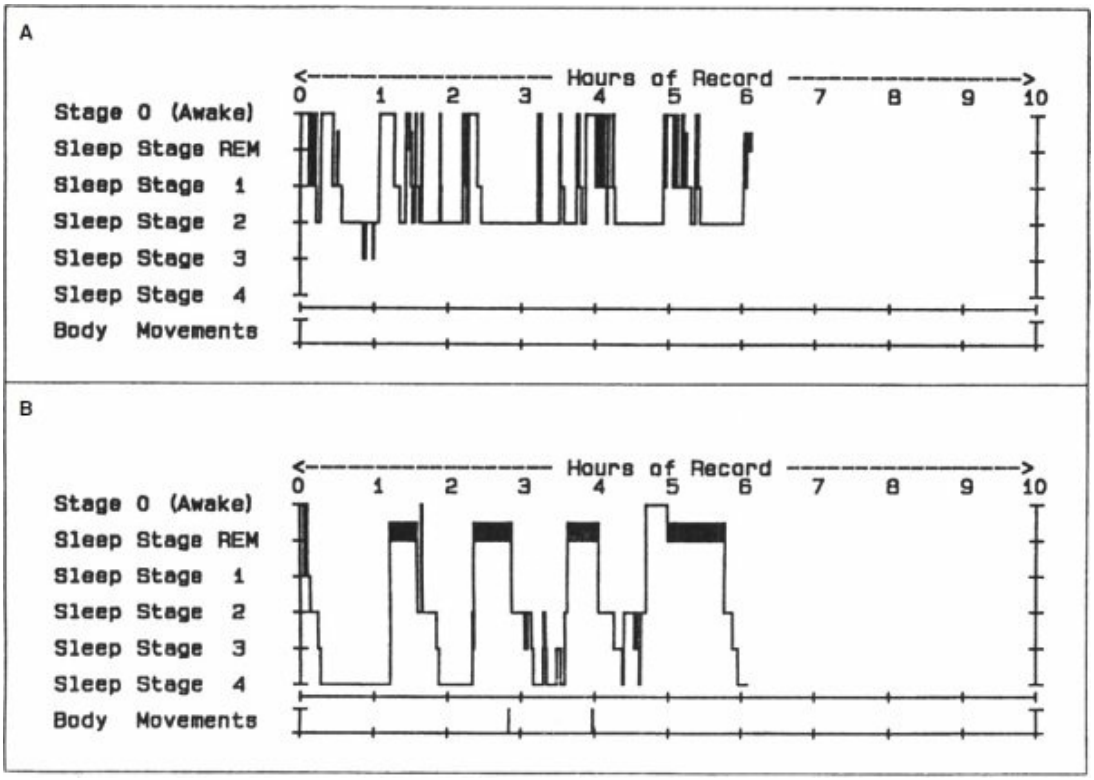

FIGURE 15-8
Sleep histogram showing CPAP-related sleep improvement. Sleep stage histogram illustrating the immediate, dramatic improvement in sleep architecture produced by treating obstructive sleep apnea with continuous positive airway pressure (CPAP) therapy. **Panel A** illustrates the abnormal sleep pattern on a night when the patient had more than 200 episodes of obstructive sleep apnea. Sleep is disturbed by frequent awakenings while REM and slow-wave (stages 3 and 4) sleep are nearly absent. **Panel B** shows data from the same patient being treated with CPAP on the next night. Normalization of sleep continuity with a massive rebound in REM and slow-wave sleep is evident.

Breathing-Related Sleep Disorders

Obstructive Sleep Apnea-Hypopnea. A number of treatments are available for OSA, including PAP, oral appliances, positional therapy, surgical intervention, and weight loss. Medications have not been useful for treating OSA. Wakefulness promoting agents, such as modafinil, solriamfetol, and pitolisant, may help with the residual sleepiness that may persist despite the use of other OSA treatments such as PAP. However, these medications do not address the pathophysiology of airway occlusion.

POSITIVE AIRWAY PRESSURE. PAP is the preferred treatment for OSA (Fig. 15-8). The PAP apparatus consists of a fan-driven blower, a nasal mask or oronasal interface, and tubing connecting the two. The airflow through the interface (usually a mask or nasal pillows) provides a positive pressure that offsets oropharyngeal collapse produced by inspiratory negative thoracic pressure. In this manner, it acts as a pneumatic splint, thereby maintaining the airway. When appropriately titrating the pressure, even the most severe sleep apnea can be alleviated. Results are often dramatic. PAP devices come in several varieties. The most common are systems that provide a preset continuous positive airway pressure (CPAP). For individuals who find it difficult to exhale against a continuous pressure, bilevel positive airway pressure (BPAP) may provide a solution. BPAP devices have different inspiratory and expiratory pressure settings. More recently, systems that sense the patient's changes in airway resistance and automatically adjust the positive airway pressure have been gaining popularity. Such automatic positive airway pressure (APAP) systems should theoretically be able to adapt to changes in pressure requirements produced by sleep deprivation, medications, weight change, sleep stage, illness, and aging. Finally, there are timed bilevel and servo-ventilation systems, but these fall into the category of noninvasive positive pressure ventilation (NIPPV) systems, which are more appropriate for treating other pulmonary diseases and breathing problems in neuromuscular diseases. The tremendous efficacy and remarkable safety of PAP therapies have made them the standard of care for patients who can tolerate sleeping with the machine. The principal therapeutic challenge is utilization. Patient education and systematic follow-up are crucial. When problems with the interface, the pressure, nasal stuffiness, and other barriers to routine, nightly use arise, we should remedy these quickly to ensure therapeutic adherence. When used properly, the success of PAP therapy has

rendered surgical intervention a secondary option, resorted to mainly after PAP failure, rejection, or nonadherence.

ORAL APPLIANCE. Oral appliances represent another therapeutic option that is gaining popularity. A variety of oral appliances have also been developed to treat snoring and can provide benefit for mild to moderate OSA cases. The general approach is to manipulate the position of the mandible, lift the palate, or retain the tongue. Randomized trials indicate that some oral appliances improve airway patency sufficiently. However, in patients with severe OSA, improvement does not always reach satisfactory levels; therefore, follow-up evaluations are critically important.

POSITIONAL THERAPY. In some patients, sleep-disordered breathing occurs only in the supine position. In such situations, preventing patients from sleeping on their backs may produce beneficial results. Tennis balls sewn onto or placed into pockets on the back of the nightshirt or foam wedges may accomplish this goal. Although such interventions seem to be useful in clinical practice, large-scale systematic clinical trials are needed.

SURGICAL INTERVENTION. Aggressive surgical treatments evolved soon after OSA's pathophysiologic and potentially life-threatening consequences were recognized. The earliest surgical intervention aimed to create a patent airway; thus, in the late 1970s, tracheostomies were performed on individuals with severe apnea. Although no longer the preferred treatment, it remains a standard against which we judge newer, more refined therapies. Second-generation surgical approaches attempt to correct airway obstructions and malformations. Early studies of uvulopalatopharyngoplasty (UPPP) suggested that modification of the soft palate effectively relieved most sleep apnea. Later follow-up results were less impressive. Approximately 30 to 50 percent of patients with sleep apnea benefit from UPPP. These patients are likely those with oropharyngeal obstruction; thus, careful attention to selection criteria presumably improves outcomes. However, if obstruction occurs in the posterior airway space (PAS), maxillomandibular surgery may be appropriate. In retrognathic patients or patients with cephalometrics revealing compromised PAS, moving the jaw forward can achieve impressive normalization of breathing during sleep.

WEIGHT LOSS. Weight loss is known to help many patients. However, because losing weight and keeping it off is difficult and unreliably achieved, the prudent clinician should recommend weight loss but also rely on other therapies.

CSA due to High-Altitude Periodic Breathing. We can treat CSA due to high-altitude periodic breathing with acetazolamide, which lowers serum pH and increases the respiratory drive. Acetazolamide side effects include metabolic acidosis, electrolyte imbalance, anaphylaxis, Stevens–Johnson syndrome, toxic epidermal necrolysis, and agranulocytosis. Common reactions include but are not limited to fatigue, anorexia, taste changes, polyuria, diarrhea, melena, tinnitus, and photosensitivity.

Circadian Rhythm Sleep–Wake Disorders

Light Therapy. Research indicates that exposing an individual to bright lights can reset the circadian pacemaker. This seems especially the case when the light is bright (higher than 10,000 lux) or in the blue spectrum. With the precise timing of bright light exposure, we can reset the biologic clock. Exposure to light modifies the set-point of the biologic clock. Using core body temperature as a physiologic marker, one can use bright lights to produce a phase delay when presented before the temperature nadir. By contrast, light exposure after the temperature nadir evokes phase advance. The closer one presents light to the point of inflection (temperature nadir), the more robust is the response in altering the cycle. Thus, we can use early-morning bright-light therapy to phase advance individuals with delayed sleep phase syndrome.

Similarly, exposure to bright light in the evening can help patients with advanced sleep phase syndrome. The blue part of the light spectrum is the crucial ingredient in phase setting and shifting. Therefore, blue light exposure (or limitation with blue-blocking eyewear) at specific times can provide therapeutic benefit. Clinicians are using light therapy to reset the circadian rhythm of shift workers, astronauts, and individuals experiencing jet lag.

Medication. Researchers posit that melatonin secretion acts as the biologic substrate for the internal circadian oscillator. Under normal circumstances,

melatonin levels begin to rise at dusk and remain elevated until dawn. Bright light suppresses the release of melatonin. Melatonin, in a sense, is the signal of darkness in the brain. As such, we can use it clinically to manage sighted patients with disturbed sleep–wake cycles. Melatonin is available over the counter in the United States. A prescription synthetic melatonin agonist (ramelteon) is also available. Ramelteon is FDA approved for treating patients with sleep-onset insomnia but is used off label for the entire spectrum of circadian rhythm sleep disorders. Outside the United States, a sustained-release prescription form of melatonin is available. Of interest, the only medication approved for shift work sleep disorder is the wake-promoting compound modafinil. Modafinil treats sleepiness occurring during night shift work.

Chronotherapy. Chronotherapy is one technique used to reset the biologic clock. It involves progressively phase delaying a person until synchronizing the circadian oscillator with the desired sleep–wake schedule. Most young and middle-aged adults have a propensity to phase delay the circadian sleep–wake rhythm progressively anyhow. Thus, phase delaying each night by 2 to 3 hours is simpler than phase advancing because it capitalizes on a natural tendency. Halting the phase delay at the appropriate moment and maintaining the desired synchrony can be a challenge. The patient also has to cope with an odd sleep–wake schedule for the better part of a week during therapy (which can interfere with school or work). For these reasons, the development of light therapy and pharmacologic interventions has overshadowed chronotherapy.

Parasomnias and Sleep-Related Movement Disorders

Nightmare Disorder. Treatment using behavioral techniques can be helpful. Desensitization and exposure therapy, image rehearsal therapy, lucid dream therapy, and cognitive therapy can help address nightmare disorder. Additionally, evidence for the use of prazosin, a CNS α-1 receptor antagonist, in the treatment of PTSD-related nightmares is growing. Nitrazepam and triazolam may also be helpful.

Recurrent Isolated Sleep Paralysis. Improved sleep hygiene and

assuring sufficient sleep are first-line therapies. Sometimes, if the individual voluntarily makes very–rapid eye movements or is touched by another person, the episode will usually terminate.

Sleep Enuresis. Treating sleep enuresis involves medication, behavioral interventions, or both. Among medications, desmopressin acetate is the preferred choice. Other medications used to treat sleep enuresis include imipramine and oxybutynin chloride. Behavioral treatments, including bladder training, using conditioning devices (bell and pad), diet modification, and fluid restriction, have reported success when properly administered. Other treatments include psychotherapy, motivational strategies, and hypnotherapy.

Restless Legs Syndrome. Pharmacologically, the dopaminergic agonists pramipexole, rotigotine, and ropinirole are FDA approved and represent the treatment of choice. Other agents used to treat RLS include dopamine precursors (e.g., levodopa), benzodiazepines, opiates (including prolonged-release oxycodone–naloxone), and antiepileptic drugs (e.g., gabapentin, pregabalin). When iron deficiency is present, or when ferritin levels are low, iron supplementation can also be helpful. Nonpharmacologic treatment includes avoiding alcohol or nicotine use close to bedtime, massaging the affected parts of the legs, taking hot baths, applying hot or cold to the affected areas, magnetic or electric stimulation therapy, and moderate exercise.

Periodic Limb Movement Disorder Treatment. Pharmacotherapy for PLMD associated with RLS is the same as for RLS. Clinical trials of pharmacotherapy for other forms of PLMD are lacking. However, benzodiazepines, especially clonazepam, reportedly improve sleep in patients with PLMD.

Sleep-Related Bruxism. The usual treatment involves having the patient wear an oral appliance to protect the teeth during sleep. There are two basic types of appliances: the soft one (mouth guard) is typically used in the short term, whereas the hard acrylic one (bite splint) is used long term and requires regular follow-up. Relaxation, biofeedback, hypnosis, physical therapy, and

stress management can also treat sleep bruxism. A variety of drug therapies have been tried (benzodiazepines, muscle relaxants, dopaminergic agonists, and propranolol); however, reliable outcome data are not available. Botulinum toxin can also improve the frequency of bruxism episodes.

Benign Sleep Myoclonus of Infancy. This benign condition typically lasts a few days to several months and does not need to be treated.

Propriospinal Myoclonus at Sleep Onset. Treatment with clonazepam or anticonvulsants may be useful.

16 Human Sexuality and Sexual Dysfunctions

Sexuality is a broad topic, and no brief synopsis can do it justice. For the psychiatrist, it loosely divides into the subjects of normal sexuality, sexual dysfunction, paraphilias, and gender dysphoria. As with other chapters, we are focusing on the disorders that might bring a patient to a psychiatrist. There are two broad categories of disorders that we loosely group under sexual disorders: sexual dysfunction and paraphilias. By sexual dysfunctions, we are referring to disorders of normal sexual functioning. The paraphilias are unusual expressions of sexuality that are considered aberrant or even illegal. As these represent fundamentally different problems that require very different approaches, we separate these into two sections. We then discuss normal sexuality as part of our consideration of the pathology and etiology of these disorders. We will discuss gender dysphoria in the next section.

For a fuller discussion, we would refer the reader to Virginia Sadock's excellent review of the subject in the *Comprehensive Textbook.*

SEXUAL DYSFUNCTIONS

The essential features of sexual dysfunctions are an inability to respond to sexual stimulation, or the experience of pain during the sexual act. Dysfunction can be defined by a disturbance in the subjective sense of pleasure or desire usually associated with sex, or by the objective performance. According to ICD-10, sexual dysfunction refers to a person's inability "to participate in a sexual relationship as he or she would wish."

In DSM-5, the sexual dysfunctions include male hypoactive sexual desire disorder, female sexual interest/arousal disorder, erectile disorder, female

orgasmic disorder, delayed ejaculation, premature (early) ejaculation, genito-pelvic pain/penetration disorder, substance/medication-induced sexual dysfunction, other specified sexual dysfunction, and unspecified sexual dysfunction. We diagnose sexual dysfunctions only when they are a significant part of the clinical picture. If more than one dysfunction exists, we should diagnose them all. Sexual dysfunctions can be lifelong or acquired, generalized or situational, and result from psychological factors, physiologic factors, combined factors, and numerous stressors, including prohibitive cultural mores, health and partner issues, and relationship conflicts. If the dysfunction is attributable entirely to a general medical condition, substance use, or adverse effects of medication, then sexual dysfunction due to a general medical condition or substance-induced sexual dysfunction is diagnosed. DSM-5 indicates the severity of the dysfunction by whether the patient's distress is mild, moderate, or severe.

Sexual dysfunctions are frequently associated with other mental disorders, such as depressive disorders, anxiety disorders, personality disorders, and schizophrenia. In many instances, sexual dysfunction is comorbid with another psychiatric disorder. If the dysfunction is mostly attributable to an underlying psychiatric disorder, we should only diagnose the underlying disorder. Sexual dysfunctions are usually self-perpetuating, with the patients increasingly subjected to ongoing performance anxiety and a concomitant inability to experience pleasure. In relationships, the sexually functional partner often reacts with distress or anger due to feelings of deprivation or a sense that he or she is an insufficiently attractive or adequate sexual partner. In such cases, the clinician must consider whether the sexual problem preceded or arose from relationship difficulties and weigh whether a diagnosis of sexual dysfunction relevant to relationship issues is appropriate.

A sex history provides essential information about patients, regardless of the presence of a sexual disorder or whether that is the patient's chief complaint. The information can be obtained gradually through open-ended questions. The outline in Table 16-1 provides a guide to the topics to be covered.

Desire, Interest, and Arousal Disorders

Male Hypoactive Sexual Desire Disorder. Male hypoactive sexual

desire disorder is a deficiency or absence of sexual fantasies and desire for sexual activity for a minimum duration of approximately 6 months (Table 16-2). Men for whom this is a lifelong condition have never experienced many spontaneous erotic/sexual thoughts. Minimal spontaneous sexual thinking or minimal desire for sex ahead of sexual experiences is not a diagnosable disorder in women, primarily if the sexual encounter then triggers the desire. The reported prevalence of low desire is highest at the younger and older ends of the age spectrum, with only 2 percent of men ages 16 to 44 affected by this disorder. A reported 6 percent of men ages 18 to 24, and 40 percent of men ages 66 to 74, have problems with sexual desire. Some men may confuse decreased desire with decreased activity. Their erotic thoughts and fantasies are undiminished, but they no longer act on them due to health issues, unavailability of a partner, or another sexual dysfunction such as erectile disorder.

A variety of causative factors are associated with low sexual desire. Patients with desire problems often use inhibition of desire defensively, to protect against unconscious fears about sex.

Abstinence from sex for a prolonged period sometimes results in suppression of sexual impulses. Loss of desire may also be an expression of hostility to a partner or the sign of a deteriorating relationship. The presence of desire depends on several factors: biologic drive, adequate self-esteem, the ability to accept oneself as a sexual person, the availability of an appropriate partner, and a good relationship in nonsexual areas with a partner. Damage to, or absence of, any of these factors can diminish desire.

In making the diagnosis, clinicians must evaluate a patient’s age, general health, any medication regimen, and life stresses. The clinician must attempt to establish a baseline of sexual interest before the disorder began. The need for sexual contact and satisfaction varies among persons. We should not make a diagnosis unless the lack of desire is a source of distress to a patient.

Table 16-1
Taking a Sex History

I. Identifying data
A. Age
B. Sex

C. Occupation
D. Relationship status—single, married, number of times previously married, separated, divorced, cohabiting, serious involvement, casual dating (difficulty forming or keeping relationships should be assessed throughout the interview)
E. Sexual orientation—heterosexual, homosexual, or bisexual (this may also be ascertained later in the interview)

II. Current functioning
A. Unsatisfactory to highly satisfactory
B. If unsatisfactory, why?
C. Feeling about partner satisfaction
D. Dysfunctions?—e.g., lack of desire, erectile disorder, inhibited female interest/arousal, anorgasmia, premature ejaculation, retarded ejaculation, pain associated with intercourse (dysfunction discussed below)
1. Onset—lifelong or acquired
a. If acquired, when?
b. Did onset coincide with drug use (medications or illegal recreational drugs), life stresses (e.g., loss of job, birth of child), interpersonal difficulties
2. Generalized—occurs in most situations or with most partners
3. Situational
a. Only with current partner
b. In any committed relationship
c. Only with masturbation
d. In socially proscribed circumstance (e.g., affair)
e. In definable circumstance (e.g., very late at night, in parental home, when partner initiated sex play)
E. Frequency—partnered sex (coital and noncoital sex play)
F. Desire/libido—how often are sexual feelings, thoughts, fantasies, dreams, experienced? (per day, week, etc.)
G. Description of typical sexual interaction
1. Manner of initiation or invitation (e.g., verbal or physical? Does same person always initiate?)

2. Presence, type, and extent of foreplay (e.g., kissing, caressing, manual or oral genital stimulation)
3. Coitus? positions used?
4. Verbalization during sex? if so, what kind?
5. Afterplay? (whether sex act is completed or disrupted by dysfunction); typical activities (e.g., holding, talking, return to daily activities, sleeping)
6. Feeling after sex: relaxed, tense, angry, loving

H. Sexual compulsivity?—intrusion of sexual thoughts or participation in sexual activities to a degree that interferes with relationships or work, requires deception and may endanger the patient

III. Past sexual history

A. Childhood sexuality

1. Parental attitudes about sex—degree of openness or reserve (assess unusual prudery or seductiveness)
2. Parents' attitudes about nudity and modesty
3. Learning about sex
   a. From parents? (initiated by child's questions or parent volunteering information? which parent? what was child's age?) subjects covered (e.g., pregnancy, birth, intercourse, menstruation, nocturnal emission, masturbation)
   b. From books, magazines, or friends at school or through religious group?
   c. Significant misinformation
   d. Feeling about information
4. Viewing or hearing primal scene—reaction?
5. Viewing sex play or intercourse of person other than parent
6. Viewing sex between pets or other animals

B. Childhood sex activities

1. Genital self-stimulation before adolescence; age? reaction if apprehended?
2. Awareness of self as boy or girl; bathroom sensual activities? (regarding urine, feces, odor, enemas)

3. Sexual play or exploration with another child (playing doctor)—type of activity (e.g., looking, manual touching, genital touching); reactions or consequences if apprehended (by whom?)

IV. Adolescence

A. Age of onset of puberty—development of secondary sex characteristics, age of menarche for girl, wet dreams or first ejaculation for boy (preparation for and reaction to)

B. Sense of self as feminine or masculine—body image, acceptance by peers (opposite sex and same sex), sense of sexual desirability, onset of coital fantasies

C. Sex activities

1. Masturbation—age begun; ever punished or prohibited? method used, accompanying fantasies, frequency (questions about masturbation and fantasies are among the most sensitive for patients to answer)
2. Homosexual activities—ongoing or rare and experimental episodes, approached by others? If homosexual, has there been any heterosexual experimentation?
3. Dating—casual or steady, description of first crush, infatuation, or first love
4. Experiences of kissing, necking, petting (“making out” or “fooling around”), age begun, frequency, number of partners, circumstances, type(s) of activity
5. Orgasm—when first experienced? (may not be experienced during adolescence), with masturbation, during sleep, or with partner? with intercourse or other sex play? frequency?
6. First coitus—age, circumstances, partner, reactions (may not be experienced during adolescence); contraception and/or safe sex precautions used

V. Adult sexual activities (may be experienced by some adolescents)

A. Premarital sex

1. Types of sex play experiences—frequency of sexual interactions, types and number of partners

2. Contraception and/or safe sex precautions used
3. First coitus (if not experienced in adolescence) age, circumstances, partner
4. Cohabitation—age begun, duration, description of partner, sexual fidelity, types of sexual activity, frequency, satisfaction, number of cohabiting relationships, reasons for breakup(s)
5. Engagement—age, activity during engagement period with fiancé(e), with others; length of engagement

B. Marriage (if multiple marriages have occurred, explore sexual activity, reasons for marriage, and reasons for divorce in each marriage)
1. Types and frequency of sexual interaction—describe typical sexual interaction (see above), satisfaction with sex life? view of partner's feeling
2. First sexual experience with spouse—when? what were the circumstances? was it satisfying? disappointing?
3. Honeymoon—setting, duration, pleasant or unpleasant, sexually active, frequency? problems? compatibility?
4. Effect of pregnancies and children on marital sex
5. Extramarital sex—number of incidents, partner; emotional attachment to extramarital partners? feelings about extramarital sex
6. Postmarital masturbation—frequency? effect on marital sex?
7. Extramarital sex by partner—effect on interviewee
8. Ménage à trois or multiple sex (swinging)
9. Areas of conflict in marriage (e.g., parenting, finances, division of responsibilities, priorities)

VI. Sex after widowhood, separation, divorce—celibacy, orgasms in sleep, masturbation, noncoital sex play, intercourse (number of and relationship to partners), other

VII. Special issues
A. History of rape, incest, sexual or physical abuse
B. Spousal abuse (current)

C. Chronic illness (physical or psychiatric)
D. History or presence of sexually transmitted diseases
E. Fertility problems
F. Abortions, miscarriages, or unwanted or illegitimate pregnancies
G. Gender identity conflict—(e.g., transsexualism, wearing clothes of opposite sex)
H. Paraphilias—(e.g., fetishes, voyeurism, sadomasochism)

Female Sexual Interest/Arousal Disorder. The combination of interest (or desire) and arousal into one dysfunction category reflects the recognition that women do not necessarily move stepwise from desire to arousal, but often experience desire synchronously with, or even following, beginning feelings of arousal. This is particularly true for women in long-term relationships. As a corollary, women experiencing sexual dysfunction may experience either inability to feel interest or arousal, and they may also have difficulty achieving orgasm or experience pain. Some may experience dysfunction across the entire range of sexual response. Complaints in this dysfunction category present variously as a decrease or paucity of erotic feelings, thoughts, or fantasies; a decreased impulse to initiate sex; a decreased or absent receptivity to partner overtures; or an inability to respond to partner stimulation (Table 16-3).

A complicating factor in this diagnosis is that a subjective sense of arousal is often poorly correlated with genital lubrication in both normal and dysfunctional women. Therefore, complaints of lack of pleasure are sufficient for this diagnosis even when vaginal lubrication and congestion are present. A woman complaining of lack of arousal may lubricate vaginally, but may not experience a subjective sense of excitement. Alterations in testosterone, estrogen, prolactin, and thyroxin levels occur in female sexual arousal

disorder. Also, medications with antihistaminic or anticholinergic properties cause a decrease in vaginal lubrication.

We should evaluate factors such as life stresses, aging, menopause, adequate sexual stimulation, and general health before making this diagnosis. Relationship problems are particularly relevant to acquired interest/arousal disorder. In one study of couples with markedly decreased sexual interaction, the most prevalent etiology was marital discord.

Male Erectile Disorder. Male erectile disorder was historically called *impotence.* The term was dropped for a more medical designation, but also because it was considered derogatory and had negative connotations for the man with the problem. However, it describes with accuracy the feelings of powerlessness, helplessness, and resultant low self-esteem men with this dysfunction frequently suffer (Table 16-4). A man with a lifelong male erectile disorder has never been able to obtain an erection sufficient for insertion. In acquired male erectile disorder, a man has successfully achieved penetration at some time in his sexual life but is later unable to do so. In situational male erectile disorder, a man can have coitus in certain circumstances but not in others; for example, he may function effectively with a sex worker but be unable to have an erection when with his partner.

Acquired male erectile disorder occurs in 10 to 20 percent of all men. Erectile disorder is the chief complaint of more than 50 percent of all men treated for sexual disorders. Lifelong male erectile disorder is rare; it occurs in about 1 percent of men younger than age 35. The incidence of erectile disorder increases with age. It has been reported variously as 2 to 8 percent of the young adult population, and much more common in older men. Male erectile disorder, however, is not universal in aging men; having an available sex partner is related to continuing potency, as is a history of consistent sexual activity and the absence of vascular, neurologic, or endocrine disease. Twenty percent of men fear erectile dysfunction before their first coitus; the reported incidence of actual erectile dysfunction during the first coitus is 8 percent.

Male erectile disorder can be organic or psychological or a combination of both, but in young and middle-aged men, the cause is usually psychological. A good history is of primary importance in determining the cause of the dysfunction. If a man reports having spontaneous erections at times when he

does not plan to have intercourse, having morning erections, or having good erections with masturbation or with partners other than his usual one, the physiologic causes of his erectile disorder can be considered negligible, and he can avoid costly diagnostic procedures. Male erectile disorder caused by a general medical condition or a pharmacologic substance is discussed later in this section.

Comments		Note: ICD-10 classifies this diagnosis as including male erectile disorder as well as female sexual arousal disorder

A man may be unable to express a sexual impulse because of fear, anxiety, anger, or moral prohibition. In an ongoing relationship, the disorder may reflect difficulties between the partners, mainly when a man cannot communicate his needs or his anger directly and constructively. Also, episodes of erectile disorder are reinforcing, with the man becoming increasingly anxious before each sexual encounter.

Mr. Y came for therapy after his wife complained about their lack of sexual interaction. The patient avoided sex because of his frequent erectile dysfunction and the painful feelings of inadequacy he suffered after his "failures." He presented as an articulate, gentle, and self-blaming man.

He was faithful to his wife but masturbated frequently. His fantasies involved explicit sadistic components, including hanging and biting women. The contrast between his angry, aggressive fantasies and his loving, considerate behavior toward his wife symbolized his conflicts about his sexuality, his masculinity, and his mixed feelings about women. The physician diagnosed him with erectile disorder, situational type.

Orgasm Disorders

Female Orgasmic Disorder. Female orgasmic disorder, sometimes called *inhibited female orgasm* or *anorgasmia*, is defined as the recurrent or persistent inhibition of female orgasm, as manifested by the recurrent delay in, or absence of, orgasm after a normal sexual excitement phase that a clinician judges to be adequate in focus, intensity, and duration—in short, a woman's inability to achieve orgasm by masturbation or coitus (Table 16-5). Women who can achieve orgasm by one of these methods are not necessarily categorized as anorgasmic, although there may be some sexual inhibition. Some anorgasmic women are not distressed by the lack of climax and derive pleasure from sexual activity. However, the woman may still present for treatment as her partner is distressed by her apparent disinterest.

Research on the physiology of the female sexual response has shown that orgasms caused by clitoral stimulation and those caused by vaginal stimulation are physiologically identical. Many women achieve orgasm during coitus by a combination of manual clitoral stimulation and penile vaginal stimulation.

A woman with a lifelong female orgasmic disorder has never experienced orgasm by any kind of stimulation. A woman with an acquired orgasmic disorder has previously experienced at least one orgasm, regardless of the circumstances or means of stimulation, whether by masturbation or while

dreaming during sleep. Studies have shown that women achieve orgasm more consistently with masturbation than with partnered sex. Lifelong female orgasmic disorder is more common among unmarried women than married women. Increased orgasmic potential in women older than 35 years of age may relate to less psychologic inhibition, greater sexual experience, or both.

Acquired female orgasmic disorder is a common complaint in clinical populations. One clinical treatment facility reported having about four times as many nonorgasmic women in its practice as female patients with all other sexual disorders. In another study, 46 percent of women complained of difficulty reaching orgasm. Inhibition of arousal and orgasmic problems often occur together. The overall prevalence of female orgasmic disorder from all causes is estimated to be 30 percent. Orgasmic dysfunction in some females may have a genetic basis and cannot be attributed solely to psychologic differences. That study demonstrated an estimated heritability for difficulty reaching orgasm with intercourse of 34 percent and an estimated heritability in women who could not climax with masturbation of 45 percent.

Severity Specifiers	**Mild:** causes mild distress **Moderate:** causes moderate distress **Severe:** causes severe distress	
Course Specifiers	Lifelong vs. Acquired Never experienced an orgasm under any conditions	
Comments		Note: ICD 10 classifies orgasmic dysfunction as occurring in men and women, including delayed ejaculation in this category as per Table 16-6

Numerous psychological factors are associated with female orgasmic disorder. They include fears of impregnation, rejection by a sex partner, and damage to the vagina; hostility toward men; poor body image; and feelings of guilt about sexual impulses. Some women equate orgasm with loss of control or with aggressive, destructive, or violent impulses; they may express their

fear of these impulses through inhibition of arousal or orgasm. Cultural expectations and social restrictions on women are also relevant. Despite the sexual revolution of the 1960s, many women in the United States still grow to believe that sexual pleasure is not a natural entitlement for so-called decent women. Nonorgasmic women may be otherwise symptom-free or may experience frustration in a variety of ways; they may have such pelvic complaints as lower abdominal pain, itching, and vaginal discharge, as well as increased tension, irritability, and fatigue.

Delayed Ejaculation. In male delayed ejaculation, sometimes called *retarded ejaculation*, a man achieves ejaculation during coitus with great difficulty, if at all (Table 16-6). The problem is rarely present with masturbation but appears as a problem during partnered sex. A man with lifelong delayed ejaculation has never been able to ejaculate during partnered sexual activity. The problem is usually most pronounced during coital activity. We would consider the disorder to be acquired if it develops after previously normal functioning. Some researchers think that orgasm and ejaculation should be differentiated, especially in the case of men who ejaculate but complain of a decreased or absent subjective sense of pleasure during the orgasmic experience (orgasmic anhedonia).

The incidence of male orgasmic disorder is much lower than the incidence of premature ejaculation or erectile disorder. The prevalence is about 5 percent. However, there may be an increase in this disorder presenting to sex therapy programs. An increase in antidepressant use may be one explanation for this. Another is the high use of Internet pornography. These sites offer a level of stimulation involving such a variety of people and acts that they may inure the man to the stimulation of more typical partnered activity. Some studies of adolescent males who use these sites frequently, before live sexual interaction, have reported that these teens do not develop neuronal synapses that will enable them to respond to usual partnered interactions with sufficient pleasure to allow them to achieve climax.

Lifelong delayed ejaculation indicates severe psychopathology. A man may come from a rigid, puritanical background; he may perceive sex as sinful and the genitals as dirty, and he may have conscious or unconscious incest wishes and guilt. He usually has difficulty with closeness in areas beyond those of sexual relations. In a few cases, an attention-deficit/hyperactivity

disorder may aggravate the condition. A man's distractibility prevents sufficient arousal for climax to occur.

In an ongoing relationship, acquired male delayed ejaculation disorder frequently reflects interpersonal difficulties. The disorder may be a man's way of coping with real or fantasized changes in a relationship, such as plans for pregnancy about which the man is ambivalent, the loss of sexual attraction to the partner, or demands by the partner for greater commitment as expressed by sexual performance. In some men, the inability to ejaculate reflects unexpressed hostility toward a woman. The problem is more common among men with obsessive-compulsive disorder (OCD) than among others.

Table 16-6
Delayed Ejaculation

	DSM-5	ICD-10
Name	Delayed Ejaculation	Orgasmic dysfunction

Psychosocial Impact	Marked distress	
Symptom Specifiers	Generalized vs. Situational	
Severity Specifiers	**Mild:** causes mild distress **Moderate:** causes moderate distress **Severe:** causes severe distress	
Course Specifiers	Lifelong vs. Acquired	
Comments		Note: ICD 10 classifies orgasmic dysfunction as occurring in men and women, including delayed ejaculation in this category as per Table 16-5

A couple presented with the man as the identified patient; he was unable to ejaculate with intercourse. He had always had difficulty reaching climax, except in rare circumstances. He ejaculated once when he was with two women at the same time and once when he was experimenting with cocaine. He currently was not using any substances except for

moderate use of alcohol. This patient was committed to his marriage, although he had extramarital sexual experiences. He did not ejaculate with coitus in those situations either, although he could climax with oral sex. He stated he was more interested in "the conquest" than in the sex itself. He could climax with masturbation, although he rarely masturbated himself, but went to massage parlors. He had issues with anger at women and considered his wife to be excessively critical.

He had difficulty doing any of the exercises that required him to pleasure his wife. His difficulty giving also made it hard for him to enjoy mutual pleasuring. It was easier for him to be the recipient of stimulation. Because of this patient's problems with impulsiveness, narcissism, and dependency, it was necessary to combine introspective psychotherapy with a regimen of behavioral exercises.

The psychiatrist diagnosed the patient with delayed ejaculation, lifelong type.

Premature (Early) Ejaculation. In premature ejaculation, men persistently or recurrently achieve orgasm and ejaculation before they wish to. The diagnosis occurs when a man regularly ejaculates before or within approximately 1 minute after penetration. DSM-5 refers only to "vaginal penetration" in its diagnostic criteria, even though the disorder can occur in gay men or those who do not engage in vaginal penetration for other reasons. DSM-5 defines the disorder as mild if ejaculation occurs within approximately 30 seconds to 1 minute of vaginal penetration, moderate if ejaculation occurs within approximately 15 to 30 seconds of vaginal penetration, and severe when ejaculation occurs at the start of sexual activity or within approximately 15 seconds of vaginal penetration. A difficulty with these specifiers involves time distortions, which patients make in both overestimating and underestimating time from penetration to climax. Clinicians need to consider factors that affect the duration of the excitement phase of the sexual response, such as age, the novelty of the sex partner, and the frequency of coitus (Table 16-7). As with the other sexual dysfunctions, we would not diagnose premature ejaculation when it is caused exclusively by organic factors or when it is symptomatic of another clinical psychiatric syndrome.

Premature ejaculation appears to be more common among college-educated men than among men with less education. The complaint is likely related to their concern for partner satisfaction, although data is limited, and we do not know for sure. Premature ejaculation is the chief complaint of about 35 to 40 percent of men treated for sexual disorders. In DSM-5, the writers state that the disorder, with its newly defined time parameter, would now be an accurate diagnosis for only 1 to 3 percent of men. Some researchers divide men who experience premature ejaculation into two groups: those who are physiologically predisposed to climax quickly because of shorter nerve latency time and those with a psychogenic or behaviorally conditioned cause. Difficulty in ejaculatory control can be associated with anxiety regarding the sex act, with unconscious fears about the vagina, or with negative cultural conditioning. Men whose early sexual contacts occurred mainly with sex workers who demanded that the sex act proceed quickly or whose sexual contacts took place in situations in which discovery would be embarrassing (e.g., in a shared dormitory room or the parental home) may be conditioned to orgasm rapidly. With young, inexperienced men, who have the problem, it may resolve in time. In ongoing relationships, the partner has a significant influence on a premature ejaculator, and a stressful marriage exacerbates the disorder. The developmental background and the psychodynamics found in premature ejaculation and erectile disorder are similar.

Table 16-7
Premature (Early) Ejaculation

# Symptoms Needed	Above occurs in most sexual encounters	
Exclusions (not result of):	Relationship problem Substance use (including prescribed meds) Another medical condition Another psychiatric condition	
Psychosocial Impact	Marked distress	Both partners do not sufficiently enjoy the sexual encounter
Symptom Specifiers	Generalized vs. Situational	
Severity Specifiers	Defined by time from penetration until ejaculation: **Mild:** 30 s–1 min **Moderate:** 15–30 s **Severe:** <15 s	
Course Specifiers	Lifelong vs. Acquired	

The focus of this diagnosis is on males, and data on premature female orgasm are lacking. There are some case reports of, for example, multiple spontaneous orgasms without sexual stimulation. In some cases, an epileptogenic focus may be the cause. There are also some rare case reports of spontaneous orgasms in women taking serotonergic antidepressants.

Orgasmic Anhedonia. Orgasmic anhedonia is a condition in which a

person has no physical sensation of orgasm, even though the physiologic component (e.g., ejaculation) remains intact. Organic causes, such as sacral and cephalic lesions that interfere with afferent pathways from the genitalia to the cortex, must be ruled out. Psychiatric causes usually relate to extreme guilt about experiencing sexual pleasure. These feelings produce a dissociative response that isolates the affective component of the orgasmic experience from consciousness. In DSM-5 this would be diagnosed as an "other specified sexual dysfunction."

Sexual Pain Disorders

Genito-Pelvic Pain/Penetration Disorder. In DSM-5, this disorder refers to one or more of the following complaints, of which any two or more may occur together: difficulty having intercourse, genito-pelvic pain, fear of pain or penetration, and tension of the pelvic floor muscles (Table 16-8). Previously, we diagnosed these pain disorders as *dyspareunia* or *vaginismus.* These former diagnoses could coexist, or one could lead to the other and could understandably lead to fear of pain with sex. Thus, it is reasonable to gather these diagnoses into one diagnostic category. For this clinical discussion, however, the distinct categories of dyspareunia and vaginismus remain clinically useful.

DYSPAREUNIA. Dyspareunia is recurrent or persistent genital pain occurring before, during, or after intercourse. Dyspareunia is related to and often coincides with vaginismus. Repeated episodes of vaginismus can lead to dyspareunia and vice versa; in either case, we should rule out somatic causes, or lack of lubrication. Perhaps 5 percent of women in North America report recurrent pain during intercourse.

In most cases, dynamic factors are considered causative. Chronic pelvic pain is a common complaint in women with a history of rape or childhood sexual abuse. Painful coitus can result from tension and anxiety about the sex act that causes women to contract their pelvic floor muscles involuntarily. The pain is real and makes intercourse unpleasant or unbearable. The anticipation of further pain may cause women to avoid coitus altogether. If a partner proceeds with intercourse regardless of a woman's state of readiness, this aggravates the condition. There is an increase in reported dyspareunia

postmenopausally due to hormonally induced physiologic changes in the vagina; however, specific complaints of difficulty having intercourse occur more often in premenopausal women. There is some increase in dyspareunia in the immediate postpartum population, but it is usually temporary. Dyspareunia may present as any of the four complaints listed under genito-pelvic pain/penetration disorder, and we would diagnose this as a genito-pelvic pain/penetration disorder.

VAGINISMUS. Vaginismus is a constriction of the outer third of the vagina due to involuntary pelvic floor muscle tightening or spasm. It then interferes with penile insertion and intercourse. This response may occur during a gynecologic examination when involuntary vaginal constriction prevents the introduction of the speculum into the vagina. We would not make the diagnosis when the dysfunction is caused exclusively by organic factors or when it is symptomatic of another mental disorder.

Vaginismus may be complete; that is, no penetration of the vagina is possible, whether by the penis, fingers, a speculum during a gynecologic examination, or even if the woman tries to use the smallest size tampon. Many women who discover this when they become sexually active have avoided the use of tampons previously. In a less severe form of vaginismus, pelvic floor muscle tightening due to pain or fear of pain makes penetration difficult, but not impossible. Penetration may be achieved with the smallest size speculum or little fingers. In mild cases, the muscles relax after the initial difficulty with penetration, and the woman can continue with sexual play, sometimes even with coitus.

Miss B was a 27-year-old single woman who presented for therapy because of an inability to have intercourse. She described episodes with a recent boyfriend in which he had tried vaginal penetration but had been unable to enter. The boyfriend did not have erectile dysfunction. Miss B experienced desire and was able to achieve orgasm through manual or oral stimulation. For almost a year, she and her boyfriend had sex play without intercourse. However, he complained increasingly about his frustration at the lack of coitus, which he had enjoyed in previous relationships. Miss B had a conscious fear of penetration and dreaded

going to the gynecologist, although she was able to use tampons when she menstruated. Her therapist diagnosed her with genito-pelvic pain/penetration disorder, lifelong type.

Table 16-8

Symptom Specifiers	
Severity Specifiers	**Mild:** causes mild distress **Moderate:** causes moderate distress **Severe:** causes severe distress
Course Specifiers	Lifelong vs. Acquired

Vaginismus is less prevalent than female orgasmic disorder. It most often afflicts highly educated women and those in high socioeconomic groups. Women with vaginismus may consciously wish to have coitus, but unconsciously wish to keep a penis from entering their bodies. Sexual trauma, such as rape, may cause vaginismus. The anticipation of pain at the first coital experience may cause vaginismus. Clinicians have noted that a strict religious upbringing in which the patient associates sex with sin is frequent in these patients. Other women have problems in dyadic relationships; if women feel emotionally abused by their partners, they may protest in this nonverbal fashion. Some women who have experienced significant pain in childhood due to surgical or dental interventions become guarded about any breach of body integrity and develop vaginismus. Vaginismus may present as any of the four complaints under genito-pelvic

pain/penetration disorder, and we should diagnose this as genito-pelvic pain/penetration disorder.

Postcoital Headache. Postcoital headache, characterized by headache immediately after coitus, may last for several hours. It is usually described as throbbing and localized to the occipital or frontal area. The cause is unknown. There may be vascular, muscle contraction (tension), or psychogenic causes. Coitus may precipitate migraine or cluster headaches in predisposed persons. In DSM-5 this disorder would not be included among the above pain disorders as the pain is not directly associated with the sexual act. When it is a source of distress or dysfunction, we list it as an "other specified sexual dysfunction."

Sexual Dysfunction due to a General Medical Condition

Male Erectile Disorder due to a General Medical Condition. The incidence of psychological male erectile disorder has been the focus of many studies. Statistics indicate that 20 to 50 percent of men with erectile disorder have an organic basis for the disorder. A physiologic etiology is more likely in men older than 50 and the most likely cause in men older than age 60. Table 16-9 lists the medical causes of male erectile disorder. Side effects of medication can impair male sexual functioning in a variety of ways (Table 16-10). Castration (removal of the testes) does not always lead to sexual dysfunction because erection may still occur. A reflex arc, fired when stimulating the inner thigh, passes through the sacral cord erectile center to account for the phenomenon.

Several procedures, benign and invasive, are used to help differentiate the causes of erectile disorder. The procedures include monitoring nocturnal penile tumescence (erections that occur during sleep), generally associated with rapid eye movement; monitoring tumescence with a strain gauge; measuring blood pressure in the penis with a penile plethysmograph or an ultrasound (Doppler) flowmeter, both of which assess blood flow in the internal pudendal artery; and measuring pudendal nerve latency time. Other diagnostic tests that delineate physiologic bases for impotence include glucose tolerance tests, plasma hormone assays, liver and thyroid function tests, prolactin and follicle-stimulating hormone (FSH) determinations, and

cystometric examinations. Invasive diagnostic studies include penile arteriography, infusion cavernosonography, and radioactive xenon penography. Invasive procedures require expert interpretation and are used only for patients who are candidates for vascular reconstructive procedures.

Dyspareunia due to a General Medical Condition. An estimated 30 percent of all surgical procedures on the female genital area result in temporary dyspareunia. Also, 30 to 40 percent of women with the complaint seen in sex therapy clinics have pelvic pathology. Organic abnormalities leading to dyspareunia and vaginismus include irritated or infected hymenal remnants, episiotomy scars, Bartholin gland infection, various forms of vaginitis and cervicitis, endometriosis, and adenomyosis. Women with myomata, endometriosis, and adenomyosis may report postcoital pain owing to the uterine contractions during orgasm. Postmenopausal women may have dyspareunia resulting from thinning of the vaginal mucosa and reduced lubrication.

Table 16-9
Diseases and Other Medical Conditions Implicated in Male Erectile Disorder

Infectious and parasitic diseases	Neurologic disorders
Elephantiasis	Multiple sclerosis
Mumps	Transverse myelitis
Cardiovascular disease[a]	Parkinson disease
Atherosclerotic disease	Temporal lobe epilepsy
Aortic aneurysm	Traumatic and neoplastic spinal cord diseases[a]
Leriche syndrome	Central nervous system tumor
Cardiac failure	Amyotrophic lateral sclerosis
Renal and urologic disorders	Peripheral neuropathy
Peyronie disease	General paresis
	Tabes dorsalis
	Pharmacologic factors
	Alcohol and other dependence-inducing substances (heroin, methadone, morphine,

- Chronic renal failure
- Hydrocele and varicocele

Hepatic disorders
- Cirrhosis (usually associated with alcohol dependence)

Pulmonary disorders
- Respiratory failure

Genetics
- Klinefelter syndrome
- Congenital penile vascular and structural abnormalities

Nutritional disorders
- Malnutrition
- Vitamin deficiencies
- Obesity

Endocrine disorders[a]
- Diabetes mellitus
- Dysfunction of the pituitary–adrenal–testis axis
- Acromegaly
- Addison disease
- Chromophobe adenoma

cocaine, amphetamines, and barbiturates)
- Prescribed drugs (psychotropic drugs, antihypertensive drugs, estrogens, and antiandrogens)

Poisoning
- Lead (plumbism)
- Herbicides

Surgical procedures[a]
- Perineal prostatectomy
- Abdominal–perineal colon resection
- Sympathectomy (frequently interferes with ejaculation)
- Aortoiliac surgery
- Radical cystectomy
- Retroperitoneal lymphadenectomy

Miscellaneous
- Radiation therapy
- Pelvic fracture
- Any severe systemic disease or debilitating condition

Adrenal neoplasia
Myxedema
Hyperthyroidism

[a]In the United States an estimated 2 million men are impotent because they have diabetes mellitus; an additional 300,000 are impotent because of other endocrine diseases; 1.5 million are impotent as a result of vascular disease; 180,000 because of multiple sclerosis; 400,000 because of traumas and fractures leading to pelvic fractures or spinal cord injuries; and another 650,000 are impotent as a result of radical surgery, including prostatectomies, colostomies, and cystectomies.

Two conditions not readily apparent on physical examination that produce dyspareunia are vulvar vestibulitis and interstitial cystitis. The former may present with chronic vulvar pain, and the latter produces pain most intensely following orgasm. Dyspareunia can also occur in men, but it is uncommon and is usually associated with an organic condition, such as Peyronie disease, which consists of sclerotic plaques on the penis that cause penile curvature.

Male Hypoactive Sexual Desire Disorder and Female Interest/Arousal Disorder due to a General Medical Condition. Sexual desire commonly decreases after major illness or surgery, particularly when the body image is affected after such procedures as mastectomy, ileostomy, hysterectomy, and prostatectomy. Illnesses that deplete a person's energy, chronic conditions that require physical and psychological adaptation, and serious illnesses that can cause a person to become depressed can all markedly lessen sexual desire.

In some cases, biochemical correlates are associated with hypoactive sexual desire disorder (Table 16-11). A recent study found markedly lower levels of serum testosterone in men complaining of low desire than in normal controls in a sleep-laboratory situation. Drugs that depress the central nervous system (CNS) or decrease testosterone production can decrease desire.

Other Male Sexual Dysfunction due to a General Medical Condition. Delayed ejaculation can have physiologic causes and can occur after surgery on the genitourinary tract, such as prostatectomy. It may also be associated with Parkinson disease and other neurologic disorders involving the lumbar or sacral sections of the spinal cord. The antihypertensive drug guanethidine monosulfate, methyldopa, the phenothiazines, the tricyclic

drugs, and the selective serotonin reuptake inhibitors (SSRIs), among others, have been implicated in retarded ejaculation. Also, we should differentiate delayed ejaculation from retrograde ejaculation, in which ejaculation occurs but the seminal fluid passes back into the bladder. Retrograde ejaculation always has an organic cause. It can develop after genitourinary surgery, and it is also associated with medications that have anticholinergic adverse effects, such as the phenothiazines.

Other Female Sexual Dysfunction due to a General Medical Condition. Some medical conditions—specifically, endocrine diseases such as hypothyroidism, diabetes mellitus, and primary hyperprolactinemia—can affect a woman's ability to have orgasms. Several drugs also affect some women's capacity to have orgasms (Table 16-12). Antihypertensive medications, CNS stimulants, tricyclic drugs, SSRIs, and, frequently, monoamine oxidase inhibitors (MAOIs) have interfered with female orgasmic capacity. One study of women taking MAOIs, however, found that after 16 to 18 weeks of pharmacotherapy, the adverse effect of the medication disappeared, and the women were able to reexperience orgasms, although they continued taking an undiminished dose of the drug.

Propranolol (Inderal)	+	–

[a]The incidence of male erectile disorder associated with the use of tricyclic drugs is low.

[b]Trazodone has been causative in some cases of priapism.

[c]All SSRIs can produce sexual dysfunction, more commonly, in men.

[d]Impairment of sexual function is not a common complication of the use of antipsychotics.

Priapism has occasionally occurred in association with the use of antipsychotics.

[e]Benzodiazepines have been reported to decrease libido, but in some patients the diminution of anxiety caused by those drugs enhances sexual function.

Substance/Medication-Induced Sexual Dysfunction. We diagnose substance-induced sexual dysfunction when evidence of substance intoxication or withdrawal is apparent from the history, physical examination, or laboratory findings. The disturbance in sexual function must be predominant in the clinical picture. Distressing sexual dysfunction occurs soon after significant substance intoxication or withdrawal, or after exposure to a medication or a change in medication use. Specified substances include alcohol, amphetamines or related substances, cocaine, opioids, sedatives, hypnotics, or anxiolytics, and other or unknown substances.

Abused recreational substances affect sexual function in various ways. In small doses, many substances enhance sexual performance by decreasing inhibition or anxiety or by causing a temporary elevation of mood. With continued use, however, erectile engorgement and orgasmic and ejaculatory capacities become impaired. The abuse of sedatives, anxiolytics, hypnotics, and particularly opiates and opioids nearly always depresses desire. Alcohol may foster the initiation of sexual activity by removing inhibition, but it also impairs performance. Cocaine and amphetamines produce the similar effects. Although no direct evidence indicates that sexual drive is enhanced, users initially have feelings of increased energy and may become sexually active; ultimately, dysfunction occurs. Men usually go through two stages: an experience of prolonged erection without ejaculation, and then a gradual loss of erectile capability.

Patients recovering from substance dependency may need therapy to regain sexual function, partly because of psychological readjustment to a nondependent state. Many substance abusers have always had difficulty with intimate interactions. Others who spent their crucial developmental years under the influence of a substance have missed the experiences that would have enabled them to learn social and sexual skills.

Almost every pharmacologic agent, particularly those used in psychiatry, has been associated with an effect on sexuality. In men, these effects include decreased sex drive, erectile failure, decreased volume of ejaculate, and delayed or retrograde ejaculation. In women, decreased sex drive, decreased

vaginal lubrication, inhibited or delayed orgasm, and decreased or absent vaginal contractions may occur. Drugs may also enhance sexual responses and increase the sex drive, but this is less common than adverse effects.

ANTIPSYCHOTIC DRUGS. Most antipsychotic drugs are dopamine receptor antagonists that also block adrenergic and cholinergic receptors, thus accounting for the adverse sexual effects (Table 16-13). Chlorpromazine and trifluoperazine are potent anticholinergics, and they impair erection and ejaculation. With some drugs, the seminal fluid backs up into the bladder rather than being propelled through the penile urethra. Patients still have a pleasurable sensation, but the orgasm is dry. When urinating after orgasm, the urine may be milky white because it contains the ejaculate. The condition is startling but harmless. Paradoxically, antipsychotics may rarely cause priapism.

Table 16-11
Neurophysiology of Sexual Dysfunction

	DA	5-HT	NE	ACh	Clinical Correlation
Erection	↑	°	α_2, β ↓ ↑	M	Antipsychotics may lead to erectile dysfunction (DA block): DA agonists may lead to enhanced erection and libido; priapism with trazodone (α_1 block); β-blockers may lead to impotence
Ejaculation and orgasm	°	± ↓	α_1 ↑	M	α-Blockers (tricyclic drugs, MAOIs, thioridazine) may lead to impaired ejaculation; 5-HT agents may inhibit orgasm

↑, facilities; ↓, inhibits or decreases; ±, some; ACh, acetylcholine; DA, dopamine; 5-HT, serotonin; M, modulates; NE, norepinephrine; °, minimal.

ANTIDEPRESSANT DRUGS. The tricyclic and tetracyclic antidepressants have anticholinergic effects that interfere with erection and delay ejaculation. Because the anticholinergic effects vary among the cyclic antidepressants, those with the fewest effects (e.g., desipramine) produce the fewest sexual adverse effects.

Some men report increased sensitivity of the glans that is pleasurable, and that does not interfere with erection, although it delays ejaculation. In some cases, however, the tricyclic causes painful ejaculation, perhaps as the result of interference with seminal propulsion caused by interference with, in turn, urethral, prostatic, vas, and epididymal smooth muscle contractions. Clomipramine may increase sex drive in some persons. Selegiline, a selective MAO type B (MAO_B) inhibitor, and bupropion may also increase sex drive,

possibly by dopaminergic activity and increased production of norepinephrine.

Venlafaxine and the SSRIs most often have adverse effects because of the rise in serotonin levels. A lowering of the sex drive and difficulty reaching orgasm occur in both sexes. Cyproheptadine, an antihistamine with antiserotonergic effects, and methylphenidate, with adrenergic effects, may reverse those adverse effects. Trazodone is associated with the rare occurrence of priapism, the symptom of prolonged erection in the absence of sexual stimuli. That symptom appears to result from the α_1-adrenergic antagonism of trazodone.

Some Pharmacologic Agents Implicated in Inhibited Female Orgasm[a]

Tricyclic antidepressants
Imipramine (Tofranil)
Clomipramine (Anafranil)
Nortriptyline (Aventyl)
Monoamine oxidase inhibitors
Tranylcypromine (Parnate)
Phenelzine (Nardil)
Isocarboxazid (Marplan)
Dopamine receptor antagonists
Thioridazine (Mellaril)
Trifluoperazine (Stelazine)
Selective serotonin reuptake inhibitors
Fluoxetine (Prozac)
Paroxetine (Paxil)
Sertraline (Zoloft)
Fluvoxamine (Luvox)
Citalopram (Celexa)

[a]The interrelation between female sexual dysfunction and pharmacologic agents has been less extensively evaluated than male reactions. Oral contraceptives are reported to decrease

libido in some women, and some drugs with anticholinergic side effects may impair arousal as well as orgasm. Prolonged use of oral contraceptives may also cause physiologic menopausal-like changes resulting in genito-pelvic pain/penetration disorder. Benzodiazepines have been reported to decrease libido, but in some patients the diminution of anxiety caused by those drugs enhances sexual function. Both increase and decrease in libido have been reported with psychoactive agents. It is difficult to separate those effects from the underlying condition or from improvement of the condition. Sexual dysfunction associated with the use of a drug disappears when use of the drug is discontinued.

The MAOIs affect biogenic amines broadly. Accordingly, they produce impaired erection, delayed or retrograde ejaculation, vaginal dryness, and inhibited orgasm. Tranylcypromine has a paradoxical sexually stimulating effect in some persons, possibly as a result of its amphetamine-like properties.

Mr. W presented with the complaint of inability to achieve orgasm. His problem dated from the time, 18 months previously, when he started fluoxetine. Before that time, he had been able to achieve orgasm through masturbation and coitus with his wife.

Mr. W tried several other SSRIs, as well as venlafaxine, but the side effect of delayed ejaculation persisted. None of the usual antidotes to SSRI-induced anorgasmia proved effective, and the patient then tried antidepressants of other categories. Mr. W was able to respond to bupropion and clonazepam. This combination treated his depression and anxiety, and his delayed ejaculation resolved.

His psychiatrist diagnosed pharmacologically induced delayed ejaculation.

Table 16-13
Diagnostic Issues with Sex and Some Antipsychotic Drugs

Differential diagnosis of drug-induced sexual dysfunction	Problem after drug therapy started or drug overdose Problem not situation or partner specific Not a lifelong or recurrent

	Thioridazine
	Fluphenazine
	Molindone
	Risperidone
	Clozapine

Table by R. T. Seagraves, M.D.

Because depression is associated with decreased libido, varying levels of sexual dysfunction and anhedonia are part of the disease process. Some patients report improved sexual functioning as their depression improves because of antidepressant medication. The phenomenon makes evaluating sexual side effects difficult; also, the side effects may disappear with time, perhaps because a biogenic amine homeostatic mechanism comes into play.

LITHIUM. Lithium regulates mood and, in the manic state, may reduce hypersexuality, possibly by a dopamine antagonist activity. Some patients may have impaired erections.

SYMPATHOMIMETICS. Psychostimulants, including amphetamines, methylphenidate, and pemoline, raise the plasma levels of norepinephrine and dopamine. They can increase libido. However, with prolonged use, men may experience a loss of desire and erections.

α-ADRENERGIC AND β-ADRENERGIC RECEPTOR ANTAGONISTS. α-Adrenergic and β-adrenergic receptor antagonists, used in the treatment of hypertension, angina, and certain cardiac arrhythmias, diminish tonic sympathetic nerve outflow from vasomotor centers in the brain. As a result, they can cause impotence, decrease the volume of ejaculate, and produce retrograde ejaculation. They can affect libido in both sexes.

ANTICHOLINERGICS. The anticholinergics block cholinergic receptors and include such drugs as amantadine and benztropine. They produce dryness of the mucous membranes (including those of the vagina) and erectile disorder. However, amantadine may reverse SSRI-induced orgasmic dysfunction through its dopaminergic effect.

ANTIHISTAMINES. Drugs such as diphenhydramine have anticholinergic activity and are mildly hypnotic. They may inhibit sexual function as a result. Cyproheptadine, although an antihistamine, also has potent activity as a serotonin antagonist. It can block the serotonergic sexual adverse effects produced by SSRIs, such as delayed orgasm.

ANTIANXIETY AGENTS. The dominant class of anxiolytics is the benzodiazepines. They act on the γ-aminobutyric acid (GABA) receptors, which are involved in cognition, memory, and motor control. Because benzodiazepines decrease plasma epinephrine concentrations, they diminish anxiety, and as a result, they improve sexual function in persons inhibited by anxiety.

ALCOHOL. Alcohol suppresses CNS activity generally and can produce

erectile disorders in men as a result. Alcohol has a direct gonadal effect that decreases testosterone levels in men; paradoxically, it can produce a slight rise in testosterone levels in women. The latter finding may account for women who report increased libido after drinking small amounts of alcohol. The long-term use of alcohol reduces the ability of the liver to metabolize estrogenic compounds in men, which produces signs of feminization (such as gynecomastia as a result of testicular atrophy).

OPIOIDS. Opioids, such as heroin, have adverse sexual effects, such as erectile failure and decreased libido. The alteration of consciousness may enhance the sexual experience of occasional users.

HALLUCINOGENS. The hallucinogens include lysergic acid diethylamide (LSD), phencyclidine (PCP), psilocybin (from some mushrooms), and mescaline (from peyote cactus). In addition to inducing hallucinations, the drugs cause loss of contact with reality and an expanding and heightening of consciousness. Some users report that the sexual experience is similarly enhanced, but others experience anxiety, delirium, or psychosis, which interfere with sexual function.

CANNABIS. The altered state of consciousness produced by cannabis may enhance sexual pleasure for some persons. Its prolonged use depresses testosterone levels.

BARBITURATES AND SIMILARLY ACTING DRUGS. Barbiturates and similarly acting sedative-hypnotic drugs may enhance sexual responsiveness in persons who are sexually unresponsive as a result of anxiety. They have no direct effect on the sex organs; however, they do produce an alteration in consciousness that some persons find pleasurable. These drugs are subject to abuse, and use can be fatal when combined with alcohol or other CNS depressants.

Methaqualone acquired a reputation as a sexual enhancer, a reputation without basis. It is no longer legally sold in the United States.

Treatment

Before 1970, the most common treatment for sexual dysfunctions was

individual psychotherapy. Classic psychodynamic theory holds that sexual inadequacy has its roots in early developmental conflicts, and the therapist treated the sexual disorder as part of a pervasive emotional disturbance. The symptoms of sexual dysfunctions, however, frequently become secondarily autonomous and continue to persist, even when other problems evolving from the patients' pathology have been resolved. The addition of behavioral techniques is often necessary to cure a sexual problem. Depending on the disorder, medications can be a first-line treatment or an adjunct to therapy.

Somatic Treatments. Biologic treatments, including pharmacotherapy, surgery, and mechanical devices, can treat specific cases of sexual disorder. Most of the recent advances involve male sexual dysfunction.

PHARMACOTHERAPY. Medications for erectile disorder include sildenafil and its congeners (Table 16-14), oral phentolamine, alprostadil, and injectable medications. Other options include papaverine, prostaglandin E1, phentolamine, or some combination of these; and transurethral alprostadil (MUSE).

Sildenafil is a nitric oxide enhancer that facilitates the inflow of blood to the penis necessary for an erection. The drug takes effect about 1 hour after ingestion, and its effect can last up to 4 hours. Sildenafil is not effective in the absence of sexual stimulation. The most common adverse events associated with its use are headaches, flushing, and dyspepsia. Persons taking organic nitrates should not take sildenafil, as the combined action of the two drugs can cause sudden, and sometimes fatal, drops in systemic blood pressure. Sildenafil is not effective in all cases of erectile dysfunction. It fails to produce an erection that is sufficiently rigid for penetration in about 50 percent of men who have had radical prostate surgery or in those with long-standing insulin-dependent diabetes. It is also ineffective in some instances of nerve damage.

A small number of patients developed nonarteritic ischemic optic neuropathy (NAION) soon after using sildenafil. This side effect may be more common in patients with cardiovascular risk factors. Although rare, sildenafil may provoke NAION in individuals with an arteriosclerotic risk profile. Exceedingly rare cases of hearing loss may also occur.

Sildenafil use in women results in vaginal lubrication, but not in increased

desire. Anecdotal reports, however, describe individual women who have experienced intensified excitement with sildenafil.

Oral phentolamine and apomorphine are not FDA approved at present but have proved useful as potency enhancers in men with minimal erectile dysfunction. Phentolamine reduces sympathetic tone and relaxes corporeal smooth muscle. Adverse events include hypotension, tachycardia, and dizziness. Apomorphine effects are mediated by the autonomic nervous system and result in vasodilation that facilitates the inflow of blood to the penis. Adverse events include nausea and sweating.

Table 16-14
Pharmacokinetics of the PDE-5 Inhibitors

		Sildenafil (Viagra)	Vardenafil (Levitra)	Vardenafil ODT (Staxyn)	Tadalafil (Cialis)	Avanafil (Stendra)

In contrast to the oral medications, injectable and transurethral forms of alprostadil act locally on the penis and can produce erections in the absence of sexual stimulation. Alprostadil contains a naturally occurring form of prostaglandin E, a vasodilating agent. Alprostadil may be administered by direct injection into the corpora cavernosa or by intraurethral insertion of a pellet through a cannula. The firm erection produced within 2 to 3 minutes after administration of the drug may last as long as 1 hour. Infrequent and reversible adverse effects of injections include penile bruising and changes in liver function test results. Possible hazardous sequelae exist, including priapism and sclerosis of the small veins of the penis. Users of transurethral alprostadil sometimes complain of burning sensations in the penis.

Two small trials found different topical agents effective in alleviating erectile dysfunction. One cream consists of three vasoactive substances

absorbed through the skin: aminophylline, isosorbide dinitrate, and co-dergocrine mesylate, which is a mixture of ergot alkaloids. The other is a gel containing alprostadil and an additional ingredient, which temporarily makes the outer layer of the skin more permeable.

Also, a cream incorporating alprostadil exists for female sexual arousal disorder. Vaginally applied phentolamine mesylate, an α-receptor antagonist, can increase vasocongestion and a subjective sense of arousal. Flibanserin is also FDA-approved to increase desire in women.

The pharmacologic treatments described in the preceding text are useful in the treatment of arousal dysfunction of various causes: neurogenic, arterial insufficiency, venous leakage, psychogenic, and mixed. When coupled with insight-oriented or behavioral sex therapy, the use of medications can reverse psychogenic arousal disorder that is resistant to psychotherapy alone, the ultimate goal being pharmacologically unassisted sexual functioning.

Other Pharmacologic Agents. Numerous other pharmacologic agents have been used to treat various sexual disorders. Intravenous methohexital sodium assists with desensitization therapy. Antianxiety agents may have some application for tense patients. The side effects of antidepressants, in particular the SSRIs and tricyclic drugs, have been used to prolong the sexual response in patients with premature ejaculation. This approach is particularly useful in patients who are refractory to behavioral techniques. Topical anesthetic creams may help decrease the intravaginal ejaculation latency time (IELT) in cases of premature ejaculation. Antidepressants can help patients who are phobic of sex and in those with posttraumatic stress disorder following rape. Trazodone is an antidepressant that improves nocturnal erections. We should always weigh the risks of taking such medications against their possible benefits. Bromocriptine treats hyperprolactinemia, which is frequently associated with hypogonadism and any associated sexual dysfunction. In such patients, it is necessary to rule out pituitary tumors.

Several substances have popular standing as aphrodisiacs; for example, ginseng root and yohimbine. Studies, however, have not confirmed any aphrodisiac properties. Yohimbine, an α-receptor antagonist, may cause dilation of the penile artery; however, the American Urologic Association does not recommend its use to treat organic erectile dysfunction. Many

recreational drugs, including cocaine, amphetamines, alcohol, and cannabis, are considered enhancers of sexual performance. Although they may provide the user with an initial benefit because of their tranquilizing, disinhibiting, or mood-elevating effects, consistent or prolonged use of any of these substances impairs sexual functioning.

Dopaminergic agents may increase libido and improve sex function. Those drugs include L-dopa, a dopamine precursor, and bromocriptine, a dopamine agonist. The antidepressant bupropion has dopaminergic effects and has increased sex drive in some patients. Selegiline, an MAOI, is selective for MAO_B and is dopaminergic. It improves sexual functioning in older persons.

HORMONE THERAPY. Androgens increase the sex drive in women and men with low testosterone concentrations. Women may experience virilizing effects, some of which are irreversible (e.g., deepening of the voice). In men, prolonged use of androgens produces hypertension and prostatic enlargement. Testosterone is most effective when given parenterally; however, effective oral and transdermal preparations are available.

Women who use estrogens for replacement therapy or contraception may report decreased libido; in such cases, a combined preparation of estrogen and testosterone may help. Estrogen itself prevents thinning of the vaginal mucous membrane and facilitates lubrication. Several forms of locally delivered estrogen—vaginal rings, vaginal creams, and vaginal tablets—provide alternate administration routes to treat women with arousal problems or genital atrophy. Because tablets, creams, and rings do not significantly increase circulating estrogen levels, we should consider these devices for patients with breast cancer with arousal problems.

ANTIANDROGENS AND ANTIESTROGENS. Estrogens and progesterone are antiandrogens that have been used to treat compulsive sexual behavior in men, usually in sex offenders. Clomiphene and tamoxifen are both antiestrogens, and both stimulate gonadotropin-releasing hormone (GnRH) secretion and increase testosterone concentrations, thereby increasing libido. Women treated for breast cancer with tamoxifen report an increased libido. However, tamoxifen may cause uterine cancer.

MECHANICAL TREATMENT APPROACHES. Male patients with

arteriosclerosis (especially of the distal aorta, known as Leriche syndrome), may lose their erection during active pelvic thrusting. The need for increased blood in the gluteal muscles and others served by the ilial or hypogastric arteries takes blood away (steals) from the pudendal artery and, thus, interferes with penile blood flow. They can obtain relief by decreasing pelvic thrusting, which is also aided by the woman's superior coital position.

VACUUM PUMP. Vacuum pumps are mechanical devices that patients without a vascular disease can use to obtain erections. The vacuum draws blood to the penis and kept there by a ring at the base of the penis. This device has no adverse effects, but it is cumbersome, and partners must be willing to accept its use. Some women complain that the penis is redder and cooler than a natural erection or find the process objectionable.

A similar device, called EROS, has been developed to create clitoral erections in women. EROS is a small suction cup that fits over the clitoral region and draws blood into the clitoris. Studies have reported its success in treating female sexual arousal disorder. Vibrators used to stimulate the clitoral area have been successful in treating anorgasmic women.

OTHER SOMATIC TREATMENTS

Male Prostheses. Surgical treatment is rarely indicated, but penile prosthetic devices are available for men with inadequate erectile responses who are resistant to other treatment methods or who have medically caused deficiencies. The two main types of prostheses are (1) a semi-rigid rod prosthesis that produces a permanent erection that can be positioned close to the body for concealment and (2) an inflatable type that is implanted with its reservoir and pump for inflation and deflation. The latter type can mimic normal physiologic functioning.

Vascular Surgery. When vascular insufficiency is present due to atherosclerosis or other blockages, bypass surgery of penile arteries may help in selected cases.

Psychosocial Treatments

DUAL-SEX THERAPY. The theoretical basis of dual-sex therapy is the concept of the marital unit or dyad as the object of therapy; the approach represented the

significant advance in the diagnosis and treatment of sexual disorders in the 20th century. The methodology was originated and developed by Masters and Johnson. In dual-sex therapy, when a dysfunctional person is in a relationship, the couple must be treated. Because both are involved in a sexually distressing situation, both must participate in the therapy program. The sexual problem often reflects other areas of disharmony or misunderstanding in the relationship so that the entire relationship is treated, with emphasis on the sexual functioning of the partners.

The keystone of the program is the roundtable session in which a male and female therapy team clarifies, discusses, and works through problems with the couple. The four-way sessions require active participation by the patients. Therapists and patients discuss the psychological and physiologic aspects of sexual functioning, and therapists have an educative attitude. Therapists suggest specific sexual activities for the couple to follow in the privacy of their home. The therapy aims to establish or reestablish communication within the partner unit. Sex is emphasized as a natural function that flourishes in the appropriate domestic climate, and improved communication is encouraged toward that end. In a variation of this therapy that has proved useful, one therapist may treat the couple. Treatment is short term and is behaviorally oriented. The therapists attempt to reflect the situation as they see it, rather than interpret underlying dynamics. An undistorted picture of the relationship presented by the therapists often corrects the myopic, narrow view held by each partner. This new perspective can interrupt the couple’s destructive pattern of relating and can encourage improved, more effective communication. Specific exercises are prescribed for the couple to treat their particular problems. Sexual inadequacy often involves a lack of information, misinformation, and performance fear. Therefore, the therapist prohibits any sexual play other than what was prescribed. Beginning exercises usually focus on heightening sensory awareness to touch, sight, sound, and smell. Initially, the therapist also prohibits intercourse, and the couple learns to give and receive bodily pleasure without the pressure of performance or penetration. At the same time, they learn how to communicate nonverbally in a mutually satisfactory way, and they learn that sexual foreplay is an enjoyable alternative to intercourse and orgasm.

During the sensate focus exercises, the couple receives much reinforcement to reduce anxiety. They can use fantasies to distract them from

obsessive concerns about performance (spectatoring). They should consider the needs of both the dysfunctional partner and the nondysfunctional partner. If either partner becomes sexually excited by the exercises, the other is encouraged to bring them to orgasm by manual or oral means. Open communication and the expression of mutual needs are encouraged. Resistances, such as claims of fatigue or not enough time to complete the exercises, are common and must be dealt with by the therapists. Issues of body image, fear of being touched, and difficulty touching oneself arise frequently. Eventually, the therapy allows genital stimulation in addition to general body stimulation. The couple should sequentially to try various positions for intercourse, without necessarily completing the act, and to use varieties of stimulating techniques before they proceed with intercourse.

Psychotherapy sessions follow each new exercise period, and problems and satisfactions, both sexual and in other areas of the couple's lives, are discussed. The therapist reviews specific instructions and introduces new exercises geared to the individual couple's progress. Gradually, the couple gains confidence and learns to communicate, verbally and sexually. Dual-sex therapy is most effective when sexual dysfunction exists apart from other psychopathology. The more difficult treatment cases involve couples with severe marital discord. Desire disorders are particularly challenging to treat. They require more extended and intensive therapy than some other disorders, and their outcomes vary greatly.

SPECIFIC TECHNIQUES AND EXERCISES. Various techniques can treat various sexual dysfunctions. In cases of vaginismus, a woman is advised to dilate her vaginal opening with her fingers or with size-graduated dilators. Dilators can also treat cases of dyspareunia. Sometimes, specially trained physiotherapists can assist the treatment by helping the patients to relax their perineal muscles.

In cases of premature ejaculation, an exercise known as the squeeze technique can raise the threshold of penile excitability. In this exercise, the man or the woman stimulates the erect penis until feeling the earliest sensations of impending ejaculation. At this point, the partner forcefully squeezes the coronal ridge of the glans, diminishing the erection and inhibiting ejaculation. The exercise program eventually raises the threshold of the sensation of ejaculatory inevitability and allows the man to focus on the sensations of arousal without anxiety and develop confidence in his sexual

performance. A variant of the exercise is the stop-start technique developed by James H. Semans, in which the woman stops all stimulation of the penis when the man first senses an impending ejaculation without squeezing. Research has shown that the presence or absence of circumcision has no bearing on a man's ejaculatory control; the glans is equally sensitive in the two states. Sex therapy has been most successful in the treatment of premature ejaculation.

A man with a sexual desire disorder or male erectile disorder can masturbate to prove that full erection and ejaculation are possible. Delayed ejaculation is managed initially by extravaginal ejaculation and then by gradual vaginal entry after stimulation to a point near ejaculation. Most importantly, the early exercises forbid ejaculation to remove the pressure to climax and allow the man to immerse himself in sexual pleasuring.

In cases of lifelong female orgasmic disorder, the woman is directed to masturbate, sometimes using a vibrator. The shaft of the clitoris is the masturbatory site most preferred by women, and orgasm depends on adequate clitoral stimulation. An area on the anterior wall of the vagina exists in some women as a site of sexual excitation, known as the *G-spot*, but reports of an ejaculatory phenomenon at orgasm in women following the stimulation of the G-spot is only anecdotal.

BEHAVIOR THERAPY. Behavioral approaches were initially designed for the treatment of phobias but are now used to treat other problems as well. Behavior therapists assume that the patient learns sexual dysfunction as maladaptive behavior, which causes them to fear sexual interaction. Using traditional techniques, therapists set up a hierarchy of anxiety-provoking situations, ranging from least threatening (e.g., the thought of kissing) to most threatening (e.g., the thought of penile penetration). The behavior therapist enables the patient to master the anxiety through a standard program of systematic desensitization, which inhibits the learned anxious response by encouraging behaviors antithetical to anxiety. The patient first deals with the least anxiety-producing situation in fantasy and progresses by steps to the most anxiety-producing situation. Medication, hypnosis, and specialized training in deep muscle relaxation can help with the initial mastery of anxiety.

Assertiveness training can help teach patients to express sexual needs

openly and without fear. The patient receives exercises in assertiveness, given in conjunction with sex therapy, and they are encouraged to make sexual requests and to refuse to comply with requests perceived as unreasonable. Sexual exercises may be prescribed for patients to perform at home, and the therapist helps the patient to establish a hierarchy, starting with those activities that have proved most pleasurable and successful in the past.

One treatment variation involves the participation of the patient's sexual partner in the desensitization program. The partner, rather than the therapist, presents items of increasing stimulation value to the patient. A cooperative partner is necessary to help the patient carry gains made during treatment sessions to sexual activity at home.

Couples who regularly practice assigned exercises appear to have a much higher likelihood of success than do more resistant couples or those whose interaction involves sadomasochistic or depressive features or mechanisms of blame and projection. Attitude flexibility is also a favorable prognostic factor. Overall, younger couples tend to complete sex therapy more often than older couples. Couples whose interactional difficulties center on their sex problems, such as inhibition, frustration, or fear of performance failure, are also likely to respond well to therapy.

MINDFULNESS. Mindfulness is a cognitive technique that has been helpful in the treatment of sexual dysfunction. The patient focuses on the moment and maintains an awareness of sensations—visual, tactile, auditory, and olfactory—that he or she experiences in the moment. The aim is to distract the patient from "spectatoring" (watching him or herself) and center the person on the sensations that lead to arousal or orgasm. Hopefully, this shift in focus allows patients to become immersed in the pleasure of the experience and remove themselves from self-judgment and performance anxiety.

GROUP THERAPY. Group therapy helps to examine both intrapsychic and interpersonal problems in patients with sexual disorders. A therapy group provides a strong support system for a patient who feels ashamed, anxious, or guilty about a particular sexual problem. It is a useful forum in which to counteract sexual myths, correct misconceptions, and provide accurate information about sexual anatomy, physiology, and varieties of behavior.

One can organize the groups in several ways. Members may all share the

same problem, such as premature ejaculation; members may all be of the same sex with different sexual problems, or groups may be composed of both men and women who are experiencing a variety of sexual problems. Group therapy can be an adjunct to other forms of therapy or the prime mode of treatment. Groups organized to treat a particular dysfunction are usually behavioral in approach.

Groups composed of married couples with sexual dysfunctions are also useful. A group provides the opportunity to gather accurate information, offers consensual validation of individual preferences, and enhances self-esteem and self-acceptance. Techniques, such as role-playing and psychodrama, may be used in treatment. Such groups are not indicated for couples when one partner is uncooperative, when a patient has a severe depressive disorder or psychosis, when a patient finds explicit sexual audiovisual material repugnant, or when a patient fears or dislikes groups.

HYPNOTHERAPY. Hypnotherapists focus specifically on the anxiety-producing situation—that is, the sexual interaction that results in dysfunction. The successful use of hypnosis enables patients to gain control over the symptom that has been lowering self-esteem and disrupting psychological homeostasis. The patient's cooperation is first obtained and encouraged during a series of nonhypnotic sessions with the therapist. Those discussions permit the development of a secure doctor–patient relationship, a sense of physical and psychological comfort on the part of the patient, and the establishment of mutually desired treatment goals. During this time, the therapist assesses the patient's capacity for the trance experience. The nonhypnotic sessions also permit the clinician to take a psychiatric history and perform a mental status examination before beginning hypnotherapy. The focus of treatment is on symptom removal and attitude alteration. The patient develops alternative means of dealing with the anxiety-provoking situation, the sexual encounter.

Also, the therapist teaches relaxation techniques for use before sexual relations. With these methods to alleviate anxiety, the physiologic responses to sexual stimulation can more readily result in pleasurable excitation and discharge. The therapy helps to remove psychological impediments to vaginal lubrication, erection, and orgasms so that normal sexual functioning ensues. Hypnosis may be added to a basic individual psychotherapy program to accelerate the effects of psychotherapeutic intervention.

ANALYTICALLY ORIENTED SEX THERAPY. Some therapists combine sex therapy with psychodynamic psychotherapy. The therapy occurs over a more extended period than usual, which allows learning or relearning of sexual satisfaction under the realities of patients' day-to-day lives. The addition of psychodynamic conceptualizations to behavioral techniques used to treat sexual dysfunctions allows the treatment of patients with sexual disorders associated with other psychopathology.

The material and dynamics that emerge in patients in analytically oriented sex therapy are the same as those in psychoanalytic therapy, such as dreams, fear of punishment, aggressive feelings, difficulty trusting a partner, fear of intimacy, oedipal feelings, and fear of genital mutilation. The combined approach of analytically oriented sex therapy is used by the general psychiatrist, who carefully judges the optimal timing of sex therapy and the ability of patients to tolerate the directive approach that focuses on their sexual difficulties.

PARAPHILIC DISORDERS

Paraphilias or perversions are sexual stimuli or acts that are deviations from normal sexual behaviors but are necessary for some persons to experience arousal and orgasm. DSM-5 only considers this a disorder when a person has acted on the fantasy or impulse, or if the fantasies or impulses lead to significant distress. Individuals with paraphilic interests can experience sexual pleasure, but they do not respond to stimuli that are typically considered erotic. The paraphiliac person's sexuality is mainly restricted to specific deviant stimuli or acts. Persons who occasionally experiment with paraphilic behavior (e.g., infrequent episode of bondage or dressing in costumes), but can respond to more typical erotic stimuli, do not have paraphilic disorders.

Paraphilic disorders can range from nearly normal behavior to behavior that is destructive or hurtful only to a person's self or to a person's self and partner, and finally to behavior that is deemed destructive or threatening to the community at large. DSM-5 lists pedophilia, frotteurism, voyeurism, exhibitionism, sexual sadism, sexual masochism, fetishism, and transvestism with explicit diagnostic criteria because of their threat to others or because they are relatively common paraphilias. Many other paraphilias exist.

A particular fantasy with its unconscious and conscious components is the pathognomonic element of the paraphilia, with sexual arousal and orgasm being associated phenomena that *reinforce the fantasy or impulse.* The influence of these fantasies and their behavioral manifestations often extend beyond the sexual sphere to pervade people's lives.

The primary functions of human sexual behavior are to assist in bonding, to create mutual pleasure in cooperation with a partner, to express and enhance love between two persons, and to procreate. Paraphilic disorders entail divergent behaviors in that those acts involve aggression, victimization, and extreme one-sidedness. The behaviors exclude or harm others and disrupt the potential for bonding between persons. Moreover, paraphilic sexual scripts often serve other vital psychic functions. They may assuage anxiety, bind aggression, or stabilize identity.

The Clinical Presentation and Diagnosis

In DSM-5, the criteria for paraphilic disorder require the patient to experience intense and recurrent arousal from their deviant fantasy for at least 6 months and to either act on the paraphilic impulse or experience significant distress as a result of the impulse. The fantasy distressing the patient contains unusual sexual material that is relatively fixed and shows only minor variations. Arousal and orgasm depend on the mental elaboration, if not the behavioral playing out of the fantasy. Sexual activity is ritualized or stereotyped and makes use of degraded, reduced, or dehumanized objects.

Exhibitionism

Exhibitionism is the recurrent urge to expose the genitals to a stranger or an unsuspecting person. Sexual excitement occurs in anticipation of the exposure, and orgasm is brought about by masturbation during or after the event. In almost 100 percent of cases, those with exhibitionism are men exposing themselves to women. The dynamic of men with exhibitionism is to assert their masculinity by showing their penises and by watching the victims' reactions—fright, surprise, and disgust. In other related paraphilias, the central themes involve derivatives of looking or showing.

A substance-abusing professional was finally able to attain sobriety at age

33 years. With this accomplishment, he met a woman and got married, began to work steadily for the first time in his life, and was able to impregnate his new wife. His preferred sexual activity had been masturbation in semi-public places. The patient had a strong sense that his mother had always thought him to be inadequate, did not like to spend time with him, and constantly made negative comparisons between him and his "all-boy" younger brother. He recalled several times when his father had tried to explain his mother's antipathy: "It is just one of those things, son: your mother does not seem to like you." Without substance abuse, he gave up his exhibitionism, but he quickly developed sexual incapacity with his wife and became "addicted" to phone sex. (Courtesy of Stephen B. Levine, M.D.)

Specifiers added to exhibitionistic disorder by DSM-5 differentiate between arousal from exposing genitals to prepubertal children, to physically mature individuals, or both (Table 16-15).

Fetishism

In fetishism, the sexual focus is on objects (e.g., shoes, gloves, pantyhose, and stockings) that are intimately associated with the human body, or on nongenital body parts. The latter focus is sometimes called *partialism*. DSM-5 applies the diagnosis of fetishistic disorder to partialism and attaches the following specifiers to fetishistic disorder: body part(s); nonliving parts; other (Table 16-16). The particular fetish used is linked to someone closely involved with a patient during childhood and has a quality associated with this loved, needed, or even traumatizing person. Usually, the disorder begins by adolescence, although the fetish may begin in childhood. Once established, the disorder tends to be chronic.

Severity Specifiers	**In a controlled environment** (lives in institution/other controlled environment)
Course Specifiers	**In full remission:** no symptoms or distress for ≥5 yr

The patient may direct sexual activity at the fetish itself (e.g., masturbation with or into a shoe), or may incorporate the fetish into sexual intercourse (e.g., the demand that high-heeled shoes be worn). The disorder is almost exclusively found in men. Learning theorists believe that the object was associated with sexual stimulation at an early age.

A 50-year-old man entered treatment with a chief complaint of erectile disorder experienced primarily with his wife. He was suffering from a moderate depression that related to both his marital issues and business problems. He had no erectile problems with women he picked up in bars or knew and arranged to meet in bars, partly because where he lived, smoking was allowed in bars. The woman's act of smoking a cigarette was necessary to his sexual arousal. His family history included an alcoholic mother and an emotionally abusive father who was a chain smoker. On family car trips, the father would smoke, with all the car windows up. If the patient complained of feeling nauseous, the father would tell him to "shut up." He recalled being very attracted to a Sunday school teacher who smoked when he was six years old. He first smoked when he was 13, sneaking and hiding behind his house. His first cigarette was one he stole from a pack on his mother's night table.

Frotteurism

Frotteurism is usually characterized by a man's rubbing his penis against the buttocks or other body parts of a fully clothed woman to achieve orgasm (Table 16-17). At other times, he may use his hands to rub an unsuspecting victim. The acts usually occur in crowded places, particularly in subways and buses. Those with frotteurism are passive and isolated, and frottage is often their only source of sexual gratification. The expression of aggression in this paraphilia is readily apparent.

Pedophilia

Pedophilia involves recurrent intense sexual urges toward, or arousal by, children. Per DSM-5, the child must be under 14 years old, and the patient must be at least 16 years old and at least five years older than the victims.

Most child molestations involve genital fondling or oral sex. Vaginal or anal penetration of children infrequently occurs, except in cases of incest. Although most child victims coming to public attention are girls, this finding may be a product of the referral process. Offenders report that when they touch a child, most (60 percent) of the victims are boys. This figure is in sharp contrast to the figure for nontouching victimization of children, such as window peeping and exhibitionism; 99 percent of all such cases occur against girls. DSM-5 includes criteria to specify the genders of the patient's target, and Table 16-18 compares the criteria for this disorder.

Of persons with pedophilia, 95 percent are heterosexual, and 50 percent have consumed alcohol to excess at the time of the incident. Many perpetrators concomitantly or have previously committed exhibitionism, voyeurism, or rape.

Incest is related to pedophilia by the frequent selection of an immature child as a sex object, the subtle or overt element of coercion, and occasionally the preferential nature of the adult–child liaison.

Table 16-17
Frotteurism

DSM-5	ICD-10

Name	Frotteuristic Disorder	Other disorder of sexual preference *Frotteurism*
Duration	≥6 mo	
Symptoms	Sexual arousal/fantasies/urges/behaviors that result from touching/rubbing against a nonconsenting individual	Sexual arousa from rubbin against people in public spaces
Psychosocial Impact	Marked distress and/or psychosocial impairment

Course Specifiers	**In full remission:** no symptoms or distress for ≥5 yr	
Comments		This category also includes *Necrophilia* in addition t behaviors such as making obscene phone calls engaging in sexual activity with animals, an

use of strangulatic for sexual excitement

A 62-year-old married janitor had worked as a fourth-grade school teacher for 26 years before he transferred school districts, and several years later mysteriously lost his second job. He was referred for help after his family discovered that he had repeatedly fondled the genitals of his 4- and 6-year-old granddaughters. A father of five who had not had sex with his wife for 30 years after strenuously objecting to her cigarette smoking, he was generous, helpful, and cooperative with his children and grandchildren. Intellectually slow, he preferred comic books and had a charming manner of playing with young children "like he was one himself." By his estimate, he had touched the buttocks and genitals of at least 300 girl students, thinking only of how they did not know what he was doing because he was affectionate, and they were too young to realize what was happening. He loved the anticipation and excitement of this behavior. His teaching career ended when parents complained to a principal. The principal discovered that the man had lost his last job for the same reason. (Courtesy of Stephen B. Levine, M.D.)

Sexual Masochism

Masochism takes its name from the 19th-century novelist Sacher-Masoch, whose characters derived sexual pleasure from being abused and dominated by women. According to the DSM-5, persons with sexual masochism have a recurrent preoccupation with sexual urges and fantasies involving the act of being humiliated, beaten, bound, or otherwise made to suffer (Table 16-19). The diagnosis includes asphyxiophilia or autoerotic asphyxiation as a subtype. It is the practice of achieving or heightening sexual arousal with restriction of breathing. Sexual masochistic practices are more common among men than among women. Persons with sexual masochism may have had childhood experiences that convinced them that pain is a prerequisite for sexual pleasure. About 30 percent of those with sexual masochism also have

sadistic fantasies. Moral masochism involves a need to suffer but does not include sexual fantasies.

Table 16-18
Pedophilia

	DSM-5	ICD-10
Name	Pedophilic Disorder	Pedophilia
Duration	≥6 mo	
Symptoms	Sexual arousal/fantasies/urges/behaviors that result from sexual activity with prepubescent children Individual must be 16 yr or older at time of diagnosis, and must also be a minimum of 5 yr older than the child of sexual interest	Sexually preferring young boys and girls Often preferring prepubertal or early pubertal age
# Symptoms Needed	Both of the above	
Exclusion	≤16 yr old Adolescent in relationship with child aged 12 or 13	
Psychosocial Impact	Marked distress and/or psychosocial impairment

Comments		ICD combined masochism

and sadism into one diagnosis

A 27-year-old woman presented for a job interview. She was accompanied by a man whom she introduced, saying, “This is my lover.” When asked about this, the woman said that her companion had ordered her to bring him and introduce him in that way. She further explained that she was part of a group that utilized sadomasochistic techniques in their sexual play.

Sexual Sadism

Sexual sadism is recurrent and intense sexual arousal from the physical and psychological suffering of another person. The name is from the Marquis de Sade, an 18th-century French author who wrote novels detailing violent sexual acts against women, and was himself imprisoned for such acts. A person must have experienced these feelings for at least 6 months and must have either acted on sadistic fantasies or experienced significant distress as a result of these fantasies to receive a diagnosis of sexual sadism disorder (Table 16-20).

The onset of the disorder is usually before the age of 18 years, and most persons with sexual sadism are male. Sexual sadism likely derives from early abusive life experiences. However, there is little data about how the disorder develops. Sexual sadism is related to rape, although rape is more aptly considered an expression of power. Some sadistic rapists, however, kill their victims after having sex (so-called lust murders). In many cases, these persons have underlying schizophrenia, and they may also suffer from a dissociative disorder or have a history of head trauma.

Voyeurism

Voyeurism, also known as *scopophilia*, is the recurrent preoccupation with fantasies and acts that involve observing unsuspecting persons who are naked or engaged in grooming or sexual activity (Table 16-21). Masturbation to orgasm usually accompanies or follows the event. The first voyeuristic act

usually occurs during childhood, and the paraphilia is most common in men. When persons with voyeurism are apprehended, the charge is usually loitering.

Transvestism

Transvestism, formerly called transvestic fetishism, is described as fantasies and sexual urges to dress in opposite gender clothing as a means of arousal and as an adjunct to masturbation or coitus. DSM also has various specifiers depending on the exact nature of the fantasy, and Table 16-22 compares the criteria for this disorder.

Table 16-20
Sexual Sadism

Course Specifiers	**In full remission:** no symptoms or distress for ≥5 yr

Transvestism typically begins in childhood or early adolescence. With time, some men want to dress and live permanently as women. Very rarely, women want to dress and live as men. DSM-5 considers this to be a combination of transvestic disorder and gender dysphoria. Usually, a person wears more than one article of opposite sex clothing; frequently, this involves an entire wardrobe. When a man with transvestism cross-dresses, the appearance of femininity may be striking, although not usually to the degree found in transsexualism. When not dressed in women's clothes, men with transvestism may be hypermasculine in appearance and occupation. Cross-dressing can range from solitary, guilt-ridden behaviors to ego-syntonic, social membership in a subculture.

The overt clinical syndrome of transvestism may begin in latency but is more often seen around pubescence or in adolescence. Frank dressing in opposite-sex clothing usually does not begin until the person is relatively independent of their parents.

Other Specified Paraphilic Disorder

DSM-5 includes a generalized category for paraphilias that cause distress but do not fit into one of the previous categories. We describe some examples of these next.

In some cases, we may not wish to specify the exact paraphilia, such as when we do not yet have enough information; in these cases, we would diagnose an unspecified paraphilic disorder.

Telephone and Computer Scatologia. Telephone scatologia involves

obscene phone calling to an unsuspecting recipient. Tension and arousal begin in anticipation of phoning; the recipient of the call listens while the telephoner (usually male) verbally exposes his preoccupations or induces her to talk about her sexual activity. The conversation is accompanied by masturbation.

Persons also use interactive computer networks, sometimes compulsively, to send obscene messages by electronic mail and to transmit sexually explicit messages and video images. Because of the anonymity of the users in chat rooms who use aliases, on-line or computer sex (cybersex) allows some persons to play the role of the opposite sex ("genderbending"), which represents an alternative method of expressing transvestic or other fantasies. A danger of on-line cybersex is that pedophiles often make contact with children or adolescents who lure children into meeting and then molest them. Many on-line contacts develop into off-line liaisons. Although some persons report that the off-line encounters develop into meaningful relationships, most such meetings are filled with disappointment and disillusionment, as the fantasized person fails to meet the unconscious expectations of the ideal partner. In other situations, when adults meet, rape or even homicide may occur.

Table 16-22

Severity Specifiers	**In a controlled environment:** lives in institution/other controlled environment	
Course Specifiers	**In full remission:** no symptoms or distress for ≥5 yr	

Necrophilia. Necrophilia is an obsession with obtaining sexual gratification from cadavers. Most persons with this disorder find corpses in morgues, but some may rob graves or even murder to satisfy their sexual urges. In the few cases studied, those with necrophilia believed that they were inflicting the greatest conceivable humiliation on their lifeless victims. Some experts consider this a type of psychosis.

Partialism. Persons with the disorder of partialism concentrate their sexual activity on one part of the body to the exclusion of all others. Mouth–genital contacts—such as cunnilingus (oral contact with a woman's external genitals), fellatio (oral contact with the penis), and anilingus (oral contact with the anus)—is typically associated with foreplay. However, when a person uses these activities as the sole source of sexual gratification and cannot have or refuses to have coitus, a paraphilia exists. It is also known as *oralism.* As described earlier, transvestism is a type of partialism but differs in that the focus is not on a sexual organ.

Zoophilia. In zoophilia, persons incorporate animals into arousal fantasies

or sexual activities, including intercourse, masturbation, and oral–genital contact. Zoophilia, as an organized paraphilia, is rare. For many persons, animals are the primary source of relatedness, so it is not surprising that some may use a broad variety of domestic animals sensually or sexually.

Sexual relations with animals may occasionally be an outgrowth of availability or convenience, especially in parts of the world where rigid convention precludes premarital sexuality and in situations of enforced isolation. Because masturbation is also available in such situations, however, a predilection for animal contact is probably present in opportunistic zoophilia.

Coprophilia, Urophilia, and Klismaphilia. Coprophilia is sexual pleasure associated with the desire to defecate on a partner, to be defecated on, or to eat feces (coprophagia). A variant is the compulsive utterance of obscene words (coprolalia). Urophilia, a form of urethral eroticism, is an interest in sexual pleasure associated with the desire to urinate on a partner or to be urinated on. The disorder may be associated with masturbatory techniques involving the insertion of foreign objects into the urethra for sexual stimulation. Similarly, klismaphilia is the use of enemas for sexual stimulation.

Hypoxyphilia. Hypoxyphilia is the desire to achieve an altered state of consciousness secondary to hypoxia while experiencing orgasm. Persons may use a drug (e.g., a volatile nitrite or nitrous oxide) to produce hypoxia. Autoerotic asphyxiation is related and is a form of sexual masochism.

Differential Diagnosis

Clinicians must differentiate a paraphilia from an experimental act that is not recurrent or compulsive and done for its novelty. Paraphilic activity most likely begins during adolescence. Some paraphilias (especially the bizarre types) are associated with other mental disorders, such as schizophrenia. Brain diseases can also release perverse impulses.

Course and Prognosis

The difficulty in controlling or curing paraphilic disorders rests in the fact

that it is hard for people to give up sexual pleasure with no assurance that alternative approaches will be as sexually gratifying. The prognosis is poor when it begins at an early age, and when it occurs frequently. Also, a lack of guilt is a bad predictor of outcome, as is a substance use disorder. The course and the prognosis are better when patients also engage in regular sexual activity. It may also be better when patients self-refer than are forced to present for legal reasons.

Treatment

There are five types of psychiatric interventions used to treat persons with paraphilic disorder: external control, reduction of sexual drives, treatment of comorbid conditions (e.g., depression or anxiety), cognitive-behavioral therapy, and dynamic psychotherapy.

Prison is an external control mechanism for sexual crimes that usually does not contain a treatment element. When victimization occurs in a family or work setting, the external control comes from informing supervisors, peers, or other adult family members of the problem and advising them about eliminating opportunities for the perpetrator to act on urges.

Drug therapy, including antipsychotic or antidepressant medication, is indicated for the treatment of schizophrenia or depressive disorders if the paraphilia is associated with these disorders. Antiandrogens, such as cyproterone acetate in Europe and medroxyprogesterone acetate (Depo-Provera) in the United States, may reduce the drive to behave sexually by decreasing serum testosterone levels to subnormal concentrations. Serotonergic agents, such as fluoxetine, have been used with limited success in some patients with paraphilia.

Cognitive-behavioral therapy can disrupt learned paraphilic patterns and modify behavior to make it socially acceptable. The interventions include social skills training, sex education, cognitive restructuring (confronting and destroying the rationalizations used to support the victimization of others), and development of victim empathy. The therapist can also teach the patient imaginal desensitization and relaxation technique. The patient can also learn what triggers the paraphilic impulse so that they can avoid these stimuli. In modified aversive behavior rehearsal, the therapist videotapes the perpetrators acting out their paraphilia with a mannequin. Then the therapist

or a peer group may confront the patient with questions about feelings, thoughts, motives associated with the act and repeatedly try to correct cognitive distortions and point out the lack of victim empathy to the patient.

Insight-oriented psychotherapy is a long-standing treatment approach. Patients have the opportunity to understand their dynamics and the events that caused the paraphilia to develop. In particular, they become aware of the daily events that cause them to act on their impulses (e.g., a real or fantasized rejection). Treatment helps them deal more effectively with life stresses and enhances their capacity to relate to a life partner. Also, psychotherapy allows patients to regain self-esteem, which in turn allows them to approach a partner in a more normal sexual manner. Sex therapy is an appropriate adjunct to the treatment of patients with specific sexual dysfunctions when they attempt nondeviant sexual activities.

Good treatment predictors include the presence of a single paraphilia, normal intelligence, the absence of substance abuse, the absence of nonsexual antisocial personality traits, and the presence of a successful adult attachment. Paraphilic disorders, however, remain significant treatment challenges even under these circumstances.

Epidemiology

Paraphilias are rare, but the insistent, repetitive nature of the disorders results in a high frequency of such acts. Thus, many people are victims of persons with paraphilic disorders. It may be that the prevalence of paraphilias is much higher than that found in clinical care, given the large commercial market in paraphilic pornography and paraphernalia. We do not know how many consumers of these materials act on their fantasies or cannot respond to typical erotic stimuli.

Among legally identified cases of paraphilic disorders, pedophilia is most common. Of all children, 10 to 20 percent have been molested by age 18. Because the act involves a child, it has gotten more attention than some other paraphilic disorders. Persons with exhibitionism who publicly display themselves to young children are also commonly apprehended. Those with voyeurism may be apprehended, but their risk is not considerable. Of adult females, 20 percent have been the targets of persons with exhibitionism and voyeurism. Sexual masochism and sexual sadism are underrepresented in any

prevalence estimates. Sexual sadism usually comes to attention only in sensational cases of rape, brutality, and lust murder. The excretory paraphilic disorders rarely come to clinical attention, as it usually takes place between consenting adults or between a sex worker and client. Persons with fetishism rarely become entangled in the legal system. Those with transvestism may be arrested occasionally for disturbing the peace or on other misdemeanor charges if they are men dressed in women's clothes, but an arrest is more common among those with gender identity disorders. Zoophilia, as an actual paraphilic disorder, is rare (Table 16-23).

As usually defined, the paraphilias seem to be mostly male conditions. Fetishism almost always occurs in men. More than 50 percent of all paraphilias have their onset before age 18. Patients with paraphilia frequently have three to five paraphilias, either concurrently or at different times in their lives. This pattern of occurrence is especially the case with exhibitionism, fetishism, sexual masochism, sexual sadism, transvestic fetishism, voyeurism, and zoophilia (see Table 16-23). The occurrence of paraphilic behavior peaks between ages 15 and 25 and gradually declines. DSM-5 suggests the paraphilia designation be reserved for those ages 18 and older to avoid pathologizing healthy sexual curiosity and occasional experimentation in adolescence. In men older than 50, criminal paraphilic acts are rare. Those that occur are practiced in isolation or with a cooperative partner.

Table 16-23
Frequency of Paraphilic Acts Committed by Patients with Paraphilia Seeking Outpatient Treatment

Diagnostic Category	Patients with Paraphilia Seeking Outpatient Treatment (%)	Paraphilic Acts per Patient with Paraphilia
Pedophilia	45	5
Exhibitionism	25	50
Voyeurism	12	17
Frotteurism	6	30

Sexual masochism	3	36
Transvestic fetishism	3	25
Sexual sadism	3	3
Fetishism	2	3
Zoophilia	1	2

Etiology

Psychosocial Factors. Many paraphilias can be traced back to childhood experiences that condition or socialize children into committing a paraphilic act. The first shared sexual experience can be significant in that regard. Molestation as a child can predispose a person to accept continued abuse as an adult or, conversely, to become an abuser of others. Also, early experiences of abuse that are not explicitly sexual, such as spanking, enemas, or verbal humiliation, can be sexualized by a child and can form the basis for a paraphilia. Such experiences can result in the development of an *eroticized child.*

A 34-year-old man presented for the treatment of an erectile disorder. He was frequently unable to obtain an erection sufficient for coitus with his wife. The problem disappeared whenever she was willing to act out his bondage fantasy and tie him up with ropes, a scenario he intensely desired. He explained that he felt free to be sexual when tied up because it reassured him that he could move vigorously and not hurt the woman. Also, he gave a history of being tied up “in fun” when he was a child by a babysitter who would then tickle him until he begged her to stop.

The onset of paraphilic acts can result from persons’ modeling their behavior on the behavior of others who have carried out paraphilic acts,

mimicking sexual behavior depicted in the media, or recalling emotionally laden events from the past, such as their molestation. Learning theory indicates that because the fantasizing of paraphilic interests begins at an early age and because children are likely to hide their fantasies from others (who might discourage them), the use and misuse of paraphilic fantasies and urges continue uninhibited until late in life. Only then do persons begin to realize that such paraphilic interests and urges are inconsistent with societal norms. By that time, however, the repetitive use of such fantasies has become ingrained, and sexual thoughts and behaviors have become associated with or conditioned to paraphilic fantasies.

In the classic psychoanalytic model, persons with a paraphilia have failed to complete the normal developmental process toward sexual adjustment, but new psychoanalytic approaches have modified the model. What distinguishes one paraphilia from another is the method chosen by a person (usually male) to cope with the anxiety caused by the threat of castration by the father and separation from the mother. However bizarre its manifestation, the resulting behavior provides an outlet for the sexual and aggressive drives that would otherwise channel into normal sexual behavior.

Biologic Factors. Several studies have identified abnormal biologic findings in persons with paraphilias. None has used random samples of such persons; instead, they have extensively investigated patients with paraphilia at large medical centers. Among these patients, those with positive physical findings included 74 percent with abnormal hormone levels, 27 percent with hard or soft neurologic signs, 24 percent with chromosomal abnormalities, 9 percent with seizures, 9 percent with dyslexia, 4 percent with abnormal electroencephalography (EEG) studies, 4 percent with major mental disorders, and 4 percent with an intellectual disorder. It is not clear whether these abnormalities are causally related or incidental to the paraphilia.

Psychophysiological tests can measure the penile volumetric size in response to paraphilic and nonparaphilic stimuli. The procedures may be of use in diagnosis and treatment but are of questionable diagnostic validity because some men can suppress their erectile responses.

SEX ADDICTION AND COMPULSIVITY

The concept of sex addiction developed over the last two decades to refer to persons who compulsively seek out sexual experiences and whose behavior becomes impaired if they are unable to gratify their sexual impulses. This concept derives from the model of substance addiction or such addictive behaviors as gambling. Addiction implies psychological dependence, physical dependence, and the presence of a withdrawal syndrome if the substance or behavior is not available.

DSM-5 does not contain the diagnosis of sex addiction or compulsive sexuality, and the concept remains controversial. Nevertheless, the phenomenon of a person whose life revolves around sex-seeking behavior and activities, who spends an excessive amount of time in such behavior, and who often tries to stop such behavior but is unable to do so is well known to clinicians. Such persons show repeated and increasingly frequent attempts to have a sexual experience, deprivation of which gives rise to symptoms of distress. When encountering such a story, this should alert the clinician to find an underlying cause for the behavior.

Sex addicts cannot control their sexual impulses, which can involve the entire spectrum of sexual fantasy or behavior. Eventually, the need for sexual activity increases, and the person's behavior is mainly motivated by the persistent desire to experience the sex act. The history usually reveals a long-standing pattern of such behavior, which the person repeatedly has tried to stop, but without success. Although a patient may have feelings of guilt and remorse after the act, these feelings do not suffice to prevent its recurrence. The patient may report that their need to act out is most severe during stressful periods or when angry, depressed, anxious, or otherwise dysphoric. Most acts culminate in sexual orgasm. Eventually, the sexual activity interferes with the person's social, vocational, or marital life, which begins to deteriorate. Table 16-24 lists the signs of sexual addiction.

Table 16-24
Signs of Sexual Addiction

1. Out-of-control behavior
2. Severe adverse consequences (medical, legal, interpersonal) due to sexual behavior

3. Persistent pursuit of self-destructive or high-risk sexual behavior
4. Repeated attempts to limit or stop sexual behavior
5. Sexual obsession and fantasy as a primary coping mechanism
6. The need for increasing amounts of sexual activity
7. Severe mood changes related to sexual activity (e.g., depression, euphoria)
8. Inordinate amount of time spent in obtaining sex, being sexual, or recovering from sexual experience
9. Interference of sexual behavior in social, occupational, or recreational activities

Some men who appear to be hypersexual, as manifested by their need to have many sexual encounters or conquests, use their sexual activities to mask deep feelings of inferiority, this is sometimes called *Don Juanism*. Some are unconsciously attracted to other men, which they deny by compulsive sexual contact with women. After having sex, most Don Juans are no longer interested in the woman. The condition is also called *satyriasis*.

In a woman, a similar condition is called nymphomania. Of the few scientific studies of the condition, those patients who were studied usually have had one or more sexual disorders, often including female orgasmic disorder. The woman often has an intense fear of losing love and, through her actions, attempts to satisfy her dependence needs rather than gratify her sexual impulses.

Comorbidity

Many sex addicts have an associated psychiatric disorder. The comorbid diagnosis may be challenging to recognize, given that the addictive disorder produces considerable stress and anxiety on its own. Most common are substance use disorders (up to 80 percent in some studies), which not only complicates the task of diagnosis, but also complicates treatment.

Treatment

Self-help groups based on the 12-step concept used in Alcoholics Anonymous (AA) have been used successfully with many sex addicts. They include such groups as Sexaholics Anonymous (SA), Sex and Love Addicts Anonymous (SLAA), and Sex Addicts Anonymous (SAA). The groups differ in that some are for men or women, or married persons or couples. All advocate some abstinence from either the addictive behavior or sex in general. Should a substance use disorder also be present, the patient often requires referral to AA or Narcotics Anonymous (NA) as well. Patients may enter an inpatient treatment unit when they lack sufficient motivation to control their behavior on an outpatient basis or pose a danger to themselves or others. Also, severe medical or psychiatric symptoms may require careful supervision and treatment best carried out in a hospital.

A 42-year-old married businessman with two children was considered a model of virtue in his community. He was active in his church and on the boards of several charitable organizations. He was living a secret life, however, and would lie to his wife, telling her that he was at a board meeting when he was visiting massage parlors for paid sex. He eventually was engaging in the behavior four to five times a day, and although he tried to quit many times, he was unable to do so. He knew that he was harming himself by putting his reputation and marriage at risk.

The patient presented himself to the psychiatric emergency room, stating that he would prefer to be dead rather than continue the behavior described. He was admitted with a diagnosis of major depressive disorder and started on a daily dose of 20 mg of fluoxetine. He also received 100 mg of medroxyprogesterone intramuscularly once a day. His need to masturbate diminished markedly and ceased entirely on the third hospital day, as did his mental preoccupation with sex. His clinicians discontinued the medroxyprogesterone on the sixth day and discharged him. He continued to take fluoxetine, enrolled in a local SA group, and entered individual and couples psychotherapy. His addictive behavior eventually stopped, he was having satisfactory sexual relations with his wife, and he was no longer suicidal or depressed.

Pharmacotherapy. Certain medications may be of use in treating sex

addiction, however, because of their specific effects on reducing the sex drive. SSRIs reduce libido in some persons. Compulsive masturbation is an example of a behavioral pattern that may benefit from such medication. Medroxyprogesterone acetate diminishes libido in men and, thus, makes it easier to control sexually addictive behavior.

There is little information on the use of antiandrogens in women to control hypersexuality; however, they might be of benefit. Antiandrogenic agents (e.g., cyproterone acetate) are not available in the United States, but in Europe, they have had varying success. Antiandrogenic medications remain controversial, and some clinicians see it as chemical castration.

Psychotherapy. Insight-oriented psychotherapy may help patients understand the dynamics of their behavioral patterns. Supportive psychotherapy can help repair the interpersonal, social, or occupational damage that occurs. Cognitive behavioral therapy helps the patient recognize dysphoric states that precipitate sexual acting out. Marital therapy or couples therapy can help the patient regain self-esteem. It is also helpful to the partners who need assistance in understanding the disease and dealing with their complex reactions to the situation. Finally, psychotherapy may help in the treatment of any associated psychiatric disorder.

NORMAL SEXUALITY

Sexuality is determined by anatomy, physiology, the culture in which a person lives, relationships with others, and developmental experiences throughout the life cycle. It includes the perception of being male or female and private thoughts and fantasies as well as behavior. To the average person, sexual attraction to another person and the passion and love that follow are deeply associated with feelings of intimate happiness.

Healthy sexual behavior brings pleasure to oneself and one’s partner and involves stimulation of the primary sex organs, including coitus; it is devoid of inappropriate feelings of guilt or anxiety and is not compulsive. Societal understanding of what defines normal sexual behavior is inconstant and varies from era to era, reflecting the cultural mores of the time.

Terms

Sexuality and personality cannot be separated as they are related; hence the term *psychosexual,* to describe personality development and functioning as affected by sexuality. The term *psychosexual* applies to more than sexual feelings and behavior, and it is not synonymous with *libido* in the Freudian sense.

Childhood Sexuality

Before Freud described the effects of childhood experiences on the personalities of adults, the universality of sexual activity and sexual learning in children was unrecognized. Most sexual learning experiences in childhood occur without the parents' knowledge, but awareness of a child's sex does influence parental behavior. Male infants, for instance, tend to be handled more vigorously, and female infants cuddled more. Fathers spend more time with their infant sons than with their daughters, and they also tend to be more aware of their sons' adolescent concerns than of their daughters' anxieties. Boys are more likely than girls to be physically disciplined. A child's sex affects parental tolerance for aggression and reinforcement or extinction of activity and intellectual, aesthetic, and athletic interests.

Observation of children reveals that genital play in infants is part of healthy development. According to Harry Harlow, interaction with mothers and peers is necessary for the development of active adult sexual behavior in monkeys, a finding that has relevance to the socialization of children. During a critical period in development, infants are especially susceptible to certain stimuli; later, they may be immune to these stimuli. We do not entirely understand the detailed relation of critical periods to psychosexual development; Freud's stages of psychosexual development—oral, anal, phallic, latent, and genital—presumably provide a broad framework.

Psychosexual Factors

Sexuality depends on four interrelated psychosexual factors: sexual identity, gender identity, sexual orientation, and sexual behavior. These factors affect personality, growth, development, and functioning. Sexuality is something more than physical sex, coital or noncoital, and something less than all behaviors directed toward attaining pleasure.

Sexual Identity, Gender Identity, and Sexual Orientation

Sexual identity is the pattern of a person's biologic sexual characteristics: chromosomes, external genitalia, internal genitalia, hormonal composition, gonads, and secondary sex characteristics. In healthy development, these characteristics form a cohesive pattern that leaves a person in no doubt about his or her sex. Gender identity is a person's sense of maleness or femaleness. Sexual identity and gender identity are interactive. Genetic influences and hormones affect behavior, and the environment affects hormonal production and gene expression (Table 16-25).

Sexual Identity. Modern embryologic studies have shown that all mammalian embryos, whether genetically male (XY genotype) or genetically female (XX genotype), are anatomically female during the early stages of fetal life. Differentiation of the male from the female results from the action of fetal androgens; the action begins about the sixth week of embryonic life and finishes by the end of the third month. Recent research has focused on the possible roles of critical genes in fetal sexual development. A testis develops because of SRY and SOX9 action, and an ovary develops in the absence of such action. DAX1 plays a part in the fetal development of both sexes, and WNT4 action is needed for the development of the müllerian ducts in the female fetus. Other studies have explained the effects of fetal hormones on the masculinization or feminization of the brain. In animals, prenatal hormonal stimulation of the brain is necessary for male and female reproductive and copulatory behavior. The fetus is also vulnerable to exogenously administered androgens during that period. For instance, if a pregnant woman receives sufficient exogenous androgens, her female fetus that possesses ovaries can develop external genitalia resembling those of a male fetus.

In the past, newborns with ambiguous genitalia were assigned their sexual identity at birth. The theory underlying this action was that parents and child would feel less confusion and that the child would accept the assigned sex and more easily develop a stable sense of being male or female. Although this worked for some children, others developed a gender identity at odds with their assigned sex. For example, an infant designated female at birth could instead feel male throughout childhood, and more emphatically at

puberty. In some cases, this conflict led to depression and even suicide. Current practice usually allows the child to develop with the ambiguity, which permits a sense of gender identity to evolve as the child grows. The gender identity is then more congruent with the child's emotional sense of maleness or femaleness. Ideally, the family receives support from a medical team composed of a pediatrician, an endocrinologist, and a psychiatrist throughout this developmental process.

Table 16-25
Classification of Intersexual Disorders[a]

Syndrome	Description
Virilizing adrenal hyperplasia (adrenogenital syndrome)	Results from excess androgens in fetus with XX genotype; most common female intersex disorder; associated with enlarged clitoris, fused labia, hirsutism in adolescence
Turner syndrome	Results from absence of second female sex chromosome (XO); associated with web neck, dwarfism, cubitus valgus; no sex hormones produced; infertile
Klinefelter syndrome	Genotype is XXY; male habitus present with small penis and rudimentary testes because of low androgen production; weak libido; usually assigned as male
Androgen insensitivity syndrome (testicular-feminizing syndrome)	Congenital X-linked recessive disorder that results in inability of tissues to respond to androgens; external genitals look female and cryptorchid testes present; in extreme form patient has breasts, normal external genitals, short blind vagina, and absence of pubic and axillary hair

Enzymatic defects in XY genotype (e.g., 5-α-reductase deficiency, 17-hydroxy-steroid deficiency)	Congenital interruption in production of testosterone that produces ambiguous genitals and female habitus
Hermaphroditism	True hermaphrodite is rare and characterized by both testes and ovaries in same person (may be 46 XX or 46 XY)
Pseudohermaphroditism	Usually the result of endocrine or enzymatic defect (e.g., adrenal hyperplasia) in persons with normal chromosomes; female pseudohermaphrodites have masculine-looking genitals but are XX; male pseudohermaphrodites have rudimentary testes and external genitals and are XY

[a]Intersexual disorders include a variety of syndromes that produce persons with gross anatomical or physiologic aspects of the opposite sex.

Gender Identity. In infants with an unambiguous sexual identity, almost everyone has a firm conviction that "I am male" or "I am female" by 2 to 3 years of age. However, even if maleness and femaleness develop typically, persons must still develop a sense of masculinity or femininity.

Gender identity, according to Robert Stoller, "connotes psychological aspects of behavior related to masculinity and femininity." Stoller considers gender social and sex biologic: "Most often, the two are relatively congruent, that is, males tend to be manly and females womanly." Nevertheless, sex and gender can develop in conflicting or even opposite ways. Gender identity results from an almost infinite series of cues derived from experiences with family members, teachers, friends, and coworkers, and from cultural phenomena. Physical characteristics derived from a person's biologic sex—such as physique, body shape, and physical dimensions—interrelate with an intricate system of stimuli, including rewards and punishment and parental

gender labels, to establish gender identity.

Thus, the formation of gender identity arises from parental and cultural attitudes, the infant's external genitalia, and genetic influence, which is physiologically active by the sixth week of fetal life. Although family, cultural, and biological influences may complicate the establishment of a sense of masculinity or femininity, persons usually develop a relatively secure sense of identification with their biologic sex—a stable gender identity.

GENDER ROLE. Related to, and in part derived from, gender identity is gender role behavior. John Money and Anke Ehrhardt described gender role behavior as all those things that a person says or does to disclose himself or herself as having the status of boy or man, girl or woman, respectively. A gender role is not established at birth, but builds gradually through (1) experiences encountered and transacted through casual and unplanned learning, (2) explicit instruction and inculcation, and (3) spontaneously putting two and two together to sometimes make four and sometimes five. The usual outcome is a congruence of gender identity and gender roles. Although biologic attributes are significant, the primary factor in achieving the role appropriate to a person's sex is learning.

Research on sex differences in children's behavior reveals more psychological similarities than differences. Girls, however, are found to be less susceptible to tantrums after the age of 18 months than are boys, and boys generally are more physically and verbally aggressive than are girls from age two onward. Little girls and little boys are similarly active, but boys are more easily stimulated to sudden bursts of activity when they are in groups. Some researchers speculate that, although aggression is a learned behavior, male hormones may have sensitized boys' neural organizations to absorb these lessons more readily than do girls.

Persons' gender roles can seem to be opposed to their gender identities. They may identify with their sex and yet adopt the dress, hairstyle, or other characteristics of the opposite sex. Alternatively, they may identify with the opposite sex and yet for expediency adopt many behavioral characteristics of their sex. A further discussion of gender issues appears in Chapter 17.

Sexual Orientation. Sexual orientation describes the object of a person's

sexual impulses: opposite sex, same-sex, or both sexes. A group of people have defined themselves as “asexual” and assert this as a positive identity. Some researchers believe this lack of attraction to any object is a manifestation of a desire disorder. Other people wish not to define their sexual orientation at all and avoid labels. Still, others describe themselves as polysexual or pansexual.

The Biology of Sexual Behavior

The Brain

CORTEX. The cortex is involved both in controlling sexual impulses and in processing sexual stimuli that may lead to sexual activity. In studies of young men, some areas of the brain are more active during sexual stimulation than others. These include the orbitofrontal cortex, which is involved in emotions; the left anterior cingulate cortex, which is involved in hormone control and sexual arousal; and the right caudate nucleus, whose activity is a factor in whether sexual activity follows arousal.

LIMBIC SYSTEM. In all mammals, the limbic system is directly involved with elements of sexual functioning. Chemical or electrical stimulation of the lower part of the septum and the contiguous preoptic area, the fimbria of the hippocampus, the mammillary bodies, and the anterior thalamic nuclei have all elicited penile erections.

Studies of the brain in women have revealed that those areas activated by emotions of fear or anxiety are notably quiescent when the woman experiences an orgasm.

BRAINSTEM. Brainstem sites exert inhibitory and excitatory control over spinal sexual reflexes. The nucleus paragigantocellularis projects directly to pelvic efferent neurons in the lumbosacral spinal cord, apparently causing them to secrete serotonin, which is known to inhibit orgasms. The lumbosacral cord also receives projections from other serotonergic nuclei in the brainstem.

BRAIN NEUROTRANSMITTERS. Many neurotransmitters, including dopamine, epinephrine, norepinephrine, and serotonin, are produced in the brain and affect sexual function. For example, an increase in dopamine likely increases

libido. Serotonin, produced in the upper pons and midbrain, exerts an inhibitory effect on sexual function. Oxytocin is released with orgasm and may reinforce pleasurable activities.

Spinal Cord. Ultimately, sexual arousal and climax are organized at the spinal level. Afferents from the pudendal, pelvic, and hypogastric nerves convey the sensory stimuli related to sexual function. Several separate experiments suggest that spinal neurons mediate sexual reflexes in the central gray region of the lumbosacral segments.

Physiologic Responses. Sexual response is a psychophysiological experience. Both psychological and physical stimuli trigger arousal and an aroused person experiences both physiologic and emotional tension. With orgasm, usually, subjective perception of a peak of physical reaction and release occurs along with a feeling of well-being. Psychosexual development, psychological attitudes toward sexuality, and attitudes toward one's sexual partner are directly involved with, and affect, the physiology of human sexual response.

Usually, men and women experience a sequence of physiologic responses to sexual stimulation. In the first detailed description of these responses, Masters and Johnson observed that the physiologic process involves increasing levels of vasocongestion and myotonia (tumescence) and the subsequent release of the vascular activity and muscle tone as a result of orgasm (detumescence). Tables 16-26 and 16-27 describe the physiologic male and female sexual response cycles. It is important to remember that the sequence of responses can overlap and fluctuate. A sexual fantasy or the desire to have sex frequently precedes the physiologic responses of excitement, orgasm, and resolution, particularly in the male. Also, a person's subjective experiences are as relevant to sexual satisfaction as the objective physiologic response. Figures 16-1 and 16-2 illustrate several possible patterns in the phases of the male sexual response and female sexual response, respectively.

Hormones and Sexual Behavior. In general, substances that increase dopamine levels in the brain increase desire, whereas substances that augment serotonin decrease desire. Testosterone increases libido in both men

and women, although estrogen is a crucial factor in the lubrication involved in female arousal and may increase sensitivity in the woman to stimulation. Recent studies indicate that estrogen is also a factor in the male sexual response and that a decrease in estrogen in the middle-aged male results in higher fat accumulation just as it does in women. Progesterone mildly depresses desire in men and women as do excessive prolactin and cortisol. Oxytocin is involved in pleasurable sensations during sex and increases in men and women after orgasm.

Gender Differences in Desire and Erotic Stimuli

Sexual impulses and desire exist in men and women. In measuring desire by the frequency of spontaneous sexual thoughts, interest in participating in sexual activity, and alertness to sexual cues, males generally possess a higher baseline level of desire than do women, which may be biologically determined. Motivations for having sex, other than desire, exist in both men and women but seem to be more varied and prevalent in women. In women, they may include a wish to reinforce the pair bond, the need for a feeling of closeness, a way of preventing the man from straying, or a desire to please the partner.

Although explicit sexual fantasies are common to both sexes, the external stimuli for the fantasies frequently differ for men and women. Many men respond sexually to visual stimuli of nude or barely dressed women. Women report responding sexually to romantic stories such as a demonstrative hero whose passion for the heroine impels him toward a lifetime commitment to her. A complicating factor is that a woman’s subjective sense of arousal is not always congruent with her physiologic state of arousal. Her sense of excitement may reflect a readiness to be aroused rather than physiologic lubrication. Conversely, she may experience signs of arousal, including vaginal lubrication, without being aware of them. This situation rarely occurs in men.

Masturbation

Masturbation is usually a standard precursor of object-related sexual behavior. To paraphrase MS Patton, no other form of sexual activity is more discussed, more condemned, and more universally practiced. Research by

Kinsey into the prevalence of masturbation indicated that nearly all men and three-fourths of all women masturbate sometime during their lives.

Longitudinal studies of development show that sexual self-stimulation is common in infancy and childhood. Just as infants learn to explore the functions of their fingers and mouths, they learn to do the same with their genitalia. At about 15 to 19 months of age, both sexes begin genital self-stimulation. Pleasurable sensations result from any gentle touch to the genital region. Those sensations, coupled with the ordinary desire for exploration of the body, produce a healthy interest in masturbatory pleasure at that time. Children also develop an increased interest in the genitalia of others—parents, children, and even animals. As youngsters acquire playmates, the curiosity about their own and others' genitalia motivates episodes of exhibitionism or genital exploration. Such experiences, unless blocked by guilty fear, contribute to continued pleasure from sexual stimulation.

With the approach of puberty, the upsurge of sex hormones, and the development of secondary sex characteristics, sexual curiosity intensifies, and masturbation increases. Adolescents are physically capable of coitus and orgasm but are usually inhibited by social restraints. The dual and often conflicting pressures of establishing their sexual identities and controlling their sexual impulses produce a strong physiologic sexual tension in teenagers that demands release, and masturbation is a healthy way to reduce sexual tensions. In general, males learn to masturbate to orgasm earlier than females and masturbate more frequently. An important emotional difference between the adolescent and the youngster of earlier years is the presence of coital fantasies during masturbation in the adolescent. These fantasies are an essential adjunct to the development of sexual identity; in the comparative safety of the imagination, the adolescent learns to perform the adult sex role. This autoerotic activity continues into the young adult years when coitus becomes more common.

Table 16-26
Male Sexual Response Cycle[a]

Organ	Excitement Phase	Orgasmic Phase	Resolution Phase

	Lasts several minutes to several hours; heightened excitement before orgasm, 30 s to 3 min	3–5 s	10–15 min; if no orgasm, ½–1 day
Skin	Just before orgasm: sexual flush inconsistently appears; maculopapular rash originates on abdomen and spreads to anterior chest wall, face, and neck and can include shoulders and forearms	Well-developed flush	Flush disappears in reverse order of appearance; inconsistently appearing film of perspiration on soles of feet and palms of hands
Penis	Erection in 10–30 s caused by vasocongestion of erectile bodies of corpus cavernosa of shaft; loss of erection may occur with introduction of asexual stimulus, loud	Ejaculation; emission phase marked by three to four 0.8-s contractions of vas, seminal vesicles, prostate; ejaculation proper	Erection: partial involution in 5–10 s with variable refractory period; full detumescence in 5–30 min

	noise; with heightened excitement, size of glands and diameter of penile shaft increase further	marked by 0.8-s contractions of urethra and ejaculatory spurt of 12–20 in at age 18, decreasing with age to seepage at 70	
Scrotum and testes	Tightening and lifting of scrotal sac and elevation of testes; with heightened excitement, 50% increase in size of testes over unstimulated state and flattening against perineum, signaling impending ejaculation	No change	Decrease to baseline size because of loss of vasocongestion; testicular and scrotal descent within 5–30 min after orgasm; involution may take several hours if no orgasmic release takes place
Cowper glands	2–3 drops of mucoid fluid that contain	No change	No change

	viable sperm are secreted during heightened excitement		
Other	Breasts: inconsistent nipple erection with heightened excitement before orgasm Myotonia: semispastic contractions of facial, abdominal, and intercostal muscles Tachycardia: up to 175 beats a minute Blood pressure: rise in systolic 20–80 mm; in diastolic 10–40 mm Respiration: increased	Loss of voluntary muscular control Rectum: rhythmical contractions of sphincter Heart rate: up to 180 beats a minute Blood pressure: up to 40–100 mm systolic; 20–50 mm diastolic Respiration: up to 40 respirations a minute	Return to baseline state in 5–10 min A refractory period follows orgasm, during which time the male cannot be rearoused to erection and is unresponsive to stimulation. The length of the refractory period is age and situation dependent

[a]A desire phase consisting of sex fantasies and desire to have sex precedes excitement phase.

Table by Virginia Sadock, M.D.

Couples in a sexual relationship do not abandon masturbation entirely. When coitus is unsatisfactory or is unavailable because of illness or the

absence of the partner, self-stimulation often serves an adaptive purpose, combining sensual pleasure and tension release.

Kinsey reported that when women masturbate, most prefer clitoral stimulation. Masters and Johnson stated that women prefer the shaft of the clitoris to the glans because the glans is hypersensitive to intense stimulation. Most men masturbate by vigorously stroking the penile shaft and glans.

Several studies found that in men, orgasm from masturbation raised the serum prostate-specific antigen (PSA) significantly. Male patients scheduled for PSA tests should be advised not to masturbate (or have coitus) for at least seven days before the examination.

Moral taboos against masturbation have generated myths that masturbation causes mental illness or decreased sexual potency. No scientific evidence supports such claims. Masturbation is a psychopathological symptom only when it becomes a compulsion beyond a person's willful control. Then, it is a symptom of emotional disturbance, not because it is sexual, but because it is compulsive. Masturbation is probably a universal aspect of psychosexual development, and, in most cases, it is adaptive.

Coitus

The first coitus is a rite of passage for both men and women. In the United States, most people have experienced coitus by young adulthood. In a study of people ages 18 to 59, over 95 percent had included coitus in their last sexual interaction.

Table 16-27
Female Sexual Response Cycle[a]

Organ	Excitement Phase	Orgasmic Phase	Resolution Phase
	Lasts several minutes to several hours; heightened excitement before orgasm,	3–15 seconds	10–15 minutes; if no orgasm, ½–1 day

	30 s to 3 min		
Skin	Just before orgasm: sexual flush inconsistently appears; maculopapular rash originates on abdomen and spreads to anterior chest wall, face, and neck; can include shoulders and forearms	Well-developed flush	Flush disappears in reverse order of appearance; inconsistently appearing film of perspiration on soles of feet and palms of hands
Breasts	Nipple erection in two-thirds of women, venous congestion and areolar enlargement; size increases to one-fourth over normal	Breasts may become tremulous	Return to normal in about 30 min
Clitoris	Enlargement in diameter of glans and shaft; just before orgasm, shaft retracts into prepuce	No change	Shaft returns to normal position in 5–10 s; detumescence in 5–30 min; if no orgasm, detumescence

			takes several hours
Labia majora	Nullipara: elevate and flatten against perineum	No change	Nullipara: decrease to normal size in 1–2 min
	Multipara: congestion and edema		Multipara: decrease to normal size in 10–15 min
Labia minora	Size increased two to three times over normal; change to pink, red, deep red before orgasm	Contractions of proximal labia minora	Return to normal within 5 min
Vagina	Color change to dark purple; vaginal transudate appears 10–30 s after arousal; elongation and ballooning of vagina; lower third of vagina constricts before orgasm	3–15 contractions of lower third of vagina at intervals of 0.8 s	Ejaculate forms seminal pool in upper two-thirds of vagina; congestion disappears in seconds or, if no orgasm, in 20–30 min
Uterus	Ascends into false pelvis; labor-like contractions	Contractions throughout orgasm	Contractions cease, and uterus descends to

	begin in heightened excitement just before orgasm		normal position
Other	Myotonia A few drops of mucoid secretion from Bartholin glands during heightened excitement Cervix swells slightly and is passively elevated with uterus	Loss of voluntary muscular control Rectum: rhythmical contractions of sphincter Hyperventilation and tachycardia	Return to baseline status in seconds to minutes Cervix color and size return to normal, and cervix descends into seminal pool

[a]A desire phase consisting of sex fantasies and desire to have sex may precede or overlap with the excitement phase.

Table by Virginia Sadock, M.D.

The young man experiencing intercourse for the first time is vulnerable in his pride and self-esteem. Cultural myths still perpetuate the idea that he should be able to have an erection with no, or little, stimulation, and that he should have an effortless mastery over the situation, even though it is an act that he has never before experienced. Cultural pressure on the woman with her first coitus reflects remaining cultural ambivalence about her loss of virginity, despite the current era of sexual liberality. This reality is illustrated by a survey that found only 50 percent of young women use contraception during their first coitus, and of that 50 percent, an even smaller number use it consistently after that. Young women with a history of masturbation are more likely to approach intercourse with positive anticipation and confidence.

In the last decade, coitus has also been part of the sexual repertoire of elderly adults, due to the development of sildenafil type drugs, which

facilitate erections in men, and hormonally enhanced creams or hormonal pills, which counteract vaginal atrophy in postmenopausal women. Before the development of these drugs, many elderly adults enjoyed gratifying sex play, exclusive of coitus.

17 Gender Dysphoria, Gender Identity, and Related Conditions

INTRODUCTION

In this chapter, we discuss gender identity and associated disorders. We start with gender identity and related conditions.

Gender identity refers to the sense one has of being male or female, which corresponds most often to the person's anatomical sex. Persons with gender dysphoria express their discontent with their assigned sex as a desire to have the body of the other sex or to be regarded socially as a person of the other sex.

The term gender dysphoria appears as a diagnosis for the first time in DSM-5 to refer to those persons with a marked incongruence between their experienced or expressed gender and the one assigned at birth. It was known as gender identity disorder in the previous edition of DSM.

In ICD-10, gender identity issues appear under Disorders of Adult Behavior and Personality in the category Gender Identity Disorders and include five diagnoses: transsexualism, dual-role transvestic, gender identity disorder of childhood, other gender identity disorders, and gender identity disorder, unspecified.

The ICD Working Group on the Classification of Sexual Disorders and Sexual Health is recommending that for ICD-11, gender identity concerns be moved from the psychological sections and is considering options that would list these concerns in a separate chapter, as medical diagnoses, or as part of a new chapter on sexual health and sexual disorders.

The term *transgender* is a general term used to refer to those who identify

with a gender different from the one they were born with (sometimes referred to as their assigned gender). Transgender people are a diverse group: those who want to have the body of another sex known as transsexuals; those who feel they are between genders, of both genders, or neither gender known as genderqueer; and those who wear clothing traditionally associated with another gender, but who maintain a gender identity that is the same as their birth-assigned gender known as cross-dressers. Contrary to popular belief, most transgender people do not have genital surgery. Some do not desire it, and others who do may be unable to afford it. Transgender people may be of any sexual orientation. For example, a transgender man, assigned female at birth, may identify as gay (attracted to other men), straight (attracted to women), or bisexual (attracted to both men and women).

DIAGNOSIS AND CLINICAL FEATURES

Children

The DSM-5 defines gender dysphoria in children as incongruence between expressed and assigned gender, with the most critical criterion being a desire to be another gender or insistence that one is another gender. By emphasizing the importance of the child's self-perception, the creators of the diagnosis attempt to limit its use to those children who clearly state their wishes to be another gender, rather than encompassing a broader group of children who might be considered by adults to be gender nonconforming. However, a child's behavior may also lead to this diagnosis. Table 17-1 compares the approaches to diagnosing gender dysphoria or gender identity disorder.

Many children with gender dysphoria prefer clothing typical of another gender, preferentially choose playmates of another gender, enjoy games and toys associated with another gender, and take on the roles of another gender during play. In gender dysphoria, these social characteristics accompany other traits that are less likely to be socially influenced, such as a strong desire to be the other gender, dislike of one's sexual anatomy, or desire for primary or secondary sexual characteristics of the desired gender. Children may express a desire to have different genitals, state that their genitals are going to change, or urinate in the position (standing or sitting) typical of another gender. Also, although the caregivers may be distressed, it is the

child who must feel clinically significant distress or impairment because of the condition for there to be a diagnosis.

Adolescents and Adults

Adolescents and adults diagnosed with gender dysphoria must also show an incongruence between expressed and assigned gender. Also, they must meet at least two of six criteria, half of which are related to their current (or in the cases of early adolescents, future) secondary sex characteristics or desired secondary sex characteristics. Other criteria include a strong desire to be another gender, be treated as another gender, or the belief that one has the typical feelings and reactions of another gender (see Table 17-1).

In practice, most adults who present to mental health practitioners with reports of gender-related concerns are aware of the concept of transgender identity. They may be interested in therapy to explore gender issues. They may also make contact to request a letter recommending hormone treatment or surgery. The cultural trope of being "trapped in the wrong body" does not apply to all, or even most, people who identify as transgender, so clinicians should be aware of using open and affirming approaches, taking language cues from their patients.

The DSM-5 criteria are noticeably open to the idea that some people do not fit into the traditional gender binary and might desire to be alternative genders, such as genderqueer. As with children, adolescents and adults should be personally distressed or impaired by their feelings. The adolescent and adult criteria also contain a posttransition specifier, which is for people living in their affirmed genders. For this specifier, they have to have had at least one medical or surgical procedure or be preparing for one.

Table 17-1
Gender Dysphoria

	DSM-5	ICD-10
Name	**Gender Dysphoria**	**Gender Identity Disorder (Several Disorders)**
Duration	≥6 mo	

Symptoms	Conflict between experienced and assigned gender: **Children** • Desire or insistence of being another gender • Dressing like the other gender • Preference for other gender roles during play • Preference for other gender toys, games, or stereotypes • Rejection of same gender toys, games, or stereotypes • Preferences for other gender playmates • Dislike of one's anatomy • Desire for physical characteristics of other gender **Adults** • Conflict between experienced gender and primary/secondary sex characteristics • Desire to remove	**Transsexualism:** desire to live as member of the opposite sex **Dual-role transvestism:** temporarily wearing clothes of opposite sex to experience the other gender, but not desiring sex change. **Gender identity disorder of childhood:** • Distress about assigned sex • Desire to be other sex • Dressing like other sex • Disliking one's assigned sex

	one's primary/secondary sex characteristics • Desire for other another gender's primary/secondary sex characteristics • Desire to be another gender • Feeling one has the psychological characteristics of another gender	
# Symptoms needed	Children: ≥6 Adults: ≥2	
Exclusions (not result of):		Not motivated by sexual excitement **In children:** Normal variants ("tomboyishness" or effeminate behavior) Ego-dystonic sexual orientation Sexual maturation disorder
Psychosocial impact	Distress or functional impairment	Distress
Symptom specifiers	With a disorder of sex development	
Course specifiers	Post transition: ≥1 procedure/treatment for gender change	

and is living as the other gender

Other Specified

The category *other specified gender dysphoria* is for cases where the presentation causes clinically significant distress or impairment but does not meet the full criteria for gender dysphoria. When using this diagnosis, the clinician should specify why the full criteria were not met.

Unspecified

The category *unspecified gender dysphoria* can be applied when full criteria are not met, and the clinician chooses not to specify the reason.

A 27-year-old assigned female at birth was referred to a gender identity clinic reporting having felt different as a child from other girls, although unable then to identify the source. As a young girl, she enjoyed playing sports with girls and boys but generally preferred the companionship of boys. She preferred wearing unisex or boyish clothes and resisted wearing a skirt or dress. Everyone referred to her as a tomboy. She tried to hide her breast development by wearing loose-fitting tops and stooping forward. Menses were embarrassing and poignantly reminded her of her femaleness, which was becoming increasingly alienating. As sexual attractions evolved, they were directed exclusively to female partners. In her late teens, she had one sexual experience with a man, and it was aversive. She began socializing in lesbian circles, but did not feel comfortable there and did not consider herself lesbian, but more a man. For sexual partners, she wanted heterosexual women and wanted to be considered by the partner as a man. As gender dysphoric feelings became increasingly pronounced, she consulted transsexual sites on the Internet and contacted a female-to-male transsexual community support group. She then set into motion the process of clinical referral. She transitioned to living as a man, had a name change, and received androgen injections. The patient's voice deepened, facial and body hair grew, menses stopped, and sex drive increased, along with clitoral hypertrophy. After 2 years,

the patient underwent a bilateral mastectomy and was on the waitlist for phalloplasty and hysterectomy–oophorectomy. Employment as a man continues, as does a 3-year relationship with a female partner. The partner has a child from a previous marriage. (Adapted from a case of Richard Green, M.D.)

DIFFERENTIAL DIAGNOSIS

Differential Diagnosis of Children

Children diagnosed with gender dysphoria predicted to be more likely than others to identify as transgender as adults are differentiated from other gender-nonconforming children by statements about desired anatomical changes, as well as the persistence of the diagnosis over time. Children whose gender dysphoria persists over time may make repeated statements about a desire to be or believe that they are another gender. Other gender-nonconforming children may make these statements for short periods but not repeatedly, or may not make these types of statements, and may instead prefer clothing and behaviors associated with another gender but show contentment with their birth-assigned gender.

The diagnosis of gender dysphoria no longer excludes intersex people and instead is coded with a specifier in the cases where intersex people are gender dysphoric about their birth-assigned gender. Medical history is important to distinguish between children with or without intersex conditions. The standards of care for intersex children have changed dramatically over the last few decades due to activism by intersex adults and supportive medical and mental health professionals. Historically, intersex babies were often subjected to early surgical procedures to create a more standard male or female appearance. These procedures had the potential to cause sexual dysfunction, such as inability to orgasm, and permanent sterility. Recently, these practices have changed considerably so that more intersex people can make decisions about their bodies later in life.

Differential Diagnosis of Adolescents and Adults

Those who meet the criteria for a diagnosis of gender dysphoria must

experience clinical distress or impairment related to their gender identity. This requirement excludes the diagnosis of transgender or gender-nonconforming people who are not clinically distressed by their gender identities. There are certain mental illnesses in which transgender identity may be a component of delusional thinking, such as in schizophrenia. However, this is extremely rare and is different from transgender identity or gender dysphoria as the gender identity issues diminish with the treatment of the psychosis. Body dysmorphic disorder may be a differential diagnosis for some patients who present with a desire to change gendered body parts. However, with body dysmorphic disorder, the focus is on the body part looking abnormal, not on gender. Transvestic disorder, discussed in the previous chapter, is a recurrent and intense sexual arousal from cross-dressing that causes clinically significant distress or impairment. This diagnosis is differentiated from gender dysphoria by the patient's gender identity being consistent with their gender assigned at birth, and by sexual excitement linked to cross-dressing coming to interfere with the person's life.

COURSE AND PROGNOSIS

Children

Children typically begin to develop a sense of their gender identity around age 3. At this point, they may develop gendered behaviors and interests, and some may begin to express a desire to be another gender. It is often around school age that children are first brought for clinical consultations, as this is when they begin to interact with classmates closely and to be scrutinized by adults other than their caregivers. Some adults who identify as transgender recall that as children, they did not show behaviors consistent with another gender then. Some say later that they worked hard to appear stereotypical to their assigned gender, whereas others deny being able to recall gender identity concerns. Approaching puberty, many children diagnosed with gender dysphoria begin to show increased levels of anxiety related to anticipated changes to their bodies.

Children diagnosed with gender dysphoria do not necessarily grow up to identify as transgender adults. Several studies have demonstrated that more than half of those diagnosed with gender identity disorder, based on the

DSM-IV, later identify with their birth-assigned gender once they reach adulthood. Those children who do identify as transgender as adults tend to have more extreme gender dysphoria as children. Many studies show increased rates of gay and bisexual identity among those who were gender nonconforming as children.

COMORBIDITY

Comorbidity in Children

Children diagnosed with gender dysphoria show higher rates than other children of depressive disorders, anxiety disorders, and impulse control disorders. This high rate is likely related to the stigma faced by these children related to their gendered behaviors and identities. There are also reports that those diagnosed with gender dysphoria are more likely than others to fall on the autism spectrum. Some researchers posit that this may be related to intrauterine hormone exposure.

Comorbidity in Adults

Adults diagnosed with gender dysphoria show higher rates than other adults of depressive disorders, anxiety disorders, suicidality, self-harming behaviors, and substance abuse. The lifetime rate of suicidal thoughts in transgender people is about 40 percent. The minority stress model predicts increases in mental illness in groups that are stigmatized, discriminated against, harassed, and abused at higher rates than others. DSM-5 reports that persons with late-onset gender dysphoria may have more significant fluctuations in the extent of their distress and more ambivalence about and less satisfaction after sex reassignment surgery.

TREATMENT

Children

Treatment of gender identity issues in children typically consists of individual, family, and group therapy that guides children in exploring their gendered interests and identities. Some providers practice reparative, or conversion therapy, which attempts to change a person’s gender identity or

sexual orientation. This type of therapy is contrary to position statements by the American Psychiatric Association and practice guidelines of the American Academy of Child and Adolescent Psychiatry, and we consider this to treatment to be unethical.

Adolescents

As gender-nonconforming children approach puberty, some show intense fear and preoccupation related to the physical changes they anticipate or are beginning to experience. In addition to providing psychotherapy, many clinicians use these adolescents' reactions to the first signs of puberty as a compass to determine if puberty-blocking medications should be a consideration. Puberty-blocking medications are gonadotropin-releasing hormone (GnRH) agonists that can temporarily block the release of hormones that lead to secondary sex characteristics, giving adolescents and their families time to reflect on the best options moving forward. GnRH agonists are used in other populations (e.g., children with precocious puberty) and thought safe. However, we should consider such steps carefully.

Adults

Treatment of adults who identify as transgender may include psychotherapy to explore gender issues, hormonal treatment, and surgical treatment. Hormonal and surgical interventions may decrease depression and improve the quality of life for such persons.

Mental Health Treatment

The history of poor treatment and medicalization of transgender people by mental health providers has led to a decreased interest on the part of trans-identified people in engaging in mental health care. Many surgeons, and some physicians who prescribe transition-related hormones, require a letter from a mental health provider, so for many transgender people, the mental health worker is a gatekeeper. Many community clinics are now using informed consent models for hormone treatment, thereby decreasing the need for mental health providers to play the role of gatekeepers. The World Professional Association for Transgender Health (WPATH) Standards of Care (SOC) for the health of transsexual, transgender, and gender-

nonconforming people have recently become more flexible and open to informed consent models. Some mental health providers are specializing in working with transgender populations, and this is increasing the rate at which transgender people engage in psychotherapy.

Hormones

Hormone treatment of transgender men most often involves testosterone, usually taken by injection every week or every other week. Initial changes with testosterone therapy include increased acne, muscle mass, and libido, as well as a cessation of menses, usually within the first few months. Subsequent and more permanent changes include deepening of the voice, increased body hair, and enlargement of the clitoris. Monitoring includes hemoglobin/hematocrit levels, as testosterone can rarely cause an increase in red blood cell counts that can lead to stroke. Like all steroid hormones, the liver metabolizes testosterone, so we should obtain routine liver function tests. Clinicians also want to monitor cholesterol and screen for diabetes, as testosterone treatment may increase the likelihood of lipid abnormalities and diabetes. Those beginning hormone treatments are routinely counseled on fertility, as future fertility may be affected by testosterone.

Transgender women may take estrogen, testosterone-blockers, or progesterone, often in combination. These hormones can cause softening of the skin and redistribution of fat, as well as breast growth. Breast development varies between people but does not generally exceed bra cup size B. Experts recommend for patients to be on hormones for 18 to 24 months before having breast augmentation, allowing the breasts to develop to their final size. Sex drive can decrease, as well as erections and ejaculation. Body hair can decrease somewhat, but often not as much as desired, prompting many women to obtain electrolysis. There is no change in voice, as testosterone has permanently altered the vocal cords, and many women seek out voice coaching. Those on estrogen should avoid cigarette smoking, as the combination can lead to an increased risk of blood clots. We should monitor blood pressure, as well as liver function and cholesterol. Also, providers routinely test prolactin as this hormone can increase with estrogen therapy, and in rare cases, transgender women may develop prolactinomas. Reproductive counseling is essential before beginning estrogen treatment

because permanent sterility is almost always the outcome.

Surgery

Many fewer people undergo gender-related surgeries than take hormones. Some people do not desire gender-related surgeries. Others cannot afford them or are not convinced that they will be satisfied with the currently available results.

The most common type of surgery for both trans men and trans women is “top surgery,” or chest surgery. Transgender men may have surgery to construct a male-contoured chest. Trans-women may have breast augmentation.

“Bottom surgery” is less common. Transgender men may have a metoidioplasty, in which the surgeon frees the clitoris from the ligament, attaching it to the body, and adds tissue increasing its length and girth. Scrotoplasty, the placement of testicular implants, is another way to create male-appearing genitalia. Phalloplasty, the creation of a penis, is less commonly performed because it is expensive, involves multiple procedures, requires donor skin from another part of the body, and has limited functionality. Bottom surgery for women is typically vaginoplasty, also commonly known as Sex Reassignment Surgery (SRS). Here, the surgeon removes the testicles, reconstructs the penis to form a clitoris, and creates a vagina. Techniques for vaginoplasty are becoming very good, but the procedure remains expensive. Because of this, some women, especially those with less money, may have orchiectomies, where the surgeon removes the testicles. These can be in-office procedures with a local anesthetic. The procedure is useful for substantially decreasing the body’s production of androgens like testosterone. Less widely discussed, but essential to many women, are facial feminization surgeries that alter the cheeks, forehead, nose, and lips to create a more feminine facial appearance. The face is often used by persons to recognize gender in another person, and having facial features that match the affirmed gender can facilitate social interaction and provide safety from harassment and violence. Transgender men rarely undergo facial surgeries, as testosterone typically causes the face to appear more masculine.

Because surgery is inaccessible to many, there are rare cases of self-surgery, and some people have surgeries performed under unsafe conditions.

Women may inject industrial-grade silicone to produce body curves. Silicone injection done without the supervision of a medical professional can result in body mutilation, infection, and even silicone blood clots that can lead to embolism and death.

EPIDEMIOLOGY

Children

Most children with gender dysphoria come to clinical attention in early grade school years. Parents, however, typically report that the cross-gender behaviors were apparent before 3 years of age. Among a sample of boys younger than age 12 referred for a range of clinical problems, the reported desire to be the other sex was 10 percent. For clinically referred girls younger than age 12, the reported desire to be the other sex was 5 percent. The sex ratio of children referred for gender dysphoria is 4 to 5 boys for each girl, which is likely due in part to societal stigma directed toward feminine boys. The sex ratio is equal in adolescents referred for gender dysphoria. Researchers have observed that many children considered to have shown gender-nonconforming behavior do not grow up to be transgender adults; conversely, many people who later come out as transgender adults report that they were not identified as gender nonconforming during childhood.

Adults

The estimates of gender dysphoria in adults emanate from European hormonal/surgical clinics with a prevalence of 1 in 11,000 male- and 1 in 30,000 female-assigned people. DSM-5 reports a prevalence rate ranging from 0.005 to 0.014 percent for male- and 0.002 to 0.003 percent for female-assigned people. Most clinical centers report a sex ratio of three to five male patients for each female patient. Most adults with gender dysphoria report having felt different from other children of their same sex, although, in retrospect, many could not identify the source of that difference. Many report feeling extensively cross-gender identified from the earliest years, with the cross-gender identification becoming more profound in adolescence and young adulthood. Overall the prevalence of male to female dysphoria is higher than female to male dysphoria. An important factor in diagnosis is that

there is greater social acceptance of birth-assigned females dressing and behaving as boys (so-called tomboys) than there is of birth-assigned males acting as females (so-called sissies). Some researchers speculate that 1 in 500 adults may fall somewhere on a transgender spectrum, based on population data rather than clinical data.

ETIOLOGY

Biologic Factors

For mammals, the resting state of tissue is initially female. Males only develop if the body introduces androgen, which is set off by the Y chromosome. The result is testicular development. Without testes and androgen, female external genitalia develop. Thus, maleness and masculinity depend on fetal and perinatal androgens. Sex steroids govern sexual behavior in lower animals, but this effect diminishes as the evolutionary tree is scaled. Sex steroids influence the expression of sexual behavior in mature men or women; that is, testosterone can increase libido and aggressiveness in women, and estrogen can decrease libido and aggressiveness in men. However, masculinity, femininity, and gender identity are more a product of postnatal life events than the prenatal hormonal organization.

Brain organization theory refers to the masculinization or feminization of the brain in utero. Testosterone affects brain neurons that contribute to the masculinization of the brain in such areas as the hypothalamus. Whether testosterone contributes to so-called masculine or feminine behavioral patterns remains a controversial issue.

Genetic causes of gender dysphoria are under study, but we have not identified candidate genes, and chromosomal variations are uncommon in transgender populations. Case reports of identical twins have shown some pairs that are concordant for transgender issues and others that are not.

A variety of other approaches to understanding gender dysphoria are underway. These include imaging studies that have shown changes in white matter tracts, cerebral blood flow, and cerebral activation patterns in patients with gender dysphoria, but this is preliminary work. An incidental finding is that transgender persons are likely to be left-handed, the significance of which is unknown.

Psychosocial Factors

Children usually develop a gender identity consonant with their assigned sex. Many factors influence the formation of gender identity, including children's temperament and the interaction of that with parents' qualities and attitudes. Culturally acceptable gender roles exist: Society does not expect boys to be effeminate, or girls to be masculine. There are boys' games (e.g., cops and robbers) and girls' toys (e.g., dolls and dollhouses). Children learn these roles, although some investigators believe that some boys are temperamentally delicate and sensitive and that some girls are aggressive and energized—traits that are stereotypically known in today's culture as feminine and masculine, respectively. However, in Western society, we have a higher tolerance for "nontraditional" gender role behaviors than we once did.

Sigmund Freud believed that gender identity problems resulted from conflicts experienced by children within the oedipal triangle. In his view, both real family events and children's fantasies fuel these conflicts. Whatever interferes with a child loving the opposite-sex parent and identifying with the same-sex parent interferes with healthy gender identity development.

Since Freud, psychoanalysts have postulated that the quality of the mother–child relationship in the first years of life is paramount in establishing gender identity. During this period, mothers usually facilitate their children's awareness of, and pride in, their gender: they value their children as little boys and girls. Analysts argue that devaluing, hostile mothering can result in gender problems. At the same time, the separation–individuation process is unfolding. When gender problems become associated with separation–individuation problems, the result can be the use of sexuality to remain in relationships characterized by shifts between a desperate infantile closeness and a hostile, devaluing distance.

Some children receive the message that they would be more valued if they adopted the gender identity of the opposite sex. Rejected or abused children may act on such a belief. A mother's death, extended absence, or depression can influence the process, and a young boy may react by totally identifying with her—that is, by becoming a mother to replace her.

The father's role is also vital in the early years, and his presence can help the separation–individuation process. Without a father, the mother and child

may remain overly close. For a girl, the father usually is the prototype of future love objects; for a boy, the father is a model for male identification.

Learning theory postulates that children may be rewarded or punished by parents and teachers based on gendered behavior, thus influencing the way children express their gender identities. Children also learn how to label people according to gender. Eventually, they also learn that we should not dictate gender based on surface appearances such as clothing or hairstyle.

18 Disruptive, Impulse-Control, and Conduct Disorders

Six conditions comprise the category of *disruptive, impulse-control, and conduct disorders.* They include two that are associated with childhood: (1) oppositional defiant disorder and (2) conduct disorder; we discuss both in Chapter 2. DSM-5 includes antisocial personality disorder in both this section and in the personality disorders section; we will consider that with the personality disorders (Chapter 19). The remaining three disorders are intermittent explosive disorder, kleptomania, and pyromania, which are discussed here as well as other specified and unspecified disorders that relate to this category.

THE CLINICAL PRESENTATION

Persons suffering from one of these disorders have either an inability to resist an intense impulse or drive or are tempted to perform a particular act that is clearly harmful to themselves or others, or both. Before the event, the individual usually experiences mounting tension and arousal, sometimes—but not consistently—mingled with conscious anticipatory pleasure. Completing the action brings immediate gratification and relief. Within a variable time afterward, the individual experiences a conflation of remorse, guilt, self-reproach, and dread. Shameful secretiveness about the repeated impulsive activity frequently expands to permeate the individual's entire life, often delaying treatment.

Intermittent Explosive Disorder

Patients with intermittent explosive disorder have discrete episodes of losing control of their aggressive impulses; these episodes can result in severe assault or the destruction of property. The aggressiveness expressed is grossly out of proportion to any stressors that may have helped elicit the events. The episodes appear within minutes or hours and, regardless of duration, remit spontaneously and quickly. After each episode, patients usually show genuine regret or guilt, and signs of generalized impulsivity or aggressiveness are absent between events. Clinicians should not diagnose intermittent explosive disorder if they can better explain the symptoms with another disorder: one can imagine a long list of possible disorders, and we discuss some differentials in that section.

A 36-year-old real estate agent sought assistance for difficulty with his anger. He was quite competent at his job, although he frequently lost clients when he became enraged over their indecisiveness. On several occasions, he became verbally abusive, leading clients to find ways out of escrow closings. The impulsive aggression also led to the termination of multiple relationships because sudden angry outbursts contained demeaning accusations toward his girlfriends. These outbursts frequently occurred in the absence of any apparent conflict. On numerous occasions, the patient became so uncontrollably enraged that he threw things across the room, including books, his desk, and the contents of the refrigerator. Between episodes, he was a kind and likable individual with many friends. He enjoyed drinking on the weekends and had a history of two arrests for driving while intoxicated. On one of these occasions, he became involved in a verbal altercation with a police officer. He had a history of drug experimentation in college that included cocaine and marijuana.

A mental status examination revealed a generally cooperative patient. However, he became quite defensive when questioned about his anger and quickly felt accused and blamed by the interviewer for his past behaviors. He had no significant medical history and no signs of neurologic problems. He had never been in psychiatric treatment before this evaluation. He was on no medications. He denied any symptoms of a mood disorder or any other antisocial activity.

Treatment included the use of carbamazepine and a combination of supportive and cognitive-behavioral psychotherapy. The patient's angry outbursts improved as he became aware of the early signs that he was about to lose control. He learned techniques to avoid confrontation when such warning signs occurred. (Courtesy of Vivien K. Burt, M.D., Ph.D. and Jeffrey William Katzman, M.D.)

Kleptomania

Patients with kleptomania (from the Greek *kleptēs,* "thief") describe a recurrent failure to resist the impulse to steal objects, even though they have no need for the objects—often it has no value to the person, monetary or otherwise, and the patient could have easily afforded it. For patients with this disorder, the goal is not to obtain a specific item, it is the act of stealing itself. After taking the objects, the patient often gives them away, returns them secretly, or hides them.

As with other impulse-control disorders, patients with kleptomania experience mounting tension before the act, followed by gratification and lessening of tension after the action. They may or may not feel guilt or remorse and might feel depressed about their behavior. The theft is not planned and does not involve others. Although patients are unlikely to take something when immediate arrest is probable (e.g., in front of a security guard at a store), they may not rationally consider the risks involved even though repeated arrests lead to pain and humiliation. Patients may feel guilt and anxiety after the theft, but they do not feel anger or vengeance.

Jane was a 42-year-old, highly successful, single executive from a wealthy background. She called herself a "shop-'til-you-drop type" and had always been able to afford the expensive designer clothing that she loved. Since college, her "legit" shopping had been paralleled by "boosting" cheap panties and brassieres from discount stores. She did not wear the stolen items; indeed, she considered them "sleazy." She could never bring herself to get rid of them either and kept boxes filled with stolen lingerie in a storage facility.

Jane talked or bought her way out of trouble until her 30s when she

was arrested while stealing pantyhose from the same K-Mart for the third time in as many months. As a condition of probation, she was ordered to see a psychiatrist. Her attendance was sporadic, and several more thefts occurred over the next 2 years. She also experienced substantial depression, which she tried to alleviate by heavy drinking.

Jane finally began taking her problem seriously after yet another arrest precipitated a suicidal gesture. She started keeping appointments regularly and consented to take citalopram and naltrexone. She believes that her participation in an Alcoholics Anonymous (AA) group for high-pressured executives has been at least as effective—if not more so—in controlling her stealing. (Courtesy of Harvey Roy Greenberg, M.D.)

Table 18-1
Intermittent Explosive Disorder

	Intermittent Explosive Disorder	
Disorder	**DSM-5**	**ICD-10**
Diagnostic name	Intermittent explosive disorder	Other habit and impulse disorders (intermittent explosive disorder)
Duration	If symptom 1, average of 2×/wk for 3 mo If symptom 2, occurs for at least 1 y	
Symptoms	Nonpremeditated, unmotivated verbal or physical aggression, out of proportion to the provocation 1. Not causing damage 2. Causing damage	Persistently repeated maladaptive behavior Failure to resist the impulse Preceded by a period of tension Followed by a period

		of release
Required number of symptoms	Either 1 or 2 above If symptom 2, has to occur at least 3 times within the year	All of above
Psychosocial consequences of symptoms	Distress or impaired functioning (social, occupational, or other significant areas) Or, financial or legal consequences	
Exclusions (not result of):	Medical illness Substance Other psychiatric disorder Age <6	Not secondary to another psychiatric syndrome
Comments		This is diagnosed as a habit and impulse disorder, "other," and not specifically defined

Required number of symptoms	All of above	All of above
Exclusions (not result of):	Anger Vengeance Psychosis Conduct disorder Mania Antisocial personality disorder	Not secondary to another psychiatric syndrome
Comments		Included among the habit and impulse disorders

Pyromania

Patients with pyromania repeatedly and deliberately set fires. They feel an urge to do this and relief or pleasure after they do. They typically are fascinated with all aspects of fires and may set off false alarms. They often are attracted to firefighting, may spend time at their local fire department, volunteer, or even become professional firefighters. Their curiosity is evident, but they show no remorse and may be indifferent to the consequences for life or property. Firesetters may gain satisfaction from the resulting destruction; frequently, they leave apparent clues.

DIAGNOSIS

Intermittent Explosive Disorder

Table 18-1 lists the diagnostic approaches to intermittent explosive disorder in DSM-5 and ICD-10. The key feature of this disorder is an aggressive outburst that has a rapid onset, typically without warning, lasting for less than 30 minutes. There is usually some provocation, although the response is disproportionate to that provocation. A less severe episode may occur in between the more severe ones.

As with most psychiatric disorders, the disorders cause significant distress or impairment in psychosocial functioning and are not better accounted for by another psychiatric, substance use, or other medical disorder. Relatively unique to this disorder is an age requirement, in which the individual has to be above the age of 6 years (or of comparable developmental level).

The diagnosis of intermittent explosive disorder should be the result of history-taking that reveals several episodes of loss of control associated with aggressive outbursts. One discrete episode does not justify the diagnosis. The histories typically describe a childhood in an atmosphere of an alcohol use disorder, violence, and emotional instability. Patients' work histories are poor; they report job losses, marital difficulties, and trouble with the law. Most patients have sought psychiatric help in the past but to no avail. Anxiety, guilt, and depression usually follow an outburst, but this is not a constant finding.

Kleptomania

Table 18-2 lists the diagnostic approaches to kleptomania in DSM-5 and ICD-10. The essential feature of kleptomania is recurrent, intrusive, and irresistible urges or impulses to steal unneeded objects. The act is accompanied by tension before the action and pleasure, gratification, or relief after it. It is not associated with anger or vengeance and is not better explained by some other disorder, as discussed in the Differential section.

Pyromania

Table 18-3 lists the diagnostic approaches to kleptomania in DSM-5 and ICD-10. To be diagnosed with pyromania, patients must set fires, not just desire or imagine them. This action is repetitive, deliberate, and purposeful. They feel tension or arousal before setting the fires as well as a fascination

and attraction to fires. They may make considerable preparations before starting the fire. After setting the fire, they feel pleasure, gratification or relief when witnessing or participating in the aftermath of the fire. Perhaps related to that gratification, they also feel a similar attraction and interest with firefighting, including the activities and equipment associated with that profession. Like the discussion of kleptomania, they do not personally benefit, financially or otherwise, from the fire, hence the distinction between pyromania and arson, and the disorder is not better explained by another cause (see the Differential section).

Other Specified or Unspecified Disorders

DSM includes “other specified or unspecified disorders” for most of the diagnostic categories. This is usually a residual category for disorders that do not meet the criteria for the major disorders in the class. In this case, this group includes some unique disorders, some of which stand at the border between impulsive and compulsive disorders (see the section on Differential Diagnosis for a discussion of the difference). Many of these, such as Internet gaming disorder and related, are better considered as addictive disorders and included in our substance use disorders chapter. This is because even though not due to substances, the phenomenology, pathology, course, and treatment approach of disorders such as Internet gaming disorder appears to be very similar.

OBJECTIVE TESTS FOR THE DISORDERS

Physical Findings and Laboratory Examination

Blood chemistry (liver and thyroid function tests, fasting blood glucose, electrolytes), urinalysis (including drug toxicology), and syphilis serology may help rule out other causes of aggression or impulsive behavior. Magnetic resonance imaging (MRI) may reveal changes in the prefrontal cortex, which is associated with loss of impulse control.

DIFFERENTIAL DIAGNOSIS FOR THE DISRUPTIVE AND IMPULSE-CONTROL DISORDERS

It can be challenging to distinguish between impulse disorders and compulsive disorders, and the terms in practice are sometimes vague and overlapping. Technically, an *impulse* is a tension state that can exist without an action; a *compulsion* is a tension state that always has an action component. In the case of compulsive disorders (such as obsessive-compulsive disorder [OCD] or trichotillomania), the patients feel "compelled" to act out their pathologic behavior; they cannot resist the impulse to do so. Impulses and compulsions also differ by their expected result: people acting on an impulse expect to receive some pleasure, whereas compulsions are often ego-dystonic, meaning that a person does not desire or enjoy the act despite feeling compelled to do it. Even this is complicated, as in some cases impulse-control disorders also elicit guilt, which disturbs the sense of pleasure. Similarly, not all compulsions are ego-dystonic; for example, compulsive video game playing may have a pleasurable component. Both impulsive and compulsive behaviors are repetitive; however, the repeated acting out of impulses leads to psychosocial impairment, whereas compulsive behavior does not always carry that risk.

Intermittent Explosive Disorder

One should only diagnose an intermittent explosive disorder after other disorders associated with the occasional loss of control of aggressive impulses have been ruled out as the primary cause. These other disorders include psychotic disorders, personality change because of a general medical condition, antisocial or borderline personality disorder, substance intoxication (e.g., alcohol, barbiturates, hallucinogens, amphetamines), epilepsy, brain tumors, degenerative diseases, and endocrine disorders.

Table 18-3
Pyromania

	Pyromania	
Disorder	**DSM-5**	**ICD-10**
Diagnostic name	Pyromania	Pyromania

Symptoms	Fire setting • 1+ incidents • Deliberate and purposeful • Preoccupied by fire, burning, and related phenomena • Followed by a period of gratification or release	Fire setting • Multiple acts or attempts • No apparent motive • Preoccupied by fire, burning, and related phenomena • Preceded by a period of tension • Followed by a period of excitement
Required number of symptoms	All of above	All of above
Exclusions (not result of):	• Conduct disorder • Mania • Antisocial personality disorder • Psychosis • Impaired cognition or judgment Motivated by: • Desire for a perceived financial or social benefit • Sociopolitical ideology • Need to conceal criminal activity • Anger • Vengeance	• Dissocial personality disorder • Alcohol or substance disorder • Feigned illness • Conduct disorder • Organic mental disorder • Schizophrenia
Comments		Included among the habit and impulse disorders

The episodic and discrete nature of intermittent explosive disorder differentiates it from conduct disorder and antisocial personality disorder, which are more pervasive patterns of behavior in which aggression is a consistent feature, and not just associated with discrete outbursts.

In schizophrenia, patients may display violent behavior in response to delusions and hallucinations, and they show gross impairments in reality testing. Hostile patients with mania may be impulsively aggressive, but the underlying diagnosis is generally apparent from their mental status examinations and clinical presentations.

Amok is a culture-bound syndrome usually associated with southeastern Asia (but also seen elsewhere), which consists of episodes of acute violent behavior for which the person claims amnesia. It is distinguished from intermittent explosive disorder by a single episode and prominent dissociative features.

Among medical disorders, certain neurologic disorders can resemble impulse-control disorders. The best-documented examples are with Parkinson disease, which can resemble both impulse-control disorders and addictive disorder.

Kleptomania

Shoplifting has become a national epidemic. Few shoplifters have true kleptomania; most are teenagers and young adults who steal in pairs or small groups for “kicks” as well as goods and do not have a psychiatric disorder.

Individuals with an antisocial personality disorder steal for personal gain, with some degree of premeditation and planning. Often they convince others to rob for them. Antisocial stealing regularly involves the threat of harm or actual violence, mainly to elude capture. Guilt and remorse are distinctively lacking, or patients are patently insincere.

Episodes of theft occasionally occur during psychotic illness, for example, acute mania, major depression with psychotic features, or schizophrenia. Psychotic stealing is a product of pathologic elevation or depression of mood or command hallucinations or delusions.

Acute intoxication with drugs or alcohol may precipitate theft in an individual with another psychiatric disorder or without significant psychopathology. Patients with Alzheimer disease or other dementing

organic illness may leave a store without paying, owing to forgetfulness rather than larcenous intent.

Some individuals with an antisocial personality disorder or no disorder may steal and then claim to suffer from kleptomania. This would be an example of malingering, not kleptomania, although with sufficiently intelligent perpetrators it may be challenging to tell the difference.

Pyromania

Clinicians should have little trouble distinguishing between pyromania and the fascination of many young children with matches, lighters, and fire as part of the normal investigation of their environments. One should also separate pyromania from incendiary acts of sabotage carried out by dissident political extremists or by arsonists.

When a fire setting occurs in conduct disorder and antisocial personality disorder, it is a deliberate act, not a failure to resist an impulse. Such individuals may set fires for profit, sabotage, or retaliation. Patients with schizophrenia or mania may set fires in response to delusions or hallucinations. Patients with brain dysfunction (e.g., dementia), mental retardation, or substance intoxication may set fires because of a failure to appreciate the consequences of the act.

COMORBIDITY

Intermittent Explosive Disorder

More than 80 percent of individuals with intermittent explosive disorder meet the criteria for another psychiatric disorder. These include other disorders of impulse-control and substance use, and mood, anxiety, personality (antisocial and borderline), posttraumatic stress, and eating disorders. Also, individuals with intermittent explosive disorder have been reported to be at increased risk of self-harm.

Kleptomania

Patients with kleptomania are said to have high lifetime comorbidity of major mood disorders (usually, but not exclusively, depressive) and various anxiety disorders. Associated conditions also include other disorders such as

pathologic gambling and compulsive shopping, eating disorders (especially bulimia nervosa), personality disorders, OCD, and substance use disorders, especially alcohol use disorder. Individuals with kleptomania are also reported to have higher rates of suicide.

Pyromania

Pyromania is significantly associated with substance use disorders (especially alcohol and marijuana use disorders), affective disorders, depressive or bipolar, and other impulse-control disorders. They are also reported to have increased suicidal thoughts.

COURSE AND PROGNOSIS

Intermittent Explosive Disorder

Intermittent explosive disorder may begin at any stage of life but usually appears between late adolescence and early adulthood. The onset can be sudden or insidious, and the course can be episodic or chronic. In most cases, the disorder decreases in severity with the start of middle age, but heightened organic impairment can lead to frequent and severe episodes. Intermittent explosive disorder is more common in men than women.

Kleptomania

Kleptomania may begin in childhood, although most children and adolescents who steal do not become kleptomaniac adults. The onset of the disorder generally is adolescence. In quiescent cases, loss or disappointment may precipitate new bouts of the disorder.

The course of the disorder waxes and wanes but tends to be chronic—the frequency of stealing ranges from less than one to multiple episodes per month. Most patients with kleptomania steal from retail stores, but they may also take from family members in their households. People with the disorder sometimes have bouts of being unable to resist the impulse to steal, followed by free periods that last for weeks or months. The spontaneous recovery rate of kleptomania is unknown.

Severe impairment and complications are usually secondary to being caught, particularly to being arrested. Many persons seem never to have

consciously considered the possibility of facing the consequences of their acts. Often, the disorder in no way impairs a person's social or work functioning.

The prognosis with treatment can be good, but few patients come for help of their own accord.

Pyromania

It should not be too surprising that we know very little about the development and course of pyromania. Most individuals with pyromania start setting fires in adolescence or young adulthood. The frequency and intensity of fire setting may increase over time or may wax and wane. The course of pyromania is unknown, but smaller studies suggest it may be chronic. Pyromania occurs more frequently in males with weaker social skills and learning difficulties.

TREATMENT APPROACH

Intermittent Explosive Disorder

A combined pharmacologic and psychotherapeutic approach has the best chance of success. Psychotherapy with patients who have an intermittent explosive disorder is difficult, however, because of their angry outbursts. Therapists may have problems with countertransference and limit-setting. Group psychotherapy may be helpful, and family therapy is useful, especially when the explosive patient is an adolescent or a young adult. A goal of treatment is to have the patient recognize and verbalize the thoughts or feelings that precede the explosive outbursts instead of acting them out. Cognitive-behavioral therapy and contingency management may be helpful.

Anticonvulsants have long been used, with mixed results, in treating explosive patients. Lithium has been reported useful in generally lessening aggressive behavior, and carbamazepine, valproate, and phenytoin have been reported helpful. Some clinicians have also used other anticonvulsants (e.g., topiramate). Clinicians occasionally use benzodiazepines but the meds can cause disinhibition, thus worsening the behaviors.

Antipsychotics and tricyclic drugs have been effective in some cases, but clinicians must then question whether schizophrenia or a mood disorder is the

correct diagnosis. With a likelihood of subcortical seizure-like activity, medications that lower the seizure threshold can aggravate the situation. Selective serotonin reuptake inhibitors (SSRIs), trazodone, and buspirone are useful in reducing impulsivity and aggression. Propranolol and other β-adrenergic receptor antagonists and calcium channel inhibitors have also been effective in some cases.

Some neurosurgeons have performed operative treatments for intractable violence and aggression. No evidence indicates that such treatment is effective.

Kleptomania

Because true kleptomania is rare, reports of treatment tend to be individual case descriptions or a short series of cases. Insight-oriented psychotherapy and psychoanalysis have been successful but depend on patients' motivations. Those who feel guilt and shame may be helped by insight-oriented psychotherapy because of their increased motivation to change their behavior.

Case reports and case series suggest that cognitive-behavioral therapy may be helpful. Specific behavior therapies, including systematic desensitization, aversive conditioning, and a combination of aversive conditioning and altered social contingencies, have been reported successful, even when motivation was lacking. SSRIs, such as fluoxetine and fluvoxamine, appear to be effective in some patients with kleptomania; however, there are also reports of fluoxetine having no benefit in kleptomania. Case reports indicated successful treatment with tricyclic drugs, trazodone, lithium, valproate, topiramate, naltrexone, methylphenidate, and electroconvulsive therapy. In a controlled trial of antidepressants, escitalopram was found to have no benefit in treating kleptomania. Though limited by small sample size and open-label design, high-dose naltrexone was reported to be effective in reducing the urge to steal in patients with kleptomania.

Pyromania

Little has been written about the treatment of pyromania, and treating firesetters has been difficult because of their lack of motivation. No single treatment has been proved effective; as a result, most therapists try various

modalities, including behavioral approaches. Among the treatments attempted, CBT appears to be the most promising.

Because of the recurrent nature of pyromania, any treatment program should include the supervision of patients to prevent a repeated episode of fire setting. Incarceration may be the only method of avoiding a recurrence while their therapy can commence.

We should treat firesetting by children with the utmost seriousness. When possible we should consider intensive interventions, but as therapeutic and preventive measures, not as punishment. In the case of children and adolescents, treatment of pyromania or fire setting should include family therapy.

Several case reports have been published using SSRIs, lithium, naltrexone, stimulants, topiramate, valproate, carbamazepine, antiandrogen agents, clonazepam, and olanzapine. Unfortunately, many have reported no benefit from pharmacotherapy.

EPIDEMIOLOGY

For all these disorders, we do not know much about their epidemiology, as they are all underreported. This is understandable given the potential ramifications of self-reporting what is usually illegal behavior.

The lifetime prevalence rate for intermittent explosive disorder is estimated to be around 5 to 8 percent, and it appears to be more common in men than in women. The men are likely to be found in correctional institutions and the women in psychiatric facilities. In one study, about 2 percent of all persons admitted to a university hospital psychiatric service had an intermittent explosive disorder; 80 percent were men.

The prevalence of kleptomania is not known, but it is estimated to be about 0.6 percent. The range varies from 4 to 24 percent of those arrested for shoplifting. The male-to-female ratio is 1:3 in clinical samples.

No information is available on the prevalence of pyromania, but only a small percentage of adults who set fires have pyromania. The disorder is found far more often in men than in women. In the United States, 60 percent of individuals who set fires are adolescents; most, however, would not meet the criteria for pyromania.

ETIOLOGY

For all of these disorders, the cause is not known. Psychodynamic, psychosocial, and biologic factors all undoubtedly play an essential role. Some disruptive and impulse-control disorders may have common underlying neurobiologic mechanisms. Fatigue, constant stimulation, and psychic trauma can lower a person's resistance to control impulses.

Intermittent Explosive Disorder

Other factors associated with impulsive aggression include childhood exposure to violence, maltreatment, and neglect. One study found that there was significant association between intermittent explosive disorder and aversive childhood parenting environment comparable to other psychopathologies. Another study found that physical abuse in childhood was independently associated with intermittent explosive disorder, with impulsivity and aggression as the mediators of the relationship between physical abuse and intermittent explosive disorder. Others have shown that intermittent explosive disorder is associated with childhood exposure to interpersonal traumatic events.

Prefrontal cortical dysfunction has been associated with impulsive aggression. Some investigators suggest that disordered brain physiology, particularly in the limbic system, is involved in most cases of episodic violence. Compelling evidence indicates that serotonergic neurons mediate behavioral inhibition. Decreased serotonergic transmission, which can be induced by inhibiting serotonin synthesis or by antagonizing its effects, reduces the impact of punishment as a deterrent to behavior. The restoration of serotonin activity (e.g., by administering L-tryptophan, a serotonin precursor) restores the behavioral effect of punishment and may aid the control of violent tendencies. Low levels of CSF 5-hydroxyindoleacetic acid (5-HIAA) correlate with violent suicide attempts and impulsive aggression in some studies. High CSF testosterone concentrations are associated with aggressiveness and interpersonal violence in men. Antiandrogenic agents have been shown to decrease aggression.

Evidence indicates that intermittent explosive disorder is more common in first-degree biologic relatives of persons with the disorder than in the general population. This association does not imply a genetic etiology, as many other

familial and social factors are surely influential. A gene–environment interaction may exist where individuals who have specific serotonin gene polymorphisms may be more prone to impulsive aggression behavior after exposure to childhood maltreatment.

Kleptomania

We know little about the etiology of kleptomania. There have been case reports of kleptomania associated with head trauma, frontal lobe lesions, cortical atrophy, dementia, and hypoglycemia secondary to insulinoma. There are implications for subtle white matter pathology based on diffusion tensor imaging results. Another study found that although, as a group, patients with kleptomania did not show deficits on neuropsychological testing, the severity of illness was associated with impairment in executive functioning.

Data are lacking and limited regarding the genetics of kleptomania. A study found that individuals with kleptomania had more first-degree relatives with alcohol use disorders compared to controls. Serotonin and dopamine, as well as the opioid and glutamatergic neurotransmitter systems, may play a role in kleptomania. Additionally, there are higher rates of OCD in relatives of individuals with kleptomania compared to the general population.

Pyromania

The etiology of pyromania is also poorly understood. The literature on the origins of pyromania has suggested factors ranging from temperament to environmental factors and parental psychopathology. Other authors have suggested pyromania, and the other impulse-control disorders, may share a neurobiologic link with substance use disorders. Limited studies suggest that pyromania may be associated with lower concentration of norepinephrine and serotonin metabolites 3-methoxy-4-hydroxyphenylglycol (MHPG) and 5-hydroxyindoleacetic acid (5-HIAA).

Personality Disorders

The person-centered approach to understanding personality and its disorders distinguish psychiatry fundamentally from all other branches of medicine. A person is a self-aware human being, as C. Robert Cloninger said, not "a machine-like object that lacks self-awareness." Personality refers to all of the characteristics that distinguish a continually developing, self-organizing human being from a predictable machine-like object. In other words, personality refers to all the ways someone shapes and adapts in a unique way to an ever-changing internal and external environment.

Persons with personality disorders are far more likely to refuse psychiatric help and to deny their problems than persons with anxiety disorders, depressive disorders, or obsessive-compulsive disorder. In general, personality disorder symptoms are ego-syntonic (i.e., acceptable to the ego, as opposed to ego-dystonic) and alloplastic (i.e., adapt by trying to alter the external environment rather than themselves). Persons with personality disorders do not feel anxiety about their maladaptive behavior. Because they do not routinely acknowledge pain from what others perceive as their symptoms, they often seem disinterested in treatment and impervious to recovery.

THE CLINICAL PRESENTATION

Persons suffering from one of these disorders have long-standing, maladaptive behavior traits that are pervasive and apparent in a wide range of personal and social contexts.

Paranoid Personality Disorder

Persons with paranoid personality disorder have long-standing suspiciousness and mistrust of persons in general. They refuse responsibility for their feelings and assign responsibility to others. They are often hostile, irritable, and angry.

Schizoid Personality Disorder

Schizoid personality disorder is characterized by a lifelong pattern of social withdrawal. Others often see persons with schizoid personality disorder as eccentric, isolated, or lonely. Their discomfort with human interaction, their introversion, and their bland, constricted affect are noteworthy.

Schizotypal Personality Disorder

Persons with schizotypal personality disorder are strikingly odd or strange, even to laypersons. Magical thinking, peculiar notions, ideas of reference, illusions, and derealization are commonplace.

Antisocial Personality Disorder

Antisocial personality disorder is an inability to conform to the social norms that ordinarily govern many aspects of a person’s adolescent and adult behavior. Although often characterized by continual antisocial or criminal acts, the disorder is not synonymous with criminality.

Borderline Personality Disorder

Patients with borderline personality disorder stand on the border between neurosis and psychosis, and they have extraordinarily unstable affect, mood, behavior, object relations, and self-image.

Histrionic Personality Disorder

Persons with histrionic personality disorder are excitable and emotional and behave in a colorful, dramatic, extroverted fashion. Accompanying their flamboyant aspects, however, is often an inability to maintain sincere, long-lasting attachments.

Narcissistic Personality Disorder

Individuals with narcissistic personality disorder have a heightened sense of self-importance, lack of empathy, and grandiose feelings of uniqueness. Underneath, however, their self-esteem is fragile and vulnerable to even minor criticism.

Avoidant Personality Disorder

Persons with avoidant personality disorder show extreme sensitivity to rejection and may lead socially withdrawn lives. Although shy, they are not asocial and show a great desire for companionship, but they need unusually strong guarantees of uncritical acceptance. We often describe this group as having an inferiority complex.

Dependent Personality Disorder

Patients with dependent personality disorder subordinate their own needs to those of others, get others to assume responsibility for significant areas of their lives, lack self-confidence, and may experience intense discomfort when alone for more than a brief period.

Obsessive-Compulsive Personality Disorder

Persons with obsessive-compulsive personality disorder typically are emotionally constricted, orderly, perseverative, stubborn, and indecisive. The essential feature of the disorder is a pervasive pattern of perfectionism and inflexibility.

Personality Change due to a General Medical Condition

Personality change due to a general medical condition is a significant occurrence. ICD-10 includes the category personality and behavioral disorders due to brain disease, damage, and dysfunction, which includes organic personality disorder, postencephalitic syndrome, and postconcussional syndrome. Persons with this disorder have a marked change in personality style and traits from their previous level of functioning. Patients must show evidence of a causative medical factor antedating the onset of personality change.

DIAGNOSIS

DSM-5's categorical approach to personality disorders is problematic. It seems counterintuitive to think that we can boil down disturbed personality into a few symptoms. Experts in the field have argued for a more dimensional approach that is grounded in research on temperament and personality, some of which we later describe. The DSM-5 Personality Disorders Workgroup did work on such a change, in which the clinician would focus on the impairments in a person's personality functioning, using an approach based on a widely accepted model of personality. Although the authors of DSM-5 did consider such a change, they felt it too radical a leap for clinical use. Instead, they included the approach that the workgroup recommended in a later section of the book, "Emerging Measures and Models." For now, the categorical approach remains. However, this remains a controversial area of psychiatry, and many rightly question the validity of this approach.

ICD-10, with its more descriptive approach, is a little less controversial. However, despite some wording differences, its approach is similar to DSM-5's, although it lists more disorders than does DSM-5.

Table 19-1 compares the general approaches to diagnosing personality disorders.

DSM-5 divides the disorders into three categories, or clusters: A, B, and C. Cluster A includes three personality disorders with odd, aloof features (paranoid, schizoid, and schizotypal). Cluster B includes four personality disorders with dramatic, impulsive, exploitative, and erratic features (borderline, antisocial, narcissistic, and histrionic). Cluster C includes three personality disorders sharing anxious and fearful features (avoidant, dependent, and obsessive-compulsive). Individuals frequently exhibit traits that are not limited to a single personality disorder. When a patient meets the criteria for more than one personality disorder, clinicians should diagnose each.

Many of the features of various personality disorders can occur during an episode of another mental disorder. We should only use a diagnosis of personality disorder when the features are typical of long-term functioning and are not limited to a discrete episode of another mental disorder. Likewise, when maladaptive behavior features are due to the direct psychological effects of another mental disorder, including substance use, a diagnosis of

personality disorder is not warranted. However, it is possible to diagnose personality change due to another medical condition such as temporal lobe epilepsy; in this case, we must specify the medical condition along with the associated diagnosis of personality change.

Table 19-1
Personality Disorders

Paranoid Personality Disorder: Specific Symptoms

DSM-5		ICD-10	
Paranoid Personality Disorder		**Paranoid Personality D**	
Suspiciousness, evident from the following (≥4): • Suspicion/persecutory thoughts • Doubting others' loyalty • Distrust, inability to confide in others • Interpreting experiences as threatening or hostile • Holds grudges • Feeling attacked by others • Distrusting partner's faithfulness	Exclusions (not result of): • *Schizophrenia* • *Depression with psychotic features* • *Other psychoses* • *Substance use* • *A medical condition*	• Excessive sensitivity to setbacks or insults • Suspiciousness • Interpreting experiences as threatening or hostile • Distrusting partner's faithfulness • May also be self-important or overall self-referential	Exc • I • S • I

Cluster A: Odd and Eccentric

Paranoid Personality Disorder. The hallmarks of paranoid personality disorder are excessive suspiciousness and distrust of others expressed as a pervasive tendency to interpret the actions of others as deliberately demeaning, malevolent, threatening, exploiting, or deceiving. This tendency begins in early adulthood and appears in a variety of contexts. Almost invariably, those with the disorder expect to be exploited or harmed by others in some way. They frequently dispute, without any justification, friends' or associates' loyalty or trustworthiness. Such persons are often pathologically jealous and, for no reason, question the fidelity of their spouses or sexual partners. Persons with this disorder externalize their own emotions and use the defense of projection; they attribute to others the impulses and thoughts that they cannot accept in themselves. Ideas of reference and logically defended illusions are common. Table 19-2 compares the different approaches to diagnosing paranoid personality disorder.

On psychiatric examination, patients with paranoid personality disorder may be formal in their style and act baffled about having to seek psychiatric help. Muscular tension, an inability to relax, and a need to scan the environment for clues may be evident, and the patient's manner is often severe and humorless. Although some premises of their arguments may be false, their speech is goal-directed and logical. Their thought content shows evidence of projection, prejudice, and occasional ideas of reference.

Schizoid Personality Disorder. Persons with schizoid personality disorder seem to be cold and aloof; they display a remote reserve and show no involvement with everyday events and the concerns of others. They appear quiet, distant, seclusive, and unsociable. They may pursue their own lives with remarkably little need or longing for emotional ties, and they are the last to be aware of changes in popular fashion. Table 19-3 compares the different approaches to diagnosing schizoid personality disorder.

The life histories of such persons reflect solitary interests and success at noncompetitive, lonely jobs that others find difficult to tolerate. Their sexual lives may exist exclusively in fantasy, and they may postpone mature sexuality indefinitely. Persons with schizoid personality disorder usually reveal a lifelong inability to express anger directly. They often lack close friends or confidants and are indifferent to praise and criticism. Although persons with schizoid personality disorder appear self-absorbed and lost in

daydreams, they have an average capacity to recognize reality.

On an initial psychiatric examination, patients with schizoid personality disorder may appear ill at ease. They rarely tolerate eye contact, and interviewers may surmise that such patients are eager for the interview to end. Their affect may be constricted, aloof, or inappropriately severe, but underneath the aloofness, sensitive clinicians can recognize fear. These patients find it challenging to be lighthearted: their efforts at humor may seem adolescent and off the mark. Their speech is goal-directed, but they are likely to give short answers to questions and to avoid spontaneous conversation. They may occasionally use unusual figures of speech, such as an odd metaphor, and may be fascinated with inanimate objects or metaphysical constructs. Their sensorium is intact, their memory functions well, and their proverb interpretations are abstract.

Table 19-3

(because of thoughts)	more like that for personality disorders

Schizotypal Personality Disorder. Schizotypal personality disorder is characterized by pervasive discomfort with and inability to maintain close relationships, as well as eccentric behavior. These individuals demonstrate peculiarities of thinking, behavior, and appearance. Taking a history may be difficult because of the patients' unusual way of communicating.

Patients with schizotypal personality disorder exhibit disturbed thinking and communicating. Although frank thought disorder is absent, their speech may be distinctive or peculiar, may have meaning only to them, and often needs interpretation. These patients may be superstitious or claim powers of clairvoyance and may believe that they have other special powers of thought and insight. Their inner world may contain vivid imaginary relationships and child-like fears and fantasies, and they may experience perceptual illusions, as well. Table 19-4 compares the different approaches to diagnosing schizotypal personality disorder.

Because persons with schizotypal personality disorder have poor interpersonal relationships and may act inappropriately, they are isolated and have few, if any, friends. Under stress, patients with schizotypal personality disorder may decompensate and have psychotic symptoms, but these are usually brief. Patients with severe cases of the disorder may exhibit anhedonia and severe depression.

Cluster B: Dramatic

Antisocial Personality Disorder. The hallmarks of antisocial personality disorder are pervasive disrespect for and infringement on the rights of others. A person has to be 18 years of age or older, has to have demonstrated this pattern of behavior since age 15, and must have demonstrated evidence of conduct disorder before the age of 15 years (conduct disorder involves a repetitive and persistent pattern of behavior in which they violate the fundamental rights of others or major age-appropriate social rules). Table 19-

5 compares the different approaches to diagnosing antisocial personality disorder.

Patients with antisocial personality disorder can often seem to be normal and even charming and ingratiating. Their histories, however, reveal many areas of disordered life functioning. Lying, truancy, running away from home, thefts, fights, substance abuse, and illegal activities are typical experiences that patients report as beginning in childhood. These patients often impress clinicians with the colorful, seductive aspects of their personalities, but the clinician may also regard them as manipulative and demanding. They frequently have a heightened sense of reality testing and often impress observers as having excellent verbal intelligence.

Table 19-5
Antisocial Personality Disorder: Specific Symptoms

DSM-5		ICD-10	
Antisocial Personality Disorder		**Dissocial Personality Disor**	
≥age 18 Began by age 15 Conduct disorder before age 15 (diagnosed or evidence for) (≥3): • Disregards legal and social rules/norms • Lies • Impulsive • Irritable or	Exclusions (not result of): • *Schizophrenia* • *Bipolar disorder*	• Disregards social norms • Unconcerned by others' feelings • Easily frustrated/distressed • Easily becomes aggressive • Blames others	Exclusic resul • Conc disc • Emo unst pers disc

aggressive
- Neglects safety (self/others)
- Irresponsible
- No remorse

Persons with antisocial personality disorder are highly representative of the so-called con men. They are incredibly manipulative and can frequently talk others into participating in schemes for easy ways to make money or to achieve fame or notoriety. These schemes may eventually lead the unwary to financial ruin, social embarrassment, or both. Those with this disorder do not tell the truth and cannot be trusted to carry out any task or adhere to any conventional standard of morality. Promiscuity, spousal abuse, child abuse, and drunk driving are frequent events in their lives. A notable finding is a lack of remorse for these actions; that is, they appear to lack a conscience.

Patients with antisocial personality disorder can fool even the most experienced clinicians. In an interview, patients can appear composed and credible, but beneath the veneer lurks tension, hostility, irritability, and rage. A stress interview, in which the clinician vigorously confronts the patient with inconsistencies in their histories, may be necessary to reveal the pathology. A diagnostic workup should include a thorough neurologic examination. Because patients often show abnormal EEG results and soft neurologic signs suggesting minimal brain damage in childhood, these findings may support the clinical impression.

Borderline Personality Disorder. Persons with borderline personality disorder almost always appear to be in a state of crisis. Mood swings are frequent. Patients can be argumentative at one moment, depressed the next, and later complain of having no feelings. Patients can have short-lived psychotic episodes rather than full-blown psychotic breaks, and the symptoms are circumscribed, fleeting, or questionable. The behavior of patients with borderline personality disorder is highly unpredictable, and their achievements are rarely at the level of their abilities. The painful nature of their lives reflects in their repetitive self-destructive acts. Such patients may

slash their wrists and perform other self-mutilation to elicit help from others, to express anger, or to numb themselves to overwhelming affect. Table 19-6 compares the different approaches to diagnosing borderline personality disorder.

Because they feel both dependent and hostile, persons with this disorder have tumultuous interpersonal relationships. They can be dependent on those with whom they are close and, when frustrated, can express enormous anger toward their intimate friends. Patients with borderline personality disorder cannot tolerate being alone, and they prefer a frantic search for companionship, no matter how unsatisfactory, to their own company. To assuage loneliness, if only for brief periods, they accept a stranger as a friend or behave promiscuously. They often complain about chronic feelings of emptiness and boredom and the lack of a consistent sense of identity (identity diffusion); when pressed, they may complain about how depressed they usually feel, despite the flurry of other affects.

Functionally, patients with borderline personality disorder distort their relationships by considering each person to be either all good or all bad. They see persons as either nurturing attachment figures or as hateful, sadistic figures who deprive them of security needs and threaten them with abandonment whenever they feel dependent. As a result of this splitting, the good person is idealized, and the bad person devalued. Shifts of allegiance from one person or group to another are frequent. Some clinicians use the concepts of panphobia, pananxiety, panambivalence, and chaotic sexuality to delineate these patients' characteristics.

Projective identification is a defense mechanism that often occurs in patients with borderline personality disorder. In this primitive defense mechanism, the patient projects intolerable aspects of themselves onto another person, inducing them to play the projected role, and the two persons act in unison. Therapists must be aware of this process so they can act neutrally toward such patients.

Histrionic Personality Disorder. Persons with histrionic personality disorder show a high degree of attention-seeking behavior. They tend to exaggerate their thoughts and feelings and make everything sound more vital than it is. They display temper tantrums, tears, and accusations when they are not the center of attention or are not receiving praise or approval. Table 19-7

compares the different approaches to diagnosing histrionic personality disorder.

Seductive behavior is typical in both sexes. Sexual fantasies about persons with whom patients are involved are common, but patients are inconsistent about verbalizing these fantasies and may be coy or flirtatious rather than sexually aggressive. Despite these behaviors, they may have a psychosexual dysfunction, such as anorgasmia. They may act on their sexual impulses to reassure themselves that they are attractive to the other sex. Their relationships tend to be superficial, however, and they can be vain, self-absorbed, and fickle. Their deep dependence needs make them overly trusting and gullible.

Table 19-6
Borderline Personality Disorder: Specific Symptoms

DSM-5	ICD-10	
Borderline Personality Disorder	**Emotionally Unstable Personality Disorder**	
Conflict/impulsivity (≥5): • Avoids abandonment • Intense, unstable relations marked by splitting • Unstable self-image • Self-harm, other impulsive behaviors • Suicidal ideation or behavior • Labile affect • Feeling empty inside • Poor anger management • Paranoia/dissociation, usually due to stress	• Impulsiveness • Labile mood • Outbursts • Interpersonal conflict Two subtypes: (1) Impulsive type (emotional lability and lack of impulse control) (2) Borderline type (poor self-image, self-worth, relationships, with associated self-harm)	Exclusions (not result of): • Dissocial personality disorder

Table 19-7
Histrionic Personality Disorder: Specific Symptoms

DSM-5	ICD-10
Histrionic Personality Disorder	**Histrionic Personality Disorder**
Needing attention, very emotional (≥5): • Uncomfortable when not the center of attention • Flirtatious, provocatively sexual • Emotionally labile • Physically provocative or flamboyant • Speech is vague • Speech is exaggerated/dramatic • Suggestible • Overestimates the intimacy of relationships	• Affect is shallow/labile • Self-dramatization • Speech and emotions are exaggerated • Suggestible • Egocentric • Not concerned with others • Attention seeking • Easily offended or hurt

The major defenses of patients with histrionic personality disorder are repression and dissociation. Accordingly, such patients are unaware of their true feelings and cannot explain their motivations. Under stress, reality testing quickly becomes impaired.

In interviews, patients with histrionic personality disorder are generally cooperative and eager to give a detailed history. Gestures and dramatic punctuation in their conversations are commonplace; they may make frequent slips of the tongue, and their language is colorful. Affective display is typical, but when pressed to acknowledge certain feelings (e.g., anger, sadness, and sexual wishes), they may respond with surprise, indignation, or denial. The results of the cognitive examination are usually normal, although they may show a lack of perseverance on arithmetic or concentration tasks, and the patients' forgetfulness of affect-laden material may be astonishing.

Narcissistic Personality Disorder. Persons with narcissistic personality disorder have a grandiose sense of self-importance; they consider themselves special and expect special treatment. Their sense of entitlement is striking. They handle criticism poorly and may become enraged when someone dares to criticize them, or they may appear utterly indifferent to criticism. Persons with this disorder want their way and are frequently ambitious to achieve fame and fortune. Their relationships are tenuous, and they can make others furious by their refusal to obey conventional rules of behavior. Interpersonal exploitativeness is commonplace. They cannot show empathy, and they feign sympathy only to achieve their selfish ends. Because of their fragile self-esteem, they are susceptible to depression. Interpersonal difficulties, occupational problems, rejection, and loss are among the stresses that narcissists commonly produce by their behavior—stresses they are least able to handle. Table 19-8 compares the different approaches to diagnosing narcissistic personality disorder.

Table 19-8
Narcissistic Personality Disorder: Specific Symptoms

DSM-5	ICD-10
Narcissistic Personality Disorder	**Narcissistic Personality**
Self-important, lacking empathy for others (≥5): • Grandiose • Preoccupied with fantasies about success • Feeling special/unique • Needing others to admire them for validation • Expecting special treatment • Exploiting others • Lacking empathy • Jealous of others' success,	Not described. Listed as an "other specific personality disorder"

assuming others are jealous of them
- Arrogance

Cluster C: Anxious

Avoidant Personality Disorder. Hypersensitivity to rejection by others is the central feature of avoidant personality disorder, and timidity is the primary personality trait that is displayed. These persons desire the warmth and security of human companionship but justify their avoidance of relationships by their fear of rejection. When talking with someone, they express uncertainty, show a lack of self-confidence, and may speak in a self-effacing manner. Because they are hypervigilant about rejection, they are afraid to speak up in public or to make requests of others. They are apt to misinterpret others' comments as derogatory or ridiculing. The refusal of any request leads them to withdraw from others and to feel hurt. Table 19-9 compares the different approaches to diagnosing avoidant personality disorder.

In the vocational sphere, patients with avoidant personality disorder often take jobs on the sidelines. They rarely attain much personal advancement or exercise much authority but seem shy and eager to please. These persons are generally unwilling to enter relationships unless they have an unusually strong guarantee of uncritical acceptance. Consequently, they often have no close friends or confidants.

In clinical interviews, patients' most striking aspect is anxiety about talking with an interviewer. Their nervous and tense manner may wax and wane depending on whether they think the interviewer likes them. They may also seem vulnerable to the interviewer's comments and suggestions and may regard a clarification or interpretation as criticism.

Dependent Personality Disorder. Dependent personality disorder is a pervasive pattern of dependent and submissive behavior. Persons with the disorder cannot make decisions without significant and unwarranted advice and encouragement from others. They avoid positions of responsibility and become anxious if asked to assume a leadership role. They prefer to be

submissive. When on their own, they find it difficult to persevere at tasks but may find it easy to perform these tasks for someone else. Table 19-10 compares the different approaches to diagnosing dependent personality disorder.

Table 19-9
Avoidant Personality Disorder: Specific Symptoms

DSM-5	ICD-10
Avoidant Personality Disorder	**Anxious [Avoidant] Personality Disorder**
Hypersensitive, lacking confidence (≥4): • Avoids others • Fears being disliked • Avoids relationships for fear of shame • Fears rejection/criticism • Inhibited in relationships • Avoids novelty for fear of embarrassment	• Fearful, insecure, feels inferior to others • Craves acceptance • Fears or is sensitive to rejection • Relationships are superficial • Avoids activities/situations perceived as risky

Table 19-10
Dependent Personality Disorder: Specific Symptoms

DSM-5	ICD-10
Dependent Personality Disorder	**Dependent Personality Disorder**
Fears separation, needs others to care for them (≥5): • Cannot make decisions alone • Avoids taking on responsibility for important things	• Relies on others and needs them for validation • Cannot make decisions without another's approval • Fears abandonment

- Cannot disagree with others for fear they will disapprove of them
- Lacks confidence, cannot initiate new things
- Seeks acceptance of others
- Fears being alone/independence
- When relationship ends, quickly seeks new one
- Fears having to take care of self
- Fears helplessness/incompetence
- Passive, lets another make decisions
- Avoids responsibility

Because persons with the disorder do not like to be alone, they seek out others on whom they can depend; their relationships, thus, are distorted by their need to be attached to another person. In a shared psychotic disorder (folie à deux), one member of the pair usually has dependent personality disorder; the submissive partner takes on the delusional system of the more aggressive, assertive partner on whom he or she depends.

Pessimism, self-doubt, passivity, and fears of expressing sexual and aggressive feelings all typify the behavior of persons with a dependent personality disorder. An abusive, unfaithful, or alcoholic spouse may be tolerated for long periods to avoid disturbing the sense of attachment.

In interviews, patients appear compliant. They try to cooperate, welcome specific questions and look for guidance.

Obsessive-Compulsive Personality Disorder. Persons with obsessive-compulsive personality disorder are preoccupied with rules, regulations, orderliness, neatness, details, and the achievement of perfection. These traits account for the general constriction of the entire personality. They insist that rules be followed rigidly and cannot tolerate what they consider infractions. Accordingly, they lack flexibility and are intolerant. They are capable of prolonged work, provided it is routinized and does not require changes to which they cannot adapt. Table 19-11 compares the different approaches to diagnosing obsessive-compulsive personality disorder.

Persons with obsessive-compulsive personality disorder have limited interpersonal skills. They are formal and severe and often lack a sense of humor. They alienate those around them, are unable to compromise, and

insist that others submit to their needs. They are eager to please those whom they see as more powerful, however, and they carry out these persons' wishes in an authoritarian manner. Because they fear to make mistakes, they are indecisive and ruminate about making decisions. Although a stable marriage and occupational adequacy are common, persons with obsessive-compulsive personality disorder have few friends. Anything that threatens to upset their perceived stability or the routine of their lives can precipitate much anxiety otherwise bound up in the rituals that they impose on their lives and try to impose on others.

In interviews, patients with an obsessive-compulsive personality disorder may have a stiff, formal, and rigid demeanor. Their affect is not blunted or flat but often constricted. They lack spontaneity, and their mood is usually serious. Such patients may be anxious about not being in control of the interview. Their answers to questions are unusually detailed. The defense mechanisms they use are rationalization, isolation, intellectualization, reaction formation, and undoing.

Other Personality Disorders

Personality Change due to Another Medical Condition. This diagnosis involves a change in personality from previous patterns of behavior or an exacerbation of previous personality characteristics. Impaired control of the expression of emotions and impulses is a cardinal feature. Emotions are characteristically labile and shallow, although euphoria or apathy may be prominent. The euphoria may mimic hypomania, but genuine elation is absent, and patients may admit to not feeling happy. There is a hollow and silly ring to their excitement and facile jocularity, particularly when the frontal lobes are involved. Also associated with damage to the frontal lobes, the so-called frontal lobe syndrome, consists of prominent indifference and apathy, characterized by a lack of concern for events in the immediate environment. Temper outbursts, which can occur with little or no provocation, especially after alcohol ingestion, can result in violent behavior. The expression of impulses may include inappropriate jokes, a coarse manner, improper sexual advances, and antisocial conduct resulting in conflicts with the law, such as assaults on others, sexual misdemeanors, and shoplifting. They typically have diminished foresight, and cannot anticipate

the social or legal consequences of actions. Persons with temporal lobe epilepsy characteristically show humorlessness, hypergraphia, hyperreligiosity, and marked aggressiveness during seizures.

Table 19-11
Obsessive-Compulsive Personality Disorder: Specific Symptoms

Obsessive-Compulsive Personality Disorder		Anankastic Personality Dis	
Orderliness, perfectionism, self-control (≥4): • Attention to rules/details/order • Cannot complete things because of needing it to be perfect • Relationships neglected because of devotion to work • Inflexible thinking • Cannot part with things	• Cannot delegate • Stingy • Stubborn/rigid	• Plagued by doubt • Perfectionism, checking, attention to detail • Stubborn/rigid • Overly cautious • Unwanted thoughts or impulses, but not to the point of obsessions or compulsions	Exclusion result • Obses comp disord

Persons with personality change due to a general medical condition have a clear sensorium. Mild disorders of cognitive function often coexist but do not amount to intellectual deterioration. Patients may be inattentive, which may account for disorders of recent memory. With some prodding, however, patients are likely to recall what they claim to have forgotten. We should suspect the diagnosis in patients who show marked changes in behavior or personality involving emotional lability and impaired impulse control, who have no history of mental disorder, and whose personality changes occur

abruptly or over a relatively brief time.

Other Specified Personality Disorder. DSM-5 reserves the category of other specified personality disorder for situations that meet the general criteria for a personality disorder, but the presentation does not fit into any of the personality disorder categories described above. Passive-aggressive personality and depressive personality are examples. A narrow spectrum of behavior or a particular trait—such as oppositionalism, sadism, or masochism—can also be classified in this category. A patient with features of more than one personality disorder but without the complete criteria of any one disorder can be assigned this classification.

Unspecified Personality Disorder. This diagnosis is like the above Other Specified Personality Disorder but is used in situations when we may choose not to indicate why the patient does not meet the criteria for a specific personality disorder. A typical example is a case in which there is not enough information to make a specific personality disorder diagnosis.

DIFFERENTIAL DIAGNOSIS

Many of the features of various personality disorders may occur during an episode of another mental disorder. Some of the personality disorders, particularly within a given cluster, may also share common features.

Paranoid Personality Disorder

Paranoid personality disorder can usually be differentiated from delusional disorder by the absence of fixed delusions. Unlike persons with schizophrenia, those with personality disorders typically lack hallucinations or formal thought disorder. However, when a brief reactive psychosis with delusions complicates the clinical picture of paranoid personality disorder, this distinction is far more complicated. Paranoid personality disorder can be distinguished from a borderline personality disorder because patients who are paranoid are rarely capable of overly involved, tumultuous relationships with others. Patients with paranoia lack the long history of antisocial behavior of persons with antisocial character. Persons with schizoid personality disorder are withdrawn and aloof and do not have paranoid ideation.

Schizoid Personality Disorder

Schizoid personality disorder differs from schizophrenia, delusional disorder, and affective disorder with psychotic features based on periods with positive psychotic symptoms, such as delusions and hallucinations, in the latter. Although patients with paranoid personality disorder share many traits with those with schizoid personality disorder, the former exhibit more social engagement, a history of aggressive verbal behavior, and a greater tendency to project their feelings onto others. If just as emotionally constricted, patients with obsessive-compulsive and avoidant personality disorders experience loneliness as dysphoric, possess a more abundant history of past object relations, and do not engage as much in autistic reverie. The chief distinction between a patient with schizotypal personality disorder and one with schizoid personality disorder is that the patient who is schizotypal is more similar to a patient with schizophrenia in oddities of perception, thought, behavior, and communication. Patients with avoidant personality disorder are isolated but do wish to participate in activities, a characteristic absent in those with schizoid personality disorder. Schizoid personality disorder is distinguished from autism spectrum disorder by more severely impaired social interactions and stereotypical behaviors and interests with autism.

Schizotypal Personality Disorder

Persons with schizotypal personality disorder can be distinguished from those with schizoid and avoidant personality disorders by the presence of oddities in their behavior, thinking, perception, and communication. Schizotypal personality disorder is difficult to distinguish from the heterogeneous group of solitary, odd children whose behavior is characterized by social isolation, eccentricity, and peculiarities in language seen in autism spectrum disorder and communication disorders. We distinguish the latter by the primacy and severity of the language disorder and accompanying compensatory efforts by the patient. Also, individuals with autism often have more severely impaired social interactions and restricted behaviors and interests than those with schizotypal disorder. Patients with schizotypal personality disorder can be distinguished from those with schizophrenia by the absence of psychosis. If psychotic symptoms do appear, they are brief and fragmentary. Patients with

paranoid personality disorder are suspicious but lack the odd behavior of patients with schizotypal personality disorder.

Antisocial Personality Disorder

Antisocial personality disorder differs from mere illegal behavior in that antisocial personality disorder involves many areas of a person's life. When illegal behavior is only for gain and does not include rigid, maladaptive, and persistent personality traits, we classify it as criminal behavior not associated with a personality disorder in DSM-5.

Many of these persons have a neurologic or mental disorder that has been either overlooked or undiagnosed. More difficult is the differentiation of antisocial personality disorder from substance use disorders. When both substance use disorders and antisocial behavior begin in childhood and continue into adult life, we should diagnose both disorders. When, however, the antisocial behavior is secondary to premorbid alcohol use disorder or another substance use disorder, the diagnosis of antisocial personality disorder is not warranted.

In diagnosing antisocial personality disorder, clinicians must adjust for the distorting effects of socioeconomic status, cultural background, and sex. Furthermore, the diagnosis of antisocial personality disorder is not warranted when intellectual disability, schizophrenia, or mania can explain the symptoms. Other personality disorders, such as narcissistic, histrionic, and paranoid, can be differentiated from antisocial personality disorder as the former personality disorders rarely include serious criminality and aggressiveness. Borderline personality disorder can sometimes be associated with criminality. However, individuals with borderline personality who commit crimes tend to display high novelty seeking and high harm avoidance behaviors, whereas those with antisocial personality tend to display high novelty seeking and low harm avoidance behaviors.

Borderline Personality Disorder

Borderline personality disorder differs from major depressive disorder, bipolar disorder, dysthymic disorder, and cyclothymia based on the presence of core borderline personality symptoms that are not typically present in mood disorders (e.g., fear of abandonment, highly unpredictable behavior,

tumultuous interpersonal relationships, seeing others as either all good or all bad, complaints of being numb or empty, and the lack of a consistent sense of identity). It differs from identity problems, which are typically limited to a developmental stage.

Borderline personality disorder differs from schizophrenia on the basis that the patient with borderline personality lacks prolonged psychotic episodes, thought disorder, and other classic schizophrenic signs. Patients with schizotypal personality disorder show marked peculiarities of thinking, strange ideation, and recurrent ideas of reference. Those with paranoid personality disorder have extreme suspiciousness. In contrast, patients with borderline personality disorder generally have short-lived psychotic episodes, when present.

Histrionic Personality Disorder

Distinguishing between histrionic personality disorder and borderline personality disorder is challenging, but in borderline personality disorder, suicide attempts, identity diffusion, and brief psychotic episodes are more likely. Although both conditions can exist in the same patient, clinicians should separate the two. Somatic symptom disorder may occur in conjunction with histrionic personality disorder, and we should diagnose both as well. Patients with brief psychotic disorder and dissociative disorders may warrant a coexisting diagnosis of histrionic personality disorder.

Narcissistic Personality Disorder

Borderline, histrionic, and antisocial personality disorders often accompany narcissistic personality disorder, so differential diagnosis is difficult. Patients with narcissistic personality disorder have less anxiety than those with borderline personality disorder; their lives tend to be less chaotic, and they are less likely to attempt suicide. Patients with antisocial personality disorder have a history of impulsive behavior, often associated with alcohol or other substance use, which frequently gets them into trouble with the law. Patients with histrionic personality disorder show features of exhibitionism and interpersonal manipulativeness that resemble those of patients with narcissistic personality disorder. Narcissistic personality disorder can be distinguished from the grandiosity of mania by the episodic course,

associated euphoria, and functional impairment in a manic or hypomanic episode.

Avoidant Personality Disorder

Avoidant personality disorder is complicated to distinguish from social anxiety disorder. In social anxiety disorder, specific situations, rather than interpersonal contact in general, are avoided. They may co-occur. Panic disorder with agoraphobia also manifests avoidance, but usually after the onset of panic attacks.

Patients with schizoid and schizotypal personality disorders may be indistinguishable from those with avoidant personality disorder. However, patients with avoidant personality disorder desire social interaction, unlike patients with schizoid personality disorder, who want to be alone. Patients with avoidant personality disorder are not as demanding, irritable, or unpredictable as those with borderline and histrionic personality disorders. Avoidant personality disorder and dependent personality disorder are similar. Patients with dependent personality disorder are presumed to have a greater fear of being abandoned or unloved than those with avoidant personality disorder, but the clinical picture may be indistinguishable.

Dependent Personality Disorder

The traits of dependence occur in many psychiatric disorders, so the differential diagnosis is difficult. Dependence is a prominent factor in patients with histrionic and borderline personality disorders. However, those with dependent personality disorder usually have a long-term relationship with one person rather than a series of persons on whom they are dependent, and they do not tend to be overly manipulative. Dependent behavior can also occur in patients with agoraphobia, panic disorder, and depressive disorders, but these patients tend to have a high level of overt anxiety, panic, or depression, respectively.

Obsessive-Compulsive Personality Disorder

When recurrent obsessions or compulsions are present, we should diagnose an obsessive-compulsive disorder. Perhaps the most challenging distinction is between outpatients with some obsessive-compulsive traits and those with an

obsessive-compulsive personality disorder. We should reserve the personality disorder diagnosis for those with significant impairments in their occupational or social effectiveness. In some cases, delusional disorder coexists with personality disorders, and we should diagnose both.

Personality Change due to Another Medical Condition

Dementia involves global deterioration in intellectual and behavioral capacities, of which personality change is just one category. A personality change may herald a cognitive disorder that eventually will deteriorate into dementia. In these cases, as deterioration begins to encompass significant memory and cognitive deficits, the diagnosis of the disorder changes from personality change caused by a general medical condition to dementia. In differentiating the specific syndrome from other disorders in which personality change may occur—such as schizophrenia, delusional disorder, mood disorders, and impulse control disorders—physicians must consider the most critical factor, the presence of a personality change due to a specific organic causative factor.

COMORBIDITY

Personality disorders occur in 10 to 20 percent of the general population and about half of psychiatric inpatients or outpatients. Personality disorders are frequently comorbid with other clinical syndromes and are predisposing factors for other psychiatric disorders and symptoms (e.g., substance use, suicide, affective disorders, impulse-control disorders, eating disorders, and anxiety disorders).

Paranoid Personality Disorder

These individuals are at increased risk for major depression, obsessive-compulsive disorder, agoraphobia, and substance use disorders. The most common co-occurring personality disorders are schizotypal, schizoid, narcissistic, avoidant, and borderline. Paranoid personality disorder may be a premorbid antecedent of delusional disorder, persecutory type.

Schizoid Personality Disorder

This personality disorder sometimes appears as the premorbid antecedent of delusional disorder, schizophrenia, or rarely major depression. Paranoid, schizotypal, and avoidant are the most common co-occurring personality disorders.

Schizotypal Personality Disorder

More than half of these patients have had at least one episode of major depression, and 30 to 50 percent have major depression concurrent with this personality disorder. The most common co-occurring personality disorders are schizoid, paranoid, avoidant, and borderline.

Antisocial Personality Disorder

These patients are at increased risk for impulse control disorders, major depression, substance use disorders, pathologic gambling, anxiety disorders, and somatic symptom disorder. Narcissistic, borderline, and histrionic are the most common co-occurring personality disorders.

Borderline Personality Disorder

These individuals are at increased risk for major depression, substance use disorders, eating disorders (notably bulimia), posttraumatic stress disorder, attention-deficit hyperactivity disorder, and somatic symptom disorder. Borderline personality disorder can co-occur with most other personality disorders.

Histrionic Personality Disorder

Patients with histrionic personality disorder are at increased risk for major depression, somatic symptom disorder, and conversion disorder. Narcissistic, borderline, antisocial, and dependent are the most common co-occurring personality disorders.

Narcissistic Personality Disorder

These patients are at increased risk for major depression and substance use disorders (especially cocaine use). The most common co-occurring personality disorders are borderline, antisocial, histrionic, and paranoid.

Avoidant Personality Disorder

Patients with avoidant personality disorder are at increased risk for mood and anxiety disorders (especially social anxiety disorder). The most common co-occurring personality disorders are schizotypal, schizoid, paranoid, dependent, and borderline. Somatic symptom disorder may be comorbid.

Dependent Personality Disorder

These patients are at increased risk for major depression, anxiety disorders, and adjustment disorder. Somatic symptom disorder may be comorbid. The personality disorders that co-occur most commonly are histrionic, avoidant, and borderline.

Obsessive-Compulsive Personality Disorder

These individuals are at increased risk for major depression and anxiety disorder. Equivocal evidence exists for an increased risk of obsessive-compulsive disorder.

COURSE AND PROGNOSIS

Personality disorders are chronic, and they last over decades. They often interfere with the treatment outcomes of comorbid psychiatric disorders and lead to personal incapacitation, morbidity, and mortality in these patients. People with personality disorders have chronic impairments in their ability to work and love, tend to be less educated, drug dependent, single, unemployed, and to have marital difficulties. They consume a large portion of community services, social welfare benefits, public health, and prison resources.

Paranoid Personality Disorder

There are no adequate, systematic long-term studies of paranoid personality disorder. In some, paranoid personality disorder is lifelong; in others, it is a harbinger of schizophrenia. In still others, paranoid traits give way to reaction formation, appropriate concern with morality, and altruistic concerns as they mature or as stress diminishes. In general, however, those with paranoid personality disorder have lifelong problems working and living with others.

Occupational and marital problems are common. Complications may

include brief reactive psychosis, particularly in response to stress.

Schizoid Personality Disorder

The onset of schizoid personality disorder usually occurs in early childhood or adolescence. As with all personality disorders, schizoid personality disorder is long-lasting but not necessarily lifelong. The proportion of patients who incur schizophrenia is unknown. These individuals frequently have severe problems in social relations, and occupational problems develop when interpersonal involvement is required. Solitary work sometimes favorably affects overall performance. Complications may include very brief reactive psychosis, particularly in response to stress.

Schizotypal Personality Disorder

This disorder can be the premorbid personality of the patient with schizophrenia. Some, however, maintain a stable schizotypal personality throughout their lives and marry and work, despite their oddities. Complications may include transient psychotic episodes, particularly in response to stress. Symptoms sometimes become so significant that individuals meet the criteria for schizophreniform disorder, delusional disorder, and brief psychotic disorder. One long-term study reported that 10 percent of those with schizotypal personality disorder eventually committed suicide.

Antisocial Personality Disorder

When an antisocial personality disorder develops, it runs an unremitting course, with the height of antisocial behavior usually occurring in late adolescence. The prognosis varies. Some reports indicate that symptoms decrease as a person ages. Even after the severe antisocial behavior “burns out,” people diagnosed with antisocial personality disorder usually continue to be irritable, impulsive, and detached. Complications may include dysphoria, tension, low tolerance for boredom, depressed mood, and premature, violent death.

Borderline Personality Disorder

The course of borderline personality disorder is variable and most commonly

follows a pattern of chronic instability in early adulthood, with episodes of severe affective and impulsive dyscontrol. The impairment and the risk of suicide are highest in the young adult years and gradually wane with advancing age. In the fourth and fifth decades, these individuals tend to attain greater stability in their relationships and functioning. Impairment typically involves frequent job losses, interrupted education, and broken marriages. Complications may include psychotic-like symptoms (hallucinations, body image distortions, hypnagogic phenomena, ideas of reference) in response to stress, as well as premature death or physical handicaps from suicide and suicidal gestures, failed suicide, and self-injurious behavior.

Histrionic Personality Disorder

With age, persons with histrionic personality disorder show fewer symptoms, but because they lack the energy of earlier years, the difference in the number of symptoms may be more apparent than real. Persons with this disorder are sensation seekers, and they may get into trouble with the law, abuse substances, and act promiscuously. Complications may include frequent suicidal gestures and threats to coerce better caregiving; interpersonal relations that are unstable, shallow, and generally ungratifying; and frequent marital problems secondary to the tendency to neglect long-term relationships for the excitement of new relationships.

Narcissistic Personality Disorder

Narcissistic personality disorder is chronic and difficult to treat. Patients with the disorder must continuously deal with blows to their narcissism resulting from their behavior or life experience. Patients handle aging poorly; they value beauty, strength, and youthful attributes, to which they cling inappropriately. They may be more vulnerable, therefore, to midlife crises than are other groups. However, narcissistic symptoms tend to diminish after the age of 40 years, when pessimism usually develops. Impairment is frequently severe and includes marital problems and interpersonal relationships in general. Complications may include social withdrawal, depressed mood, and dysthymic or major depressive disorder in reaction to criticism or failure.

Avoidant Personality Disorder

Avoidant personality disorder frequently begins in childhood with shyness and fear of strangers and new situations. Impairment can be severe and typically includes occupational and social difficulties. However, many persons with avoidant personality disorder can function in a protected environment. Some marry, have children, and live their lives surrounded only by family members. If their support system fails, however, they are subject to depression, anxiety, and anger. Phobic avoidance is common, and patients with the disorder may give histories of social anxiety disorder or incur social anxiety disorder in the course of their illness.

Dependent Personality Disorder

We know little about the course of dependent personality disorder. Occupational functioning tends to be impaired because persons with the disorder cannot act independently and without close supervision. Social relationships are limited to those on whom they can depend, and many suffer physical or mental abuse because they cannot assert themselves. They risk major depressive disorder if they lose the person on whom they depend, but with treatment, the prognosis is favorable. Complications may include low socioeconomic status and inadequate family and marital functioning, as well as mood disorders, anxiety disorders, adjustment disorder, and social anxiety disorder.

Obsessive-Compulsive Personality Disorder

The course of obsessive-compulsive personality disorder is variable and unpredictable. Occupational and social difficulties are typical. From time to time, persons may develop obsessions or compulsions in the course of their disorder. Some adolescents with obsessive-compulsive personality disorder evolve into warm, open, and loving adults; in others, the disorder can be either the harbinger of schizophrenia or—decades later and exacerbated by the aging process—major depressive disorder.

Persons with obsessive-compulsive personality disorder may flourish in positions demanding methodical, deductive, or detailed work, but they are vulnerable to unexpected changes, and their personal lives may remain barren. Depressive disorders, especially those of late-onset, are common.

Complications may include distress and difficulties when confronted with new situations that require flexibility and compromise, as well as myocardial infarction secondary to features typical of type A personalities, such as time urgency, hostility, and competitiveness.

Personality Change due to Another Medical Condition

Both the course and the prognosis of personality change due to a general medical condition depend on its cause. If the disorder results from structural damage to the brain, the disorder tends to persist. In cases of head trauma or vascular accident, the disorder may follow a period of coma and delirium, and it may be permanent. The personality change can evolve into dementia in cases of brain tumors, multiple sclerosis, and Huntington disease. Personality changes produced by chronic intoxication, medical illness, or drug therapy (such as levodopa for parkinsonism) may reverse with appropriate treatment of the cause. Some patients require custodial care or at least close supervision to meet their basic needs, avoid repeated conflicts with the law, and protect themselves and their families from the hostility of others and destitution resulting from impulsive and ill-considered actions.

TREATMENT APPROACH

Individuals with personality disorders do not recognize that they are ill and seldom seek help unless others (such as a spouse or parents) are insistent. This usually happens when maladaptive behaviors create marital, family, and career problems, or when other disorders (e.g., anxiety, depression, substance use) or somatic symptoms (e.g., obesity, heart disease, COPD) complicate their clinical picture. In general, patients with personality disorders require a multifaceted treatment plan that often combines psychotherapy and pharmacotherapy.

Combining Psychotherapy and Pharmacotherapy

Most patients with a personality disorder will require a combination of psychotherapy and pharmacotherapy. Psychotherapy is the primary treatment, as it promotes the maturation of character and, ultimately, the encouragement of the patient’s capacity to develop better adaptive solutions. However,

psychotherapy is very hard to implement in the setting of unstable affect and risky or self-destructive behaviors, all very common in the initial stages of treatment. During these early stages, pharmacotherapy achieves a relatively prompt control of affect and behavior. Most importantly, this nonspecific improvement sets a more suitable platform for the work in psychotherapy.

Pharmacotherapy. In the treatment of patients with personality disorders, medications can target specific symptoms of their disorders with the goals of relieving subjective distress, risky or self-destructive behaviors, or conflict with others, thereby preparing them for or allowing them to participate in psychotherapeutic approaches. We should identify target symptoms, in order to choose agents that effect those symptoms. Table 19-12 summarizes drug choices for various target symptoms of personality disorders.

Paranoid Personality Disorder

Psychotherapy. Psychotherapy is the treatment of choice for those with paranoid personality disorder. Therapists should be straightforward in all their dealings with these patients. If the patient accuses the therapist of an inconsistency or a fault, such as lateness for an appointment, honesty and an apology are preferable to a defensive explanation. Therapists must remember that trust and tolerance of intimacy are troubled areas for patients with this disorder. Individual psychotherapy thus requires a professional and not overly warm style from therapists. Clinicians' overzealous use of interpretation—especially interpretation about deep feelings of dependence, sexual concerns, and wishes for intimacy—increases patients' mistrust significantly. Generally, patients who are paranoid do not do well in group psychotherapy, although it can be useful for improving social skills and diminishing suspiciousness through role-playing. Many cannot tolerate the intrusiveness of behavior therapy, also used for social skills training.

At times, patients with paranoid personality disorder behave so threateningly that therapists must control or set limits on their actions. Delusional accusations should be realistically handled, but gently and without humiliating patients. Patients who are paranoid are profoundly frightened when they feel that those trying to help them are weak and helpless; therefore, therapists should never offer to take control unless they are willing

and able to do so.

Pharmacotherapy. There is little evidence to guide the use of pharmacotherapy in paranoid personality disorder. Treatment selection should be tailored to the individual patient and guided by target symptoms, such as the use of low-dose novel antipsychotics for psychotic symptoms or the use of anticonvulsants for irritability.

Schizoid Personality Disorder

Psychotherapy. The treatment of patients with schizoid personality disorder is similar to that of those with paranoid personality disorder. Patients who are schizoid tend toward introspection; however, these tendencies are consistent with psychotherapists' expectations, and such patients may become devoted if distant patients. As trust develops, patients who are schizoid may, with great trepidation, reveal a plethora of fantasies, imaginary friends, and fears of unbearable dependence—even of merging with the therapist.

In group therapy settings, patients with schizoid personality disorder may be silent for long periods; nonetheless, they do become involved. The patients should be protected against aggressive attack by group members for their proclivity to be silent. With time, the group members become important to patients who are schizoid and may provide the only social contact in their otherwise isolated existence.

Pharmacotherapy. Limited evidence exists to guide the psychopharmacologic treatment of patients with schizoid personality disorder. The use of psychotropics to target specific symptoms, such as social and emotional detachment, may be appropriate.

Schizotypal Personality Disorder

Psychotherapy. The principles of treatment of schizotypal personality disorder do not differ from those of schizoid personality disorder, but clinicians must deal sensitively with the former, mainly using care to avoid ridiculing or judging patients' odd beliefs. Schizotypal patients have peculiar

patterns of thinking, and some are involved in cults, strange religious practices, or the occult.

Pharmacotherapy. Antipsychotic medication may be useful for dealing with ideas of reference, illusions, and other symptoms of the disorder and can be an adjunct to psychotherapy. Antidepressants are useful when a depressive component of the personality is present.

Antisocial Personality Disorder

Psychotherapy. There is limited evidence to guide the use of psychotherapeutic approaches in antisocial personality disorder. Overall, the limited evidence suggests that these individuals seem to respond better to contingency management and other reward-based interventions than they do to cognitive behavioral therapy.

Pharmacotherapy. Pharmacotherapy can deal with incapacitating symptoms such as anxiety, rage, and depression, but because patients often misuse substances, we should use medications judiciously. One might use anticonvulsants to treat aggressive behaviors, especially if there are abnormal waveforms on an EEG. β-Adrenergic receptor antagonists, lithium, and antipsychotics may also reduce aggression.

Borderline Personality Disorder

Psychotherapy. Psychotherapy for patients with borderline personality disorder is an area of intensive investigation and has been the treatment of choice. It seems to be most successful in combination with pharmacotherapy.

Psychotherapy is difficult for the patient and therapist alike. Patients regress quickly, act out their impulses, and show labile or fixed negative or positive transferences, which are difficult to analyze. Projective identification may also cause countertransference problems when therapists are unaware that patients are unconsciously trying to coerce them to act out a particular behavior. The splitting defense mechanism causes patients to love and hate therapists and others in the environment alternately. A reality-oriented approach is more effective than in-depth interpretations of the unconscious.

Table 19-12
Pharmacotherapy of Target Symptom Domains of Personality Disorders

Choice of Drugs According to Target Symptoms of Personality Disorders		
Target Symptom	**Drug/Treatment of Choice**	**Not Recommended**
I. Mood Dysregulation and Anxiety		
Anxiety		
Chronic cognitive	Psychotherapy, SSRIs, SNRIs, MAOIs, Low-Dose Novel Psychotropics (aripiprazole, quetiapine) Valproate and other GABA analogs (clonazepam and buspirone)	Benzodiazepines
Chronic somatic	MAOIs, SNRIs (duloxetine, milnacipran) Pregabalin and other GABA analogs, TCAs, beta-blockers	If used—benzodiazepir with long half- and short trial preferred
Obsessions	SSRIs, Antipsychotics (quetiapine), TCAs (clomipramine), Mild NMDA antagonists	

	(riluzole, memantine)	
Acute and severe	Mirtazapine, Novel Psychotropics (quetiapine, aripiprazole, clozapine), TCAs, clonazepam, valproates, lithium	
Depression		
Atypical depression/dysphoria Classical depression	MAOIs, SSRIs, SNRIs, Aripiprazole, Lurasidone, ziprasidone, quetiapine, Atypical antipsychotics (as monotherapy or augmentation)	TCAs
Emotional lability/rapid cycling	Lithium, Lamotrigine, Valproate, Lower-dose antipsychotics (olanzapine, aripiprazole, clozapine, ziprasidone)	TCAs (“catecholamin stress”), Standard antidepressan (risk of switchi to mania)
II. Behavior Dyscontrol		
Aggression/impulsivity		
Affective aggression “Hot temper” with normal	Lithium, SSRIs, Anticonvulsants,	Benzodiazepines (disinhibition)

EEG	Low-dose antipsychotics	
Predatory aggression (cold blooded revenge/cruelty)	No Effective Pharmacologic Tx	Benzodiazepines (disinhibition)
Organic-like aggression (traumatic brain injury)	Beta-Blockers, Valproates, Quetiapine, Carbamazepine (CBMZ), TCAs, cholinesterase inhibitors (donepezil)	Benzodiazepines (disinhibition, delirium)
Ictal aggression (abnormal EEG)	CBMZ, Diphenylhydantoin, Valproate Benzodiazepines (clonazepam)	TCAs, Low-poten typical antipsychotics (both increase risk of seizure
III. Social and Emotional Detachment		
Chronic asociality and disinterest		
Blunted affect	Low-Dose Antipsychotics (aripiprazole, olanzapine, low-dose clozapine, sulpiride)	
IV. Cognitive-Perceptual Distortions/Psychotic Symptoms		
Acute and brief psychotic episodes	Novel Antipsychotics (Risperdal, olanzapine) Typical neuroleptics (for the duration of	

	psychosis)
Chronic and low-level psychotic-like symptoms	Novel Antipsychotics

Adapted with permission of the Center for Well-Being at Washington University.

Therapists have used behavior therapy to help patients manage their impulses and angry outbursts and to reduce their sensitivity to criticism and rejection. Social skills training, especially with videotape playback, helps patients to see how their actions affect others and thereby improve their interpersonal behavior.

Patients with borderline personality disorder often do well in a hospital setting in which they receive intensive psychotherapy on both an individual and a group basis. In a hospital, they can also interact with trained staff members from a variety of disciplines and receive occupational, recreational, and vocational therapy. Such programs are especially helpful when the home environment is detrimental to a patient's rehabilitation because of intrafamilial conflicts or other stresses, such as abuse. Within the protected environment of the hospital, we can give limits to patients who are excessively impulsive, self-destructive, or self-mutilating, and observe their actions. Under ideal circumstances, patients remain in the hospital until they show marked improvement, up to 1 year in some cases. We can then discharge patients to specialized support systems, such as day hospitals, night hospitals, and halfway houses.

DIALECTICAL BEHAVIOR THERAPY. Dialectical behavior therapy (DBT) is the psychosocial treatment that has received the most empirical support for patients with borderline personality disorder. The method is eclectic, drawing on concepts derived from supportive, cognitive, and behavioral therapies. There are four primary modes of treatment in DBT: group skill training, individual therapy, phone consultation, and consultation team. Patients are seen weekly, with the goal of improving interpersonal skills and decreasing self-destructive behavior. Patients with borderline personality disorder receive help in dealing with the ambivalent feelings that are characteristic of the disorder. As with other behavioral approaches, DBT assumes all behavior

(including thoughts and feelings) is learned and that patients with borderline personality disorder behave in ways that reinforce or even reward their behavior, regardless of how maladaptive it is. See Chapter 23 for a more detailed discussion of DBT.

MENTALIZATION-BASED TREATMENT. Another type of psychotherapy for borderline personality disorder is called mentalization-based therapy (MBT). Mentalization is a social construct that allows a person to be attentive to the mental states of oneself and of others; it comes from a person's awareness of mental processes and subjective states that arise in interpersonal interactions. MBT is based on a theory that borderline personality symptoms, such as difficulty regulating emotions and managing impulsivity, are a result of patients' reduced capacities to mentalize. Thus, recovery of mentalization should help patients build relationship skills as they learn to regulate their thoughts and feelings better. MBT was effective for borderline personality disorder in several randomized, controlled research trials.

TRANSFERENCE-FOCUSED PSYCHOTHERAPY. Transference-focused psychotherapy (TFP) is a modified form of psychodynamic psychotherapy used for the treatment of borderline personality disorder grounded in object relations theory. The therapist relies on two major processes in working with the patient: the first is clarification, in which the transference is analyzed more directly than in traditional psychotherapy so that the patient becomes quickly aware of his or her distortions about the therapist, and the second is confrontation, whereby the therapist points out how these transferential distortions interfere with interpersonal relations toward others (objects). The mechanism of splitting used by borderline patients is characterized by their having a good object and a bad object, and they use this as a defense against anxiety. If therapy is successful, then the need for splitting diminishes, object relations are improved, and the patient achieves a more normal level of functioning. Studies comparing TFP, DBT, psychodynamic psychotherapy, and supportive psychotherapy show that all are useful and all show varying degrees of success.

Pharmacotherapy. Pharmacotherapy is useful to deal with specific personality features that interfere with patients' overall functioning.

Antipsychotics may help control anger, hostility, and brief psychotic episodes. Antidepressants improve the depressed mood common in patients with borderline personality disorder. Benzodiazepines should be avoided not only due to the risk of abuse, but also because patients may become disinhibited with this class of drugs. Anticonvulsants, such as carbamazepine, may improve functioning for some patients. Serotonergic agents, such as selective serotonin reuptake inhibitors (SSRIs), have been helpful in some cases.

Histrionic Personality Disorder

Psychotherapy. Patients with histrionic personality disorder are often unaware of their real feelings; clarification of their inner feelings is a necessary therapeutic process. Psychoanalytically oriented psychotherapy is probably the treatment of choice for histrionic personality disorder.

Pharmacotherapy. Pharmacotherapy can be adjunctive to target symptoms (e.g., the use of antidepressants for depression and somatic complaints, antianxiety agents for anxiety, and antipsychotics for derealization and illusions).

Narcissistic Personality Disorder

Psychotherapy. Because patients must renounce their narcissism to make progress, the treatment of narcissistic personality disorder is challenging. Some experts have advocated using psychoanalytic approaches to effect change, but much research is required to validate the diagnosis and to determine the best treatment. Some clinicians advocate group therapy for their patients so they can learn how to share with others and, under ideal circumstances, can develop an empathic response to others.

Pharmacotherapy. Lithium can help patients whose clinical picture includes mood swings. Because patients with narcissistic personality disorder tolerate rejection poorly and are susceptible to depression, antidepressants, especially serotonergic drugs, may also be of use.

Avoidant Personality Disorder

Psychotherapy. Psychotherapeutic treatment depends on solidifying an alliance with patients. As trust develops, a therapist must convey an accepting attitude toward the patient's fears, especially the fear of rejection. The therapist eventually encourages a patient to move out into the world to take what they perceive as significant risks of humiliation, rejection, and failure. However, therapists should be cautious when giving assignments to exercise new social skills outside therapy; failure can reinforce the patient's already weak self-esteem. Group therapy may help patients understand how their sensitivity to rejection affects them and others. Assertiveness training is a form of behavior therapy that may teach patients to express their needs openly and to enlarge their self-esteem.

Pharmacotherapy. Pharmacotherapy can help manage anxiety and depression when they are associated with the disorder. Some patients are helped by β-adrenergic receptor antagonists, such as atenolol, to manage autonomic nervous system hyperactivity, which tends to be high in patients with avoidant personality disorder, especially when they approach feared situations. Serotonergic agents may help with rejection sensitivity. Theoretically, dopaminergic drugs might engender novelty-seeking behavior in these patients; however, the patient must be psychologically prepared for any new experience that might result.

Dependent Personality Disorder

Psychotherapy. The treatment of dependent personality disorder is often successful. Insight-oriented therapies enable patients to understand the antecedents of their behavior, and with the support of a therapist, patients can become more independent, assertive, and self-reliant. Behavioral therapy, assertiveness training, family therapy, and group therapy have all been used, with successful outcomes in many cases.

A pitfall may arise in treatment when a therapist encourages a patient to change the dynamics of a pathologic relationship (e.g., supports a physically abused wife in seeking help from the police). At this point, patients may become anxious and unable to cooperate in therapy; they may feel torn

between complying with the therapist and losing an external pathologic relationship. Therapists must show great respect for these patients' feelings of attachment, no matter how pathologic these feelings may seem.

Pharmacotherapy. Pharmacotherapy can help deal with specific symptoms, such as anxiety and depression, which are commonly associated features of dependent personality disorder. Patients who experience panic attacks or who have high levels of separation anxiety may benefit from symptom-targeted pharmacotherapy, such as antidepressant agents.

Obsessive-Compulsive Personality Disorder

Psychotherapy. Unlike patients with other personality disorders, some individuals with obsessive-compulsive personality disorder are often aware of their suffering and seek treatment on their own. Though limited evidence exists to guide treatment, there have been several studies that support cognitive therapy or cognitive behavioral therapy as an effective treatment for individuals with this disorder, delivered either individually or in a group. Additionally, interpersonal psychotherapy may improve depressive symptoms in individuals with obsessive-compulsive personality disorder.

Pharmacotherapy. There is limited evidence for the pharmacologic treatment of obsessive-compulsive personality disorder. Some studies have suggested benefits from fluvoxamine and carbamazepine, and in those patients with comorbid depression, citalopram may be helpful. In one study comparing citalopram and sertraline, both medications reduced the number of obsessive-compulsive personality disorder traits, though citalopram performed better than sertraline.

Personality Change due to Another Medical Condition

Management of personality change disorder involves the treatment of the underlying medical condition when possible. Psychopharmacological treatment of specific symptoms may help in some cases, such as antidepressants for depression or anticonvulsants for irritability, aggression, or impulsivity.

Patients with severe cognitive impairment or weakened behavioral controls

may need counseling to help avoid difficulties at work or to prevent social embarrassment. As a rule, patients' families need emotional support and concrete advice on how to help minimize patients' undesirable conduct. Patients should avoid alcohol, and we should curtail social engagements when patients tend to act in a grossly offensive manner.

EPIDEMIOLOGY

Personality disorders are common. They occur in 10 to 20 percent of the general population, and approximately 50 percent of all psychiatric patients.

Paranoid Personality Disorder

Data suggest that the prevalence of paranoid personality disorder is 0.5 to 4.4 percent of the general population. Those with the disorder rarely seek treatment themselves; when referred to treatment by a spouse or an employer, they can often pull themselves together and appear undistressed. Relatives of patients with schizophrenia show a higher incidence of paranoid personality disorder than control participants. Some evidence suggests a more specific familial relationship with delusional disorder, persecutory type. The diagnosis is more common in men.

Schizoid Personality Disorder

The prevalence of schizoid personality disorder is estimated to be 3.1 to 4.9 percent of the general population, according to DSM-5. This diagnosis is more common in men. Persons with the disorder tend to gravitate toward solitary jobs that involve little or no contact with others. Many prefer night work to day work so that they need not deal with many persons. There appears to be an increased prevalence among the relatives of individuals with schizophrenia or schizotypal personality disorder.

Schizotypal Personality Disorder

Schizotypal personality disorder occurs in 3.9 to 4.6 percent of the population, according to DSM-5. The sex ratio is unknown; however, it is frequent in females with fragile X syndrome. A higher association of cases exists among the biologic relatives of patients with schizophrenia than among

control participants and a higher incidence among monozygotic twins than among dizygotic twins (33 percent vs. 4 percent in one study).

Antisocial Personality Disorder

According to DSM-5, prevalence rates for antisocial personality disorder are 3 percent for males and 1 percent for females in the general population. It is frequent among the first-degree biologic relatives of individuals with this disorder. Biologic relatives of females with antisocial personality disorder are at increased risk for the same disorder compared to biologic relatives of males with antisocial personality disorder. Genetic studies have suggested familial transmission of antisocial personality disorder, substance use, and somatic symptom disorder (most studies used the previous criteria for the related somatization disorder), the former two being characteristic of males, and the latter of females in the same family. Adoption studies have shown that both genetic and environmental factors contribute to the risk of this disorder. Both adopted and biologic children of parents with antisocial personality disorder are at increased risk for this disorder. Conduct disorder (before the age of 10 years) and accompanying attention-deficit hyperactivity disorder increases the likelihood of developing antisocial personality in adult life. Conduct disorder is more likely to develop into antisocial personality disorder with erratic parenting, neglect, or inconsistent parental discipline.

Borderline Personality Disorder

Borderline personality disorder is thought to be present in about 2 percent of the general population and is more common in women than in men. The disorder is more common in younger than in older samples, suggesting a natural tendency toward maturation and remission. Physical and sexual abuse, neglect, hostile conduct, and early parental loss or separation are common in the childhood histories of patients with this disorder. Borderline personality disorder is five times more common among relatives of individuals with the same disorder than the general population. An increased prevalence of mood disorders, antisocial personality disorder, and substance use disorder is common in first-degree relatives of persons with borderline personality disorder.

Histrionic Personality Disorder

Limited data from general population studies suggest a prevalence of histrionic personality disorder of about 2 percent. Although traditionally thought to occur more frequently in women, there is some evidence to suggest that this disorder might be equally frequent among men and women. Histrionic personality disorder tends to run in families. Some experts suggest that there is a genetic link between histrionic and antisocial personality disorder and alcohol use disorder.

Narcissistic Personality Disorder

According to DSM-5, estimates of the prevalence of narcissistic personality disorder range from less than 1 percent in the general population to 2 to 16 percent in the clinical population; this disorder is more common in men.

Avoidant Personality Disorder

The prevalence of the disorder is about 0.5 to 2 percent of the general population, according to DSM-5. It occurs in men and women equally.

Dependent Personality Disorder

Dependent personality disorder is equally common in women and men. DSM-5 reports an estimated prevalence of 0.5 to 0.6 percent. Persons with chronic physical illness in childhood or separation anxiety disorder may be most susceptible to dependent personality disorder.

Obsessive-Compulsive Personality Disorder

DSM-5 reports an estimated prevalence ranging from 2 to 8 percent of the general population. It is more common in men than in women. Some studies have demonstrated a familial aggregation of this disorder.

ETIOLOGY

Genetic Factors

The best evidence that genetic factors contribute to personality disorders comes from investigations of more than 15,000 pairs of twins in the United

States. The concordance for personality disorders among monozygotic twins was several times that among dizygotic twins. Moreover, according to one study, monozygotic twins reared apart are about as similar as monozygotic twins reared together. Similarities include multiple measures of personality and temperament, occupational and leisure-time interests, and social attitudes.

Cluster A personality disorders are more common in the biologic relatives of patients with schizophrenia than in control groups. Adoption, family, and twin studies demonstrate an increased prevalence of schizotypal features in the families of schizophrenic patients, mainly when schizotypal features were not associated with comorbid affective symptoms. Less correlation exists between paranoid or schizoid personality disorder and schizophrenia.

Cluster B personality disorders have a genetic basis. Antisocial personality disorder is associated with alcohol use disorders. Depression is common in the family backgrounds of patients with borderline personality disorder. These patients have more relatives with mood disorders than do control groups, and persons with borderline personality disorder often have a mood disorder as well. There is a strong association between histrionic personality disorder and somatic symptom disorder; patients with each disorder show an overlap of symptoms.

Cluster C personality disorders may also have a genetic base. Patients with avoidant personality disorder often have high anxiety levels. Obsessive-compulsive traits are more common in monozygotic twins than in dizygotic twins, and patients with obsessive-compulsive personality disorder show some signs associated with depression—for example, shortened rapid eye movement (REM) latency period and abnormal dexamethasone-suppression test (DST) results.

Biologic Factors

Hormones. Persons who exhibit impulsive traits also often show high levels of testosterone, 17-estradiol, and estrone. In nonhuman primates, androgens increase the likelihood of aggression and sexual behavior, but the role of testosterone in human aggression is unclear. DST results are abnormal in some patients with borderline personality disorder who also have depressive symptoms.

Platelet Monoamine Oxidase. Low platelet monoamine oxidase (MAO) levels are associated with activity and sociability in monkeys. College students with low platelet MAO levels report spending more time in social activities than students with high platelet MAO levels. Low platelet MAO levels occur in some patients with schizotypal disorders.

Smooth Pursuit Eye Movements. Smooth pursuit eye movements are saccadic (i.e., jumpy) in persons who are introverted, who have low self-esteem and tend to withdraw, and who have schizotypal personality disorder. These findings have no clinical application, but they do indicate the role of inheritance.

Neurotransmitters. Studies of personality traits and the dopaminergic and serotonergic systems indicate an arousal-activating function for these neurotransmitters. Levels of 5-hydroxyindoleacetic acid (5-HIAA), a metabolite of serotonin, are low in persons who attempt suicide and in patients who are impulsive and aggressive. Raising serotonin levels with serotonergic agents such as fluoxetine can produce dramatic changes in some character traits of personality. In many persons, serotonin reduces depression, impulsiveness, and rumination and can produce a sense of general well-being. Increased dopamine concentrations in the central nervous system produced by certain psychostimulants (e.g., amphetamines) can induce euphoria. The effects of neurotransmitters on personality traits have generated much interest and controversy about whether personality traits are inborn or acquired.

Table 19-13
Medical Conditions Associated with Personality Change

Head trauma
Cerebrovascular diseases
Cerebral tumors
Epilepsy (particularly, complex partial epilepsy)
Huntington disease
Multiple sclerosis
Endocrine disorders

Heavy metal poisoning (manganese, mercury)
Neurosyphilis
Acquired immune deficiency syndrome (AIDS)

Electrophysiology. Changes in electrical conductance on the electroencephalogram (EEG) occur in some patients with personality disorders, most commonly antisocial and borderline types; these changes appear as slow-wave activity on EEGs.

Other Biologic Factors. In the case of personality change due to another medical condition, structural damage to the brain is usually the cause, and head trauma is probably the most common cause. Cerebral neoplasms and vascular accidents, particularly of the temporal and frontal lobes, are also common causes. The conditions most often associated with personality change are listed in Table 19-13.

Psychoanalytic Factors

Sigmund Freud suggested that personality traits are related to a fixation at one psychosexual stage of development. For example, those with an oral character are passive and dependent because they are fixated at the oral stage when the dependence on others for food is prominent. Those with an anal character are stubborn, parsimonious, and highly conscientious because of struggles over toilet training during the anal period.

Wilhelm Reich subsequently coined the term *character armor* to describe individuals' characteristic defensive styles for protecting themselves from internal impulses and interpersonal anxiety in significant relationships. Reich's theory has had a broad influence on contemporary concepts of personality and personality disorders. For example, each human being's unique stamp of personality depends on their characteristic defense mechanisms. Each personality disorder has a cluster of defenses that help psychodynamic clinicians recognize the type of character pathology present. Persons with paranoid personality disorder, for instance, use projection, whereas schizoid personality disorder is associated with withdrawal.

When defenses work effectively, persons with personality disorders master feelings of anxiety, depression, anger, shame, guilt, and other affects. Their

behavior is ego-syntonic; that is, it creates no distress for them even though it may adversely affect others. They may also be reluctant to engage in a treatment process; because their defenses are essential to controlling unpleasant affects, they are not interested in surrendering them.

In addition to characteristic defenses in personality disorders, another central feature is internal object relations. During development, a person develops particular patterns of the self in relation to others. Through introjection, children internalize a parent or another significant person as an internal presence that continues to feel like an object rather than a self. Through identification, children internalize parents and others in such a way that they incorporate the traits of the external object into the self, and the child "owns" the traits. These internal self-representations and object representations are crucial in developing the personality and, through externalization and projective identification, are played out in interpersonal scenarios in which they coerce others into playing a role in the person's internal life. Hence, persons with personality disorders are also identified by particular patterns of interpersonal relatedness that stem from these internal object relations patterns.

Defense Mechanisms. To help those with personality disorders, psychiatrists must appreciate patients' underlying defenses, the unconscious mental processes that the ego uses to resolve conflicts among the four lodestars of the inner life: instinct (wish or need), reality, important persons, and conscience. When defenses are most effective, especially in those with personality disorders, they can abolish anxiety and depression at the conscious level. Thus, abandoning a defense increases conscious awareness of anxiety and depression—a primary reason that those with personality disorders are reluctant to alter their behavior.

Although we tend to characterize patients with personality disorders by their most dominant or rigid mechanism, each patient uses several defenses. Therefore, the management of defense mechanisms used by patients with personality disorders is discussed here as a general topic and not as an aspect of the specific disorders. While many formulations are presented here in the language of psychoanalytic psychiatry, it is possible to translate them into principles consistent with cognitive and behavioral approaches.

FANTASY. Many people who are labeled schizoid—those who are eccentric, lonely, or frightened—seek solace and satisfaction within themselves by creating imaginary lives, especially imaginary friends. In their extensive dependence on fantasy, these persons often seem to be strikingly aloof. Therapists must understand that the unsociableness of these patients rests on a fear of intimacy. Rather than criticizing them or feeling rebuffed by their rejection, therapists should maintain a quiet, reassuring, and considerate interest without insisting on reciprocal responses. Recognition of patients' fear of closeness and respect for their eccentric ways are both therapeutic and useful.

DISSOCIATION. Dissociation is an unconscious defense mechanism that involves separating a mental or behavioral process (e.g., thought, feeling) from the rest of the person's psychic activity. Patients with borderline personality disorder may demonstrate dissociation during times of increased stress, including derealization or depersonalization.

ISOLATION. Isolation involves the separation of an idea or memory from its attached emotion. It is characteristic of controlled, orderly persons who are often labeled obsessive-compulsive personalities. These individuals remember the truth in fine detail but without affect. In a crisis, patients may show intensified self-restraint, overly formal social behavior, and obstinacy. Patients' quests for control may annoy clinicians or make them anxious. Often, such patients respond well to precise, systematic, and rational explanations and value efficiency, cleanliness, and punctuality as much as they do clinicians' effective responsiveness. Whenever possible, therapists should allow such patients to control their own care and should not engage in a battle of wills.

PROJECTION. In projection, patients attribute their unacknowledged feelings to others. Patients' excessive faultfinding and sensitivity to criticism may appear to therapists as prejudiced, hypervigilant, and injustice-collecting, but the therapist should not respond with defensiveness and argument. Instead, clinicians should frankly acknowledge even minor mistakes on their part and should discuss the possibility of future difficulties. Strict honesty, concern for patients' rights, and maintaining the same formal, concerning distance as

used with patients who use fantasy defenses are all helpful. Confrontation guarantees a lasting enemy and early termination of the interview. Therapists need not agree with patients' injustice-collecting, but they should ask whether both can agree to disagree.

The technique of counterprojection is especially helpful. Clinicians acknowledge and give paranoid patients full credit for their feelings and perceptions; they neither dispute patients' complaints nor reinforce them but agree that the world described by patients is conceivable. Interviewers can then talk about real motives and feelings, misattributed to someone else, and begin to cement an alliance with patients.

SPLITTING. In splitting, the patient divides persons toward whom they are, or have been, ambivalent into good and bad. For example, in an inpatient setting, a patient may idealize some staff members and uniformly disparage others. This defense behavior can be highly disruptive in a hospital ward and can ultimately provoke the staff to turn against the patient. When staff members anticipate the process, discuss it at staff meetings, and gently confront the patient with the fact that no one is all good or all bad, the phenomenon of splitting can be dealt with effectively.

ACTING OUT. In acting out, patients directly express unconscious wishes or conflicts through action to avoid being conscious of either the accompanying idea or the affect. Tantrums, apparently motiveless assaults and pleasureless promiscuity are typical examples. Because the behavior occurs outside reflective awareness, acting out appears to observers to be unaccompanied by guilt, but when acting out is impossible, the conflict behind the defense may be accessible. The clinician faced with acting out, either aggressive or sexual, in an interview situation, must recognize that the patient has lost control, that the patient will mishear anything the interviewer says, and that getting the patient's attention is of paramount importance. Depending on the circumstances, a clinician's response may be, "How can I help you if you keep screaming?" Alternatively, if the patient's loss of control seems to be escalating, say, "If you continue screaming, I will leave." An interviewer who feels genuinely frightened of the patient can simply leave and, if necessary, ask for help from ward attendants or the police.

PROJECTIVE IDENTIFICATION. The defense mechanism of projective identification appears mainly in borderline personality disorder and consists of three steps. First, the patient projects an aspect of the self onto someone else. The projector then tries to coerce the other person into identifying what they projected. Finally, the recipient of the projection and the projector feel a sense of oneness or union.

Temperament

Temperament refers to the body's biases in the modulation of conditioned behavioral responses to prescriptive physical stimuli. Behavioral conditioning (i.e., procedural learning) involves presemantic sensations that elicit basic emotions, such as fear or anger, independent of conscious recognition, descriptive observation, reflection, or reasoning. Pioneering work by A. Thomas and S. Chess conceptualized temperament as the stylistic component ("how") of behavior, as differentiated from the motivation ("why") and the content ("what") of behavior. Modern concepts of temperament emphasize its emotional, motivational, and adaptive aspects. Specifically, four major temperament traits have been identified and subjected to extensive neurobiologic, psychosocial, and clinical investigation: harm avoidance, novelty seeking, reward dependence, and persistence. These four temperaments are now understood to be genetically independent dimensions that occur in all possible combinations within the same individual rather than as mutually exclusive categories.

Psychobiology of Temperament. Temperament traits of harm avoidance, novelty seeking, reward dependence, and persistence are heritable differences underlying one's automatic response to danger, novelty, social approval, and intermittent reward, respectively. These four temperaments are closely associated with the four basic emotions of fear (harm avoidance), anger (novelty seeking), attachment (reward dependence), and ambition (persistence).

Individual differences in temperament and basic emotions modify the processing of sensory information and shape early learning characteristics, especially associative conditioning of unconscious behavior responses and preattentive components of perception. Temperament occurs in terms of

heritable biases in emotionality and learning that underlie the acquisition of emotion-based, automatic behavioral traits and habits observable early in life and relatively stable over one's lifespan.

Each of the four major dimensions is a normally distributed quantitative trait, moderately heritable, observable early in childhood, relatively stable in time, and moderately predictive of adolescent and adult behavior. The four dimensions are genetically homogeneous and independently inherited from one another, as per several extensive international twin studies. Temperamental differences, which are not very stable initially, tend to stabilize during the second and third years of life. Accordingly, ratings of these four temperament traits at ages 10 to 11 years were moderately predictive of personality traits at ages 15, 18, and 27 years in a large sample of Swedish children.

The four dimensions are universal across different cultures, ethnic groups, and political systems on every inhabited continent. We call these aspects of personality temperaments because they are heritable, manifest early in life, are developmentally stable, and are consistent in different cultures. Temperament traits are similar to crystallized intelligence in that they do not show the rapid changes with increasing age or across birth cohorts found for fluid intelligence and character traits. Table 19-14 summarizes contrasting sets of behaviors that distinguish extreme scorers on the four dimensions of temperament. Note that each extreme of these dimensions has specific adaptive advantages and disadvantages so that neither high nor low scores inherently mean better adaptation.

Each of the four temperament dimensions has unique genetic determinants according to family and twin studies, as well as studies of genetic associations with specific DNA markers.

HARM AVOIDANCE. Harm avoidance involves a heritable bias in the inhibition of behavior in response to signals of punishment and frustrative non-reward. High harm avoidance is a fear of uncertainty, social inhibition, shyness, passive avoidance of problems/danger, rapid fatigability, and pessimistic worry in anticipation of problems even in situations that do not worry others. Those low in harm avoidance are carefree, courageous, energetic, outgoing, and optimistic, even in situations that worry most people.

The psychobiology of harm avoidance is complex. Benzodiazepines

disinhibit avoidance by γ-aminobutyric acid (GABA)-ergic inhibition of serotonergic neurons originating in the dorsal raphe nuclei. The anterior serotonergic cells in the dorsal raphe nucleus intermingle with the dopaminergic cells of the ventral tegmental area, and both groups innervate the same structures (e.g., basal ganglia, accumbens, amygdala), providing opposing dopaminergic-serotonergic influences in the modulation of approach and avoidance behavior. Persons given serotonin drugs show decreased harm avoidance behavior.

Table 19-14
Descriptors of Individuals Who Score High or Low on the Four Temperament Dimensions

	Descriptors of Extreme Variants	
Temperament Dimension	**High**	**Low**
Harm avoidance	Pessimistic	Optimistic
	Fearful	Daring
	Shy	Outgoing
	Fatigable	Energetic
Novelty seeking	Exploratory	Reserved
	Impulsive	Deliberate
	Extravagant	Thrifty
	Disorderly	Orderly
Reward dependence	Sentimental	Detached
	Open	Aloof
	Warm	Cold
	Affectionate	Independent
Persistence	Industrious	Lazy

	Determined	Spoiled
	Ambitious	Underachiever
	Perfectionist	Pragmatist

NOVELTY SEEKING. Novelty seeking reflects a heritable bias in the initiation or activation of appetitive approach in response to novelty, approach to signals of reward, active avoidance of conditioned signals of punishment, and escape from unconditioned punishment. Novelty seeking is an exploratory activity in response to novelty, impulsiveness, extravagance in approach to cues of reward, and active avoidance of frustration. Individuals high in novelty seeking are quick-tempered, curious, easily bored, impulsive, extravagant, and disorderly. Those low in novelty seeking are slow tempered, uninquiring, stoical, reflective, frugal, reserved, tolerant of monotony, and orderly.

Dopaminergic projections have a crucial role in novelty seeking. Novelty seeking seems to involve increased reuptake of dopamine at presynaptic terminals, thereby requiring frequent stimulation to maintain optimal levels of postsynaptic dopaminergic stimulation. Studies of candidate genes involved in dopamine neurotransmission, have provided evidence of association with novelty seeking and no other dimension of temperament.

REWARD DEPENDENCE. Reward dependence reflects the maintenance of behavior in response to cues of social reward. Individuals high in reward dependence are tender-hearted, sensitive, dedicated, dependent, and warmly sociable. Those low in reward dependence are practical, tough-minded, cold, socially insensitive, irresolute, and indifferent if alone.

Noradrenergic projections from the locus coeruleus and serotonergic projections from the median raphe likely influence such reward conditioning. The “love hormone” oxytocin’s plasma level is positively correlated ($r = 0.5$) with individual differences in reward dependence but not other dimensions of personality.

PERSISTENCE. Persistence reflects the maintenance of behavior despite frustration, fatigue, and intermittent reinforcement. It manifests as industriousness, determination, ambitiousness, and perfectionism. Highly persistent individuals are hard-working, perseverant, and ambitious

overachievers who tend to intensify their effort in response to anticipated rewards and view frustration and fatigue as personal challenges. Those low in persistence are indolent, inactive, unstable, and erratic; they tend to give up easily when faced with frustration, rarely strive for higher accomplishments, and manifest little perseverance even in response to intermittent reward.

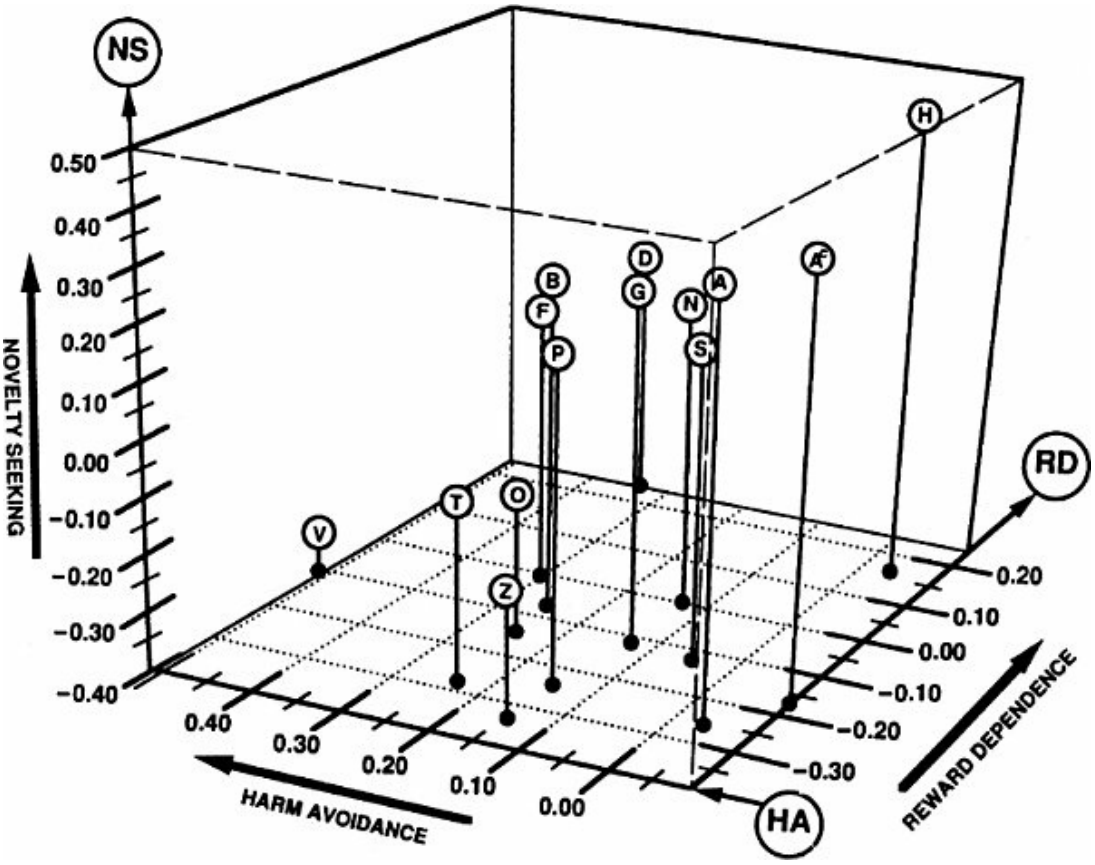

FIGURE 19-1
Correlations between individual personality disorder subtypes and temperament traits of harm avoidance (HA), novelty seeking (NS), and reward dependence (RD). A, antisocial; Ac, antisocial children; B, borderline; D, dependent; F, self-defeating; G, passive aggressive; H, histrionic; N, narcissistic; O, obsessive; P, paranoid; S, sadistic; GT, schizotypal; V, avoidant; Z, schizoid.

Individual differences in persistence have been strongly correlated ($r = 0.8$) with responses measured by fMRI in a circuit involving the ventral striatum, orbitofrontal cortex/rostral insula, and dorsal anterior cingulate cortex.

Figure 19-1 illustrates the interrelationships between the personality disorders and the temperament traits of harm avoidance, novelty seeking, and reward dependence.

Other Conditions that May be a Focus of Clinical Attention

INTRODUCTION

DSM-5 includes a section called Other Conditions that May be a Focus of Clinical Attention. ICD-10 has a similar section called Factors Influencing Health Status and Contact with Health Services. These sections are for conditions that are not mental disorders but that have led to contact with the mental health care system. In some instances, one of these conditions will be noted during a psychiatric evaluation (e.g., divorce), although there is no mental disorder. In other instances, the diagnostic evaluation reveals no mental disorder, but there is a need to note the primary reason for contact with the mental health care system (e.g., homelessness).

In some cases, we may eventually find a mental disorder, but the focus of attention or treatment is on a condition that is not caused by a mental disorder. For example, a patient with an anxiety disorder may receive treatment for a marital problem that is unrelated to the anxiety disorder itself.

Table 20-1 includes the many conditions DSM-5 lists that may be a focus of clinical attention, or that may influence the diagnosis, treatment, or course of a mental disorder contained in DSM-5. The list of conditions that make up this category covers the entire life cycle from infancy through childhood, adolescence, adulthood, and old age. The list of conditions covers almost every conceivable life circumstance, from divorce to problems related to being in military service. Each of these conditions or circumstances is capable of having a profound input on a particular mental illness or the human experience in general.

MALINGERING

Malingering is the deliberate falsification of physical or psychological symptoms in an attempt to achieve a secondary gain such as avoiding military duty, avoiding work, obtaining financial compensation, evading criminal prosecution, or obtaining drugs. Under some circumstances, malingering may represent adaptive behavior—for example, as mentioned below, feigning illness while a captive of the enemy during wartime.

The clinician should consider possible malingering when encountering any combination of the following: (1) medicolegal context of presentation (e.g., the person is referred by an attorney to the clinician for examination), (2) evident discrepancy between the individual's claimed stress or disability and the objective findings, (3) lack of cooperation during the diagnostic evaluation and in complying with the prescribed treatment regimen, and (4) the presence of antisocial personality disorder.

Diagnosis and Clinical Features

Avoidance of Criminal Responsibility, Trial, and Punishment. Criminals may pretend to be incompetent to avoid standing trial; they may feign insanity at the time of the perpetration of the crime, malinger symptoms to receive a less harsh penalty, or attempt to act too incapacitated (incompetent) for punishment.

Avoidance of Military Service or Particularly Hazardous Duties. Persons may malinger to avoid conscription into the armed forces, and, after being conscripted, they may feign illness to escape from particularly onerous or hazardous duties.

Financial Gain. Malingerers may seek financial gain in the form of undeserved disability insurance, veterans' benefits, workers' compensation, or tort damages for purported psychological injury.

Avoidance of Work, Social Responsibility, and Social Consequences. Individuals may malinger to escape from unpleasant vocational or social circumstances or to avoid the social and litigation-related

consequences of vocational or social improprieties.

An owner of a previously successful photographic equipment supplier declared bankruptcy in a way that the government maintained was illegal. Subsequently, the government indicted the defendant on various counts of fraud. The defendant's counsel maintained that the defendant was too depressed to cooperate with him and that, because of that depression, he experienced memory loss that made it impossible to understand what had occurred and, therefore, impossible to provide a meaningful defense. The government's forensic psychiatrist evaluated the defendant to ascertain the nature of his depression and to determine whether it was causing cognitive problems.

When asked early in his evaluation when his birthday was, he responded, "Oh, what does it matter? It was in the 40s or 50s." Similarly, when queried about where he was born, he said, "Somewhere in Hungary." Even when pressed for more specifics, he refused to elaborate. Nevertheless, at many points later in his evaluation, he responded with complete, often detailed information about transactions not related to those for which he was under indictment. It was the impression of the evaluator that the defendant was malingering grossly and inconsistently, incompatible with the kinds of decreases in cognitive skills that occasionally attend major depression. (Adapted from a case of Mark J. Mills, J.D., M.D. and Mark S. Lipian, M.D., Ph.D.)

Table 20-1
Conditions that May be a Focus of Clinical Attention

Relational Problems

- Problems Related to Family Upbringing
  - Parent–Child Problem
  - Sibling Problem
  - Upbringing Away from Parents
  - Parental Relationship Distress
- Other Problems Related to Primary Support System

- Relationship Distress with Spouse or Partner
- Separation or Divorce
- Emotional Distress within Family
- Uncomplicated Bereavement

Abuse and Neglect

- Problems of Child Maltreatment and Neglect
  - Child Physical Abuse
  - Child Sexual Abuse
  - Child Neglect
  - Child Psychological Abuse
- Problems of Adult Maltreatment and Neglect
  - Physical Violence of Spouse or Partner
  - Sexual Violence of Spouse or Partner
  - Spouse or Partner Neglect
  - Psychological Spouse or Partner Abuse
  - Adult Abuse by Nonspouse or Nonpartner (e.g., Physical, Sexual, Psychological)

Educational and Occupational Problems

- Educational Problems
- Occupational Problems
  - Related to Current Military Deployment Status
  - Other (e.g., Job change, Loss of job, Stress)

Housing and Economic Problems

- Housing Problems
  - Homelessness
  - Inadequate Housing (e.g., Lack of Heat or Electricity, Insect or Rodent Infestation)
  - Neighbor, Lodger, or Landlord Discord
  - Residential Institution (Does Not Include Psychological Reaction to Change in Living Situation; see Adjustment Disorders, Chapter 10)
- Economic Problems
  - Lack of Adequate Food or Safe Drinking Water

- Extreme Poverty
- Low Income

Other Problems Related to the Social Environment
- Phase of Life Problem
- Acculturation Difficulty
- Social Exclusion or Rejection
- Discrimination or Persecution

Problems Related to Crime or Interaction with the Legal System (e.g., Victim of Crime, Imprisonment, Release from Prison)

Other Health Service Encounters for Counseling and Medical Advice (e.g., Sexual Counseling)

Problems Related to Other Psychological, Personal, and Environmental Circumstances
- Religious or Spiritual Problem
- Victim of Terrorism or Torture
- Exposure to Disaster or War

Other Circumstances of Personal History
- Adult Antisocial Behavior
- Child or Adolescent Antisocial Behavior
- Problems Related to Access to Medical and Other Health Care
- Nonadherence to Medical Treatment (e.g., Overweight or Obesity, Malingering, Wandering Associated with a Mental Disorder)
- Borderline Intellectual Functioning

Adapted from *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed., American Psychiatric Association; 2013.

Facilitation of Transfer from Prison to Hospital. Prisoners may malinger (fake bad) to obtain a transfer to a psychiatric hospital from which they may hope to escape or in which they expect to do "easier time." The prison context may also give rise to dissimulation (faking good). However, the prospect of an indeterminate number of days on a mental health ward may prompt an inmate with actual psychiatric symptoms to make every effort to

conceal them.

Admission to a Hospital. In this era of deinstitutionalization and homelessness, individuals may malinger to gain admission to a psychiatric hospital. The individual may see such institutions as providing free room and board, a haven from the police, or refuge from rival gang members or disgruntled drug cronies who have made street life even more unbearable and hazardous than it usually is.

> A robust, neatly attired man presented to the psychiatric emergency department in the early-morning hours. He stated that "the voices" were worse than before and that he wished readmission to the hospital. When the psychiatrist challenged him, observing that his discharge was just that afternoon, that he routinely left the hospital in the morning and demanded rehospitalization at night, and that, despite multiple hospitalizations, clinicians increasingly doubted his reported history of hallucinations, the man became belligerent. When the psychiatrist still refused to admit him, the patient grabbed the psychiatrist's clothes, threatening him but inflicting no harm. The psychiatrist asked the hospital police to escort him off the grounds. The treatment team told the patient that he could seek readmission to his regular ward during the day. Subsequent contact with the patient's ward revealed that their diagnoses were substance abuse and homelessness; his apparent schizophrenia appeared never to have been an actual issue in his treatment. (Courtesy of Mark J. Mills, J.D., M.D. and Mark S. Lipian, M.D., Ph.D.)

Drug Seeking. Malingerers may feign illness to obtain favored medications, either for personal use or, in a prison setting, as currency to barter for cigarettes, protection, or other inmate-provided favors.

> The plaintiff, a woman in her late 20s, was injured while dancing at a club. Although her claim initially appeared bona fide, subsequent investigation cast doubt on the mechanism of injury that she claimed—namely, that a misplaced electrical cord under a carpet caused her to slip.

This was true, she claimed, even though she had been dancing in a particularly jerky manner that could have easily caused problems without tripping.

Subsequently, she sought medical and surgical treatment for torn cartilage in her injured knee. Even though the initial surgery went well, she kept reinjuring the knee with various "slips." As a result, she requested narcotic analgesics. A careful medical record review revealed that she was obtaining such medications from multiple practitioners and that she had forged at least one prescription.

In reviewing the case before binding arbitration, it was the opinion of the orthopedic and psychiatric consultants that, although the initial injury and reported pain were real, the plaintiff consciously elaborated her injuries to obtain the desired narcotic analgesics. (Courtesy of Mark J. Mills, J.D., M.D. and Mark S. Lipian, M.D., Ph.D.)

Child Custody. Minimizing difficulties or faking good for the sake of obtaining child custody can occur when one party accurately accuses the other of being an unfit parent because of psychological conditions. The accused party may feel compelled to minimize symptoms or to portray him- or herself in a positive light to reduce the chances of being deemed unfit and losing custody.

Differential Diagnosis

The challenge is to differentiate malingering from an actual physical or psychiatric illness. Furthermore, the possibility of partial malingering, which is an exaggeration of existing symptoms, must be entertained. Also, the possibility exists of unintentional, dynamically driven misattribution of genuine symptoms (e.g., of depression) to an incorrect environmental cause (e.g., to sexual harassment rather than to narcissistic injury).

We should also remember that a real psychiatric disorder and malingering are not mutually exclusive.

Factitious disorder is distinguished from malingering by motivation (sick role vs. tangible pain), whereas the somatoform disorders involve no conscious volition. In conversion disorder, as in malingering, objective signs cannot account for subjective experience, and differentiation between the two

disorders can be difficult. Table 20-2 lists some variables that may aid in distinguishing between these two conditions.

Epidemiology

There is perhaps a 1 percent prevalence of malingering among mental health patients in civilian clinical practice, with the estimate rising to 5 percent in the military. In a litigious context, during interviews of criminal defendants, the estimated prevalence of malingering is much higher—between 10 and 20 percent. Approximately 50 percent of children presenting with conduct disorders have reported lying-related issues.

Although there is no apparent familial or genetic patterns, and no clear-cut sex or age bias at onset, malingering does appear to be highly prevalent in some military, prison, and litigious populations and, in Western society, in men from youth through middle age. Associated disorders include conduct and anxiety disorders in children and antisocial, borderline, and narcissistic personality disorders in adults.

Etiology

Although there do not seem to be any biologic factors causally related to malingering, its frequent association with antisocial personality disorder raises the possibility that hypoarousability may be an underlying metabolic factor. Still, no predisposing genetic, neurophysiologic, neurochemical, or neuroendocrinologic forces are presently known.

Table 20-2
Factors Aiding in the Differentiation between Malingering and Conversion Disorder

1. Malingerers are more likely to be suspicious, uncooperative, aloof, and unfriendly; patients with conversion disorder are likely to be friendly, cooperative, appealing, dependent, and clinging.
2. Malingerers may try to avoid diagnostic evaluations and refuse recommended treatment; patients with conversion disorder likely welcome evaluation and treatment, “searching for an answer.”
3. Malingerers likely refuse employment opportunities designed to

circumvent their disability; patients with conversion disorder likely accept such opportunities.

4. Malingerers are more likely to provide extremely detailed and exacting descriptions of events precipitating their “illness”; patients with conversion disorder are more likely to report historical gaps, inaccuracies, and vagaries.

Course and Prognosis

Malingering persists as long as the malingerer believes it will likely produce the desired rewards. In the absence of concurrent diagnoses, after the individual has attained the goal, the feigned symptoms disappear. In some structured settings, such as the military or prison units, ignoring the malingered behavior may result in its disappearance, mainly if an expectation of continued productive performance, despite complaints, is made clear. In children, malingering is most likely associated with a predisposing anxiety or conduct disorder; proper attention to this developing problem may alleviate the child’s propensity to malinger.

Treatment

The appropriate stance for the psychiatrist is clinical neutrality. If malingering is suspected, a careful differential investigation should ensue. If, after the diagnostic evaluation, malingering seems most likely, the clinician should tactfully but firmly confront the patient with the apparent outcome. The clinician should also try to understand the underlying reasons for the ruse, and explore alternative, more acceptable pathways to the desired outcome. Coexisting psychiatric disorders should be thoroughly assessed. Only if the patient is utterly unwilling to interact with the physician under any terms other than manipulation should the physician abandon the interaction.

BEREAVEMENT

Normal bereavement begins immediately after or within a few months of the loss of a loved one. Typical signs and symptoms include feelings of sadness, preoccupation with thoughts about the deceased, tearfulness, irritability,

insomnia, and difficulties concentrating and carrying out daily activities. Based on the cultural group, bereavement is limited to a varying time, usually 6 months, but it can be longer. Normal bereavement, however, can lead to a full depressive disorder that requires treatment. Some grieving individuals present with symptoms characteristic of a major depressive episode such as depressed mood, insomnia, anorexia, and weight loss. The duration of grief and bereavement varies considerably among different cultural groups and within the same cultural group. The diagnosis of depressive disorder is generally not given unless the symptoms are still present 2 months after the loss. However, the presence of specific symptoms that are not characteristic of a "normal" grief reaction may help differentiate bereavement from depression. These include (1) guilt about things other than actions taken or not taken by the survivor at the time of the death, (2) thoughts of death other than the survivor feeling that he or she would be better off dead or should have died with the deceased person, (3) morbid preoccupation with worthlessness, (4) marked psychomotor retardation, (5) prolonged and marked functional impairment, and (6) hallucinatory experiences other than thinking that he or she hears the voice of or transiently sees the image of the deceased person.

OCCUPATIONAL PROBLEMS

Occupational problems often arise during stressful changes in work, namely, at initial entry into the workforce or when making job changes within the same organization to a higher position because of excellent quality performance or to a parallel position because of corporate need. Distress often occurs when not choosing these changes or if the person feels unprepared for the change. It is also true during layoffs and at retirement, especially if retirement is mandatory, and the person is unprepared for this event. Work distress can result if one's work situation changes to work overload, or conversely, a lack of challenge. Also, an individual may feel unable to fulfill work expectations, perhaps because they lack sufficient authority to enact any change or meet with conflicting expectations. Working with harsh or unreasonable superiors can be another common source of work distress.

Work Choices and Changes

Young adults without role models or guidance from families, mentors, or others in their communities too often underestimate their potential lifetime abilities to learn a trade or earn a college or postgraduate degree. Also, women and members of minority groups often feel less prepared to accept work challenges, fear rejection, and do not apply for jobs for which they are qualified. On the other hand, men, in fields in which they are underrepresented, often and confidently move up the career ladder faster (glass elevator). As part of initial interviews for evaluation of occupational problems, patients should be encouraged to consider their heretofore unrecognized, unadmitted talents; long-held, yet unexpressed, dreams and goals regarding work; actual successes in work and school; and motivation to risk learning what they would find satisfying.

Minorities and those in low-paying and low-skilled jobs too often have less job security. Business and institutional reorganization and consequent downsizing, factory closings, and moves affect many, often leaving these workers feeling hopeless and helpless about future employment, on welfare, angry, and depressed.

With ongoing and often sudden downsizing of corporations and businesses, men and women continue to struggle with unexpected job loss and premature retirement even when finances are not an issue. Also, men, in particular, define themselves by their work roles and thus experience more occupational distress from these changes. Women may adjust faster to retirement, but they often have less financial security than men. Even today, white women earn approximately 80 cents on the dollar, and African American and Hispanic women earn even less for comparable work. In addition to lower pay, women may have lower status, find themselves widowed more often than men, and are more likely to be caring for children, grandchildren, and elderly relatives. Women represent more of the single working parent group and the working poor.

Stress and the Workplace

More than 30 percent of workers report that they are under stress at work. At least 15 percent of occupational disability claims involve workplace distress. Expected distress follows recognized and uncontrollable work changes—

downsizing, mergers and acquisitions; work overload; and chronic physical strains, including work noise, temperature, bodily injuries, and strain from performing computer work.

Work frustration can also arise from an individual worker's unrecognized (and therefore unresolved) psychodynamic issues, such as working appropriately with superiors and not relating to one's supervisor as a parent figure. Other developmental issues include unresolved problems with competition, assertiveness, envy, fear of success, and the inability to communicate verbally in a constructive manner.

After the September 11, 2001, World Trade Center tragedy, a 32-year-old married male firefighter, who had been away on vacation that day with his wife and children, began to exhibit changed behaviors at home and work. At home, he appeared not to listen to his two children and, instead, focused his attention on television sporting events. At work, he also appeared to be more focused on cooking the same dinners for his peers and watching television than on interacting verbally with his remaining peers and the new chief. In several months, a chaplain visited the station several times and talked to the firefighters about survivor guilt and the 9/11 tragedy, and the firefighter began to return somewhat to his former healthier behaviors. (Courtesy of Leah J. Dickstein, M.D.)

Often, work conflicts reflect similar conflicts in the worker's personal life, and referral for treatment, unless there is insight, is in order. Some studies have found that massage therapy, meditation, and yoga at intervals during the workday relieve stress when used regularly. Approaches using cognitive therapy have also helped people reduce work pressure.

Suicide Risk

Some occupations—health professionals, financial service workers, and police, the first and latter groups because of more access to lethal drugs and weapons—both attract persons with high suicide risk and involve increased chronic distress that may lead to higher suicide rates.

Career and Job Problems of Women

Most women work outside the home out of necessity to support themselves or their dependents (whether children or adults) or as part of a working couple. With the divorce rate remaining at the 50 percent level, many women find themselves economically more impoverished after a divorce than when married, although divorced men usually find their economic status improved. Despite more than four decades of increasing knowledge about and concern for women's status in the workplace, unique gender issues, bias, and lack of accommodation to their unique needs at certain life stages (i.e., pregnancy and postpartum, the primary responsibility for young healthy and ill children) continue. However, women were the largest group establishing new small businesses in the 1990s. Many have left large corporations where they felt undervalued because of their gender. Women experience problems when they are the sole woman in a man's field. Despite increasing recognition of the need for men in relationships with women to assume home and family responsibilities, fewer than 25 percent of men do so equitably.

Women of childbearing and child-rearing ages continue to find themselves in conflict with job expectations, opportunities, and personal responsibilities. High-quality, on-site, dependent-care facilities with extended hours are rare and often out of range financially. Major unresolved work issues that are unique to women at certain life stages include flextime and paid and unpaid dependent leave options. Beyond dependent care issues, women in the workforce continue to experience distress after chronic and repeated sexual harassment, despite its illegality and media attention. Increasingly, more women have travel responsibilities, work long hours, work shifts beyond daylight hours, and experience personal workplace violence.

Among dual-career families and partners, the woman is more likely to move when the man chooses to move for a work opportunity than vice versa. Consequently, a woman's career is interrupted more often. There is now less hesitation to have the two members of a relationship work for the same organization than previously, albeit usually in different departments. Work distress may also stem from continuous miscommunication, especially that based on gender.

Working Teenagers

With unemployment increasing, many teenagers work part time while attending high school. Consequently, stress can arise because of less parent–teenager interaction and constructive parental control issues about teens' use of earnings, time spent away from home, and consequent behaviors both in and outside the home. When both parents or a single parent, as well as the teenager, work outside the home, often on different schedules, parent–teen verbal communication must be proactive, transparent, and ongoing.

Working within the Home

Although most women with children of all ages must work outside the home, at times, they may be home full time or part time or may work at home. When their husbands or partners work full time outside the home, problems may develop from each one's perceived expectations of the other. Women who care for children and their home exclusively may be seen by their partners as not only economically dependent and inferior but also not as competent and not understanding of the man's stressors and needs. Ongoing respectful listening and verbal communication must be encouraged.

People in organizations are increasingly taking work home as their work expectations increase. This work-at-home experience can and does interfere with personal lives and satisfaction, which can then have further repercussions at work.

Chronic Illness

As general and other medical and psychiatric treatments for chronic diseases improve, employers have been increasingly concerned about accommodating patients with acquired immunodeficiency syndrome (AIDS), diabetes mellitus, and other disorders. The issue of mandatory testing for AIDS and substance abuse (alcohol and other illegal substances) continues to be of concern. Employee assistance programs offering education about general and mental health topics have proved timely and cost-effective.

Domestic Violence

Although occurring in the home, signs and symptoms that interfere with work may help identify victims of domestic violence. Trained professionals must question all employees experiencing work distress about domestic violence

and, when indicated, refer individuals for assistance, which includes safety in the workplace.

Job Loss

Regardless of the reason for job loss, most people experience distress, at least temporarily, including symptoms of normal grief, loss of self-esteem, anger, and reactive depressive and anxiety symptoms, as well as somatic symptoms and possibly the onset of or increase in substance abuse or domestic violence. Timely education, support programs, and vocational guidance can be helpful, as is access to treatment.

Vocational Rehabilitation

Rehabilitation is often necessary for those traumatized by stresses in the workplace, those who had to take a leave for medical or psychiatric reasons, and those who lose their jobs. Individual or group counseling enables persons to improve personal relationships, raise self-esteem, or learn new work skills. Patients with schizophrenia may benefit from sheltered workshops in which they perform work geared to their level of function. Some patients with schizophrenia or autism do well in tasks that are repetitive or require obsessive concern with details.

ADULT ANTISOCIAL BEHAVIOR

Characterized by activities that are illegal, immoral, or both, antisocial behavior usually begins in childhood and often persists throughout life. The term *antisocial behavior* somewhat confusingly applies both to persons' actions that are not due to a mental disorder and to actions by those who never received a neuropsychiatric workup to determine the presence or absence of a mental disorder. As Dorothy Lewis noted, the term can apply to behavior by otherwise normal persons who "struggle to make a dishonest living."

Diagnosis and Clinical Features

The diagnosis of adult antisocial behavior is one of exclusion. Substance dependence in such behavior often makes it difficult to separate the antisocial

behavior related primarily to substance dependence from disordered behaviors that occurred either before substance use or during episodes unrelated to substance dependence.

It is also essential that we differentiate this from an antisocial personality disorder, and when a patient meets the criteria for the personality disorder, that diagnosis would supersede this one.

During the manic phases of bipolar I disorder, certain aspects of behavior, such as wanderlust, sexual promiscuity, and financial difficulties can be similar to adult antisocial behavior. Patients with schizophrenia may have episodes of adult antisocial behavior, but the symptom picture is usually clear, especially regarding thought disorder, delusions, and hallucinations on the mental status examination.

Neurologic conditions can be associated with adult antisocial behavior, and, when indicated, a full workup, including neuroimaging, can help identify a cause of the behavior. We should consider complex partial seizures in the differential diagnosis. When making a clear-cut diagnosis of epilepsy or encephalitis, we should then consider whether the disorder is contributing to antisocial behavior. Abnormal EEG findings are prevalent among violent offenders: an estimated 50 percent of aggressive criminals have abnormal EEG findings.

Persons with adult antisocial behavior have difficulties in work, marriage, and money matters and conflicts with various authorities. Table 20-3 summarizes the symptoms of adult antisocial behavior.

Epidemiology

Depending on the specifics of the case finding, adult antisocial behavior may range from 5 to 15 percent of the population. Within prison populations, investigators report prevalence figures between 20 and 80 percent. Men account for more adult antisocial behavior than do women.

Table 20-3
Symptoms of Adult Antisocial Behavior

Life Area	Antisocial Patients with Significant Problems in Area (%)

Work problems	85
Marital problems	81
Financial dependence	79
Arrests	75
Alcohol abuse	72
School problems	71
Impulsiveness	67
Sexual behavior	64
Wild adolescence	62
Vagrancy	60
Belligerence	58
Social isolation	56
Military record (of those serving)	53
Lack of guilt	40
Somatic complaints	31
Use of aliases	29
Pathologic lying	16
Drug abuse	15
Suicide attempts	11

Data from Robins L. *Deviant Children Grown Up: A Sociological and Psychiatric Study of Sociopathic Personality*. Baltimore, MD: Williams & Wilkins; 1966.

Etiology

Antisocial behaviors in adulthood are characteristic of a variety of persons, ranging from those with no demonstrable psychopathology to those who are

severely impaired and have psychotic disorders, cognitive disorders, and retardation, among other conditions. A comprehensive neuropsychiatric assessment of antisocial adults is indicated and may reveal potentially treatable psychiatric and neurologic impairments. Only in the absence of mental disorders can patients be categorized as displaying adult antisocial behavior. Genetic and social factors may influence adult antisocial behavior.

Genetic Factors. Some studies found a 60 percent concordance rate in monozygotic twins and about a 30 percent concordance rate in dizygotic twins. Adoption studies show a high rate of antisocial behavior in the biologic relatives of adoptees identified with antisocial behavior and a high incidence of antisocial behavior in the adopted-away offspring of those with antisocial behavior. The prenatal and perinatal periods of those who subsequently display antisocial behavior often are associated with low birth weight, mental retardation, and prenatal exposure to alcohol and other drugs of abuse.

Social Factors. Studies have shown that in neighborhoods in which families with low socioeconomic status (SES) predominate, the sons of unskilled workers are more likely to commit more offenses and more serious criminal offenses than do the sons of middle-class and skilled workers, at least during adolescence and early adulthood. These data are not as precise for women, but the findings are generally similar in studies from many countries. Areas of family training differ by SES group. Middle-SES parents use love-oriented techniques in discipline. They withdraw affection rather than impose physical punishment, as is done in low-SES groups. Negative parental attitudes toward aggressive behavior attempt to curb that behavior, and the ability to communicate parental values are more characteristic of middle- and high-SES groups than of low ones. Adult antisocial behavior is associated with the use and abuse of alcohol and other substances and with the easy availability of handguns.

Treatment

In general, therapists are pessimistic about treating adult antisocial behavior. They have little hope of changing a pattern that has been present almost continuously throughout a person’s life. Psychotherapy has not been

effective, and no breakthroughs with biologic treatments, including medications, have occurred.

Therapists show more enthusiasm for the use of therapeutic communities and other forms of group treatment, although the data provide little basis for optimism. Many adult criminals, incarcerated in institutional settings, have shown some response to group therapy approaches. The history of violence, criminality, and antisocial behavior has shown that such behaviors seem to decrease after age 40 years. Recidivism in criminals, which can reach 90 percent in some studies, also decreases in middle age.

Prevention. Because antisocial behavior often begins during childhood, the primary focus must be on delinquency prevention. Any measures that improve the physical and mental health of socioeconomically disadvantaged children and their families are likely to reduce delinquency and violent crime. Often, recurrently violent persons have sustained many insults to the central nervous system (CNS) prenatally and throughout childhood and adolescence. Consequently, we need to develop programs to educate parents about the dangers to their children of CNS injury from maltreatment, including the effects of psychoactive substances on the brains of growing fetuses. Public education about the releasing effect of alcohol on violent behaviors (as well as its contribution to vehicular homicide) may also reduce crime.

In a Surgeon General's Workshop on Violence and Public Health (1985), the work group on preventing assault and homicide emphasized the importance of discouraging corporal punishment in the home, forbidding it in the schools, and even abolishing capital punishment by the state, saying that all are models and sanctions for violence. No evidence indicates that capital punishment reduces crime in the states that have it. Opponents of capital punishment see it as "vengeance," not punishment.

Although persons disagree about the contribution of violence in the media to violent crime, the propaganda potential of the media is universally recognized. We have not fully realized the extent to which the media, such as television, can be used to transmit positive social values. The guidelines issued by the television industry to indicate the amount of sex and violence in programs is an attempt to deal with the issue; however, program content that espouses traditional societal values would be beneficial.

The most successful preventive measures within the field of medicine have

come from community-wide public health programs (e.g., campaigns against smoking) and from programs that detect individual vulnerabilities (e.g., individual monitoring of blood pressure). Studies of adult antisocial behavior reveal the contribution of broad cultural factors and constellations of individual biopsychosocial vulnerabilities. Prevention programs must recognize and address both kinds of factors.

RELIGIOUS OR SPIRITUAL PROBLEM

A religious or spiritual problem can bring the person to the psychiatrist under one of several circumstances. For example, a person may begin to question his or her faith and choose not to discuss the problem with a spiritual advisor. Alternatively, a person may wish to convert to a new faith, to marry or improve a marriage when the partner is of a different faith.

Psychiatrists must enable and assist patients in distinguishing religious thought or experience from psychopathology and, if this is a problem, encourage patients to work through the issues independently or with assistance. Religious imagery may be recognized in mental illness when persons state they believe that they have been commanded by God to take a dangerous or grandiose action.

Religious experiences may factor into a person's life in unexpected ways, as in the following case. A midcareer male surgeon who was very successful but long overcommitted to his private practice and his academic responsibilities revealed to his often-neglected wife that, at age 9 years, he was approached by his religious leader to get close physically and ultimately engaged in sexual acts over several years. Believing it was his fault, he never told anyone and decided never to have children. After telling his wife about the experience, they engaged in family therapy to work through the stresses the confession produced in their marriage.

Cults

Recently, cults have appeared to be less popular and less attractive to naïve late adolescents and young adults seeking assistance in discovering who they are as they struggle to develop more mature relationships with their parents.

Cults are led by charismatic leaders, often out of control themselves, with inappropriate and often unethical values but purporting to offer acceptance and guidance to troubled followers. Cult members are actively controlled and forced to dissolve allegiance to family and others to serve the cult leader's directives and personal needs. These young members often come from educated families who then seek professional help in persuading their children to leave the cult and enter deprogramming therapy to restore psychological stability to the former cult members. Deprogramming and adjustment back into the family, society, and an independent life are time-intensive and long term with resultant posttraumatic stress disorder (PTSD), which must be recognized and treated.

ACCULTURATION PROBLEM

Acculturation is the process whereby a person from one culture changes in their manner, custom, and dress to adapt to a different culture. It leads to assimilation in which the person has identified with the new culture, usually without conflict or ambivalence. In some cases, however, significant cultural change can evoke severe distress, termed *culture shock.* This condition arises when individuals suddenly find themselves in a new culture in which they feel entirely alien. They may also feel conflict over which lifestyles to maintain, change, or adopt. Children and young adult immigrants often adapt more quickly than do middle-aged and elderly immigrants. Younger immigrants often learn the new language more efficiently and continue to mature in the new culture, but those who are more senior, having had more stability and unchanging routines in their former culture, struggle more to adapt. Culture shock from immigration differs from the restless and continuous moving of psychiatric patients secondary to their illness.

Culture shock can occur within a person's own country with geographic, school, and work changes, such as joining the military, experiencing school busing, moving across the country, or moving to a vastly different neighborhood or from a rural area to a metropolis. Reactive symptoms, which are understandable, include anxiety, depression, isolation, fear, and a sense of loss of identity as the person adjusts. If the person is part of a family or group making this transition and the move is positive and planned, stress can be lower. Furthermore, if one can maintain selected cultural mores safely as they

integrate into the new culture, it may be less stressful.

Constant geographic moves because of chosen work opportunities or necessity involve a large proportion of workers in the United States. Joining activities in the new community and actively trying to meet neighbors and coworkers can lessen the culture shock.

An 18-year-old, first-year female college student offered an academic scholarship by a small Southern college with a major in her field of interest, realized on her return home to the Midwest for winter break that she felt like a misfit among her dorm peers. They were friendly yet generally kept their distance from her after class. At home, she discussed her experiences with high school friends, who replied that they had heard about such cultural dissonance from peers at their Midwestern colleges. The student returned to college feeling that it was not her fault or imagination and slowly began to reach out more assertively to her peers so they could get to know her beyond stereotypical beliefs and so she could do the same.

Brainwashing

First practiced by the Chinese Communists on American prisoners during the Korean War, *brainwashing* is the deliberate creation of culture shock. Individuals are isolated, intimidated, and made to feel different and out of place to break their spirits and destroy their coping skills. When a person appears mentally weak and helpless, the aggressors impose new ideas on them that they would never have accepted in their normal state. As with those involved in cults, on release and return to their homes, brainwashed individuals with PTSD require deprogramming treatment, including re-education and ongoing supportive psychotherapy, both on an individual and group basis. Treatment is usually long-term to rebuild healthy self-esteem and coping skills.

Prisoners of War and Torture Victims

Prisoners who survive war or torture experiences do so because of personal inner strengths developed in their earlier lives, beginning within their

emotionally healthy and caring families; if they come from troubled families, they are more likely to commit suicide during imprisonment and torture. Prisoners must continuously cope with ongoing anxiety, fear, isolation from known lives, and complete loss of all control over their lives. Those who appear to cope best believe they must survive for a reason (e.g., to tell others what they experienced or to find and return to loved ones). Prisoners who cope best describe living simultaneously on two levels—coping in the here and now to survive the situation while maintaining constant mental connections to their past values and experiences and those important to them.

Beyond the surviving prisoner's personal difficulties, including PTSD, if and when his or her survival behavior continues, his or her family may be affected by the surviving prisoner's inordinate fear of police and strangers, overprotection and overburdening of children to replace those significant others lost, lack of sharing of the past, continued isolation from current communities, or inappropriately expressed anger. Thus, another generation (i.e., children of survivors) can be affected in their personal development and psychological functioning and may require psychiatric evaluation and treatment. (See also Chapter 10, Trauma and Stressor-Related Disorders, for further discussion of these topics.)

A 75-year-old Catholic female survivor of the Pawiak prison in Warsaw, Poland, and then of a concentration camp after her capture as a member of the underground in World War II stated that she had wanted to become a painter. In camp, she carved the Madonna and Child on her toothbrush and sent it home to her mother. She made other clandestine carvings for several women in her barracks to send home to their families, which pleased everyone. After the war, she became a well-known sculptress with exhibits throughout Europe. Many of her art pieces taught people about suffering and respect for others who are of different religions and cultures.

PHASE OF LIFE PROBLEM

Phase of life problems may occur at any point along the life cycle: the first day of school as a child, the divorce of a parent during adolescence, starting

college as a young adult, marriage, having children, illness, caring for aged parents, and many others. Although, on some level, adults recognize that life events will intrude on expected plans in the course of a lifetime, unexpected, multiple, significant negative occurrences, especially if they are chronic, overwhelm a person's ability to recover and function constructively. The typical phase of life problems include relationship changes, such as a changed significant personal relationship or loss, job crises, and parenthood.

Because of sex-role socialization and consequent cultural expectations, where men appear externally better able to handle these phases of life problems, women, people with lower SES, and minority group members appear more vulnerable to negative experiences, perhaps because they feel less empowered psychologically. Significant life changes precipitate distress in the form of anxiety and depressive symptoms, an inability to express reactive emotions directly, and often difficulties in coping with ongoing or changed life responsibilities.

Individuals with positive attitudes, healthy family and personal relationships, and mature defense mechanisms and coping styles, including essential trust in self and others, good verbal communication skills, a capacity for creative and positive thinking, and the ability to be flexible, reliable, and energetic, appear to be best able to cope with phase of life problems. Furthermore, a capacity for sublimation; adequate financial and work status; solid values; and healthy, feasible goals can enable people to face, accept, and deal realistically with expected and unexpected life problems and changes.

NONCOMPLIANCE WITH TREATMENT

Compliance is the degree to which a patient carries out the recommendations of the treating physician. A positive doctor–patient relationship can help foster compliance, but even in those circumstances, the patient may be reluctant to comply with a physician's advice. In psychiatry, a significant concern is medication noncompliance, which may result from discomforting side effects, expense, personal value judgments, and denial of illness, among many others. We should only use this category when the problem is sufficiently severe to warrant independent clinical attention.

RELATIONAL PROBLEMS

An adult's psychological health and sense of well-being depend, to a significant degree, on the quality of his or her critical relationships—that is, on patterns of interaction with a partner and children, parents and siblings, and friends and colleagues. Problems in the interaction between any of these significant others can lead to clinical symptoms and impaired functioning among one or more members of the relational unit. Relational problems may be a focus of clinical attention (1) when a relational unit is distressed and dysfunctional or threatened with dissolution and (2) when the relational problems precede, accompany, or follow other psychiatric or medical disorders. Indeed, the relational context of the patient influences other medical or psychiatric symptoms. Conversely, the functioning of a relational unit is affected by a member's general and other medical or psychiatric illness. Relational disorders require a different clinical approach than other disorders. Instead of focusing primarily on the link between symptoms, signs, and the workings of the individual mind, the clinician must also focus on interactions between the individuals involved. Also, the clinician should consider how these interactions are related to the general and other medical or psychiatric symptoms in a meaningful way.

Definition

Relational problems are patterns of interaction between members of a relational unit that are associated with significantly impaired functioning in one or more individual members. Thus one may have parent–child problems, sibling-related problems, or other dyad or triad impairments. At times the entire unit, such as the family itself, may be dysfunctional.

Epidemiology

No reliable figures are available on the prevalence of relational problems. They can be assumed to be ubiquitous; however, most relational problems resolve without professional intervention. We should consider the nature, frequency, and effects of the problem on those involved before using this diagnosis. For example, divorce, which occurs in just under 50 percent of marriages, is a problem that partners resolve through the remedy of divorce.

We do not need to use this diagnosis for most divorces. If the persons cannot resolve their disputation and continue to live together in a sadomasochistic or pathologically depressed relationship with unhappiness and abuse, then they should be so labeled. Relationship problems between involved persons that cannot be resolved by friends, family, or clergy require professional intervention by psychiatrists, clinical psychologists, social workers, and other mental health professionals.

Relational Problem Related to a Mental Disorder or General Medical Condition

When a family member is ill either from a psychiatric or medical illness, there are reverberations throughout the family unit. Studies indicate that whereas satisfying relationships may have a health-protective influence, relationship distress tends to be associated with an increased incidence of illness. Psychophysiologic mechanisms help to explain how relational systems affect physical or mental health—for example, the intense emotions generated in human attachment systems can affect vascular reactivity and immune processes. Thus, stress-related psychological or physical symptoms can be an expression of family dysfunction.

Adults must often assume responsibility for caring for aging parents while they are still caring for their children, and this dual obligation can create stress. When adults take care of their parents, both parties must adapt to a reversal of their former roles, and the caretakers not only face the potential loss of their parents but also must cope with evidence of their mortality.

Some caretakers abuse their aging parents, a problem that is now receiving attention. Abuse is most likely to occur when the caretaking offspring have substance abuse problems, are under economic stress, and have no relief from their caretaking duties or when the parent is bedridden or has a chronic illness requiring constant nursing attention. Women suffer abuse more often than men, and most abuse occurs in persons older than age 75 years.

The development of chronic illness in a family member stresses the family system and requires adaptation by both the sick person and the other family members. The person who has become sick must frequently face a loss of autonomy, an increased sense of vulnerability, and sometimes a taxing medical regimen. The other family members must experience the loss of the

person as he or she was before the illness, and they usually have substantial caretaking responsibility—for example, in debilitating neurologic diseases, including dementia of the Alzheimer's type, and diseases such as AIDS and cancer. In these cases, the whole family must deal with the stress of prospective death as well as the current illness. Some families use the anger engendered by such situations to create support organizations, increase public awareness of the disease, and rally around the sick member. However, chronic illness frequently produces depression in family members and can cause them to withdraw from or attack one another. The burden of caring for ill family members falls disproportionately on the women in a family—mothers, daughters, and daughters-in-law.

Chronic emotional illness also requires major adaptations by families. For instance, family members may react with chaos or fear of the psychotic productions of a family member with schizophrenia. The regression, exaggerated emotions, frequent hospitalizations, and economic and social dependence of a person with schizophrenia can stress the family system. Family members may react with hostile feelings (referred to as expressed emotion) that are associated with a poor prognosis for the person who is sick. Similarly, a family member with bipolar I disorder can disrupt a family, particularly during manic episodes.

Family devastation can occur when illness (1) suddenly strikes a previously healthy person, (2) occurs earlier than expected in the life cycle (some impairment of physical capacities is expected in old age, although many older persons are healthy), (3) affects the economic stability of the family, and (4) when there are few options for improving the condition of the sick family member.

Parent–Child Relational Problem

Parents differ widely in sensing the needs of their infants. Some quickly note their child's moods and needs; others are slow to respond. Parental responsiveness interacts with the children's temperament to affect the quality of the attachment between child and parent. The diagnosis of the parent–child relational problem applies when the focus of clinical attention is a pattern of interaction between parent and child that is associated with clinically significant impairment in individual or family functioning or with clinically

significant symptoms. Examples include impaired communication, overprotection, and inadequate discipline.

Research on parenting skills has isolated two primary dimensions: (1) a permissive–restrictive dimension and (2) a warm and accepting versus a cold and hostile dimension. A typology that separates parents on these dimensions distinguishes among *authoritarian* (restrictive and cold), *permissive* (minimally restrictive and accepting), and *authoritative* (restrictive as needed but also warm and accepting) parenting styles. Children of authoritarian parents tend to be withdrawn or conflicted; those of permissive parents are likely to be more aggressive, impulsive, and low achievers; and children of authoritative parents seem to function at the highest level, socially and cognitively. However, switching from an authoritarian to a permissive mode may create a negative reinforcement pattern.

Difficulties in many situations stress the usual parent–child interaction. Substantial evidence indicates that marital discord leads to problems in children, from depression and withdrawal to conduct disorder and poor performance at school. Parents may resort to *triangulation*, where they recruit a child as an ally in the struggle with the partner. Divorces and remarriages stress the parent–child relationship and may create painful loyalty conflicts. Stepparents often find it challenging to assume a parental role and may resent the special relationship that exists between their new marital partner and the children from that partner's previous marriages. The resentment of a stepparent by a stepchild and the favoring of a natural child are usual reactions in a new family's initial phases of adjustment. When a second child is born, both familial stress and happiness may result, although happiness is the dominant emotion in most families. The birth of a child can also be troublesome when parents had adopted a child in the belief that they were infertile. Single-parent families usually consist of a mother and children, and their relationship is often affected by financial and emotional problems.

Other situations that can produce a parent–child problem are the development of fatal, disabling, or chronic illness, such as leukemia, epilepsy, sickle-cell anemia, or spinal cord injury, in either the parent or child. The birth of a child with congenital disabilities, such as cerebral palsy, blindness, or deafness, may also produce parent–child problems. These situations, which are not rare, challenge the emotional resources of those involved. Parents and the child must face present and potential loss and must

adjust their day-to-day lives physically, economically, and emotionally. These situations can strain the healthiest families and produce parent–child problems not only with the sick person but also with the unaffected family members. In a family with a severely sick child, parents may resent, prefer, or neglect the other children because the ill child requires much time and attention.

Parents with children who have emotional disorders face particular problems, depending on the child's illness. In families with a child with schizophrenia, family treatment is beneficial and improves the social adjustment of the patient. Similarly, family therapy is useful when a child has a mood disorder. In families with a substance-abusing child or adolescent, family involvement is crucial to help control the drug-seeking behavior and to allow family members to verbalize the feelings of frustration and anger that are invariably present.

Normal developmental crises can also be related to parent–child problems. For instance, adolescence is a time of frequent conflict as the adolescent resists rules and demands, increasing autonomy and, at the same time, elicits protective control by displaying immature and dangerous behavior.

The parents of sons ages 18, 15, and 11 years presented with distress about the behavior of their middle child. The family had been cohesive with satisfactory relationships among all members until 6 months before this consultation. At that time, the 15-year-old son began seeing a girl from a comparatively unsupervised household. Frequent arguments had developed between parents and son regarding going out on school nights, curfews, and neglect of schoolwork. The son's combativeness and lowered academic achievement upset his parents to a great deal. They had not experienced similar conflicts with their oldest child. The adolescent, however, maintained a good relationship with his siblings and friends, did not have behavior problems at school, continued to participate in the school basketball team, and was not a substance user.

Daycare Centers. Quality of care during the first 3 years of life is crucial to neuropsychologic development. The National Institute of Child Health and Human Development does not consider daycare harmful to children,

especially when the caregivers and daycare teachers provide consistent, empathetic, nurturing care. Not all daycare centers can meet that level of care, however, especially those located in impoverished urban areas. Children receiving less than optimal caring exhibit decreased intellectual and verbal skills that indicate delayed neurocognitive development. They may also become irritable, anxious, or depressed, which interferes with the parent–child bonding experience, and they are less assertive and less effectively toilet trained by the age of 5 years.

Currently, more than 55 percent of women are in the workforce, many of whom have no choice but to place their children in daycare centers. Close to 50 percent of entering medical students are women; few medical centers, however, make adequate provisions for on-site daycare centers for their students or staff. Similarly, corporations need to provide on-site, high-quality care for the children of their employees. Not only will that approach benefit the children, but also corporate economic benefits will accrue as a result of reduced absenteeism, increased productivity, and happier working mothers. Such programs have the added benefit of decreasing stresses on marriages.

Partner Relational Problem

Partner relational problems may include negative communication (e.g., criticisms), distorted communication (e.g., unrealistic expectations), or noncommunication (e.g., withdrawal) associated with clinically significant impairment in individual or family functioning or symptoms in one or both partners.

When persons have partner relational problems, psychiatrists must assess whether a patient's distress arises from the relationship or a mental disorder. Mental disorders are more common in single persons—those who never married or who are widowed, separated, or divorced—than among married persons. Clinicians should evaluate developmental, sexual, and occupational and relationship histories, for purposes of diagnosis.

Marriage demands a sustained level of adaptation from both partners. In a troubled marriage, a therapist can encourage the partners to explore areas such as the extent of communication between the partners, their ways of solving disputes, their attitudes toward childbearing and child-rearing, their relationships with their in-laws, their attitudes toward social life, their

handling of finances, and their sexual interaction. The birth of a child, abortion or miscarriage, economic stresses, moves to new areas, episodes of illness, significant career changes, and any situations that involve a significant change in marital roles can precipitate stressful periods in a relationship. Illness in a child exerts the most significant strain on a marriage, and marriages in which a child has died through illness or accident more often than not end in divorce. Complaints of lifelong anorgasmia or impotence by marital partners usually indicate intrapsychic problems, although sexual dissatisfaction is involved in many cases of marital maladjustment.

Adjustment to marital roles can be a problem when partners are from different backgrounds and have grown up with different value systems. For example, members of low SES groups perceive a wife as making most of the decisions in the family, and they accept physical punishment as a way to discipline children. Middle-class persons perceive family decision-making processes as shared, with the husband often being the final arbiter, and they prefer to discipline children verbally. Therapists and partners can handle the problems involving conflicts in values, adjustment to new roles, and poor communication by examining the couple's relationship, as in marital therapy.

Epidemiologic surveys show that unhappy marriages are a risk factor for major depressive disorders. Marital discord also affects physical health. For example, in a study of women age 30 to 65 years with coronary artery disease, marital stress worsened the prognosis 2.9 times for recurrent coronary events. Marital conflict was also associated with a 46 percent higher relative death risk among female patients having hemodialysis and with elevations in serum epinephrine, norepinephrine, and corticotrophin levels in both men and women. In one study, patients with high levels of hostile marital behavior had slower healing wounds, lower production of proinflammatory cytokines, and higher cytokine production in peripheral blood. Overall, women show better psychological and physiologic responsiveness to conflict than men.

Physician Marriages. Physicians have a higher risk of divorce than other occupational groups. The incidence of divorce among physicians is about 25 to 30 percent. Specialty choice influenced divorce. The highest rate of divorce occurred in psychiatrists (50 percent) followed by surgeons (33

percent) and internists, pediatricians, and pathologists (31 percent). The average age at first marriage was 26 years among all groups.

It is not clear why physicians are at high risk for divorce. Factors implicated include the stresses of dealing with dying patients, making life-and-death decisions, working long hours, and the constant risk of malpractice litigation. Such stressors may predispose physicians to a variety of emotional ills, with the most common being depression and substance abuse, including alcoholism. Such persons generally cannot deal with the complex interactions required to maintain successful long-term relationships of any kind, and marriage requires the most interpersonal skills of all.

Sibling Relational Problem

Sibling relationships tend to be characterized by competition, comparison, and cooperation. Intense sibling rivalry can occur with the birth of a child and can persist as the children grow up, compete for parental approval, and measure their accomplishments against one another. Alliances between siblings are equally common. Siblings may learn to protect one another against parental control or aggression. In households with three children, one pair tends to become tightly involved with one another, leaving the extra child in the position of an outsider.

Relational problems can arise when a family treats siblings unequally; for instance, idealizing one child while casting another in the role of the family scapegoat. Differences in gender roles and expectations expressed by the parents can underlie sibling rivalry. Parent–child relationships also are dependent on personality interactions. A child's resentment directed at a parental figure or a child's own disavowed dark emotions can be projected onto a sibling and can fuel an intense hate relationship.

An ill child creates stress for the child's siblings. Parental concern and attention to the sick child can elicit envy in the siblings. Also, chronic disability can leave the sick child feeling devalued and rejected by siblings, and the latter may develop a sense of superiority and may feel embarrassed about having a disabled sister or brother. Twin relationships have become an area of increasing study. Preliminary data show that twins are more likely to be cooperative than competitive. Whether or not identical twins should be dressed differently during their toddler years to ensure a separate identity is

open to question as is the issue of whether or not they should be in separate classrooms when they begin school.

Other Relational Problems

People, across the life cycle, may become involved in relational problems with leaders and others in their communities at large. In such relationships, conflicts are frequent and can bring about stress-related symptoms. Many relational problems of children occur in the school setting and involve peers. Impaired peer relationships can be the chief complaint in attention-deficit or conduct disorders, as well as in depressive and other psychiatric disorders of childhood, adolescence, and adulthood.

Racial, ethnic, and religious prejudices and ignorance cause problems in interpersonal relationships. In the workplace and communities at large, sexual harassment is often a combination of inappropriate sexual interactions, inappropriate displays of abuse of power and dominance, and expressions of negative gender stereotypes. This harassment most often victimizes women and gay men. However, it can also affect children and adolescents of both sexes.

B Treatment Across the Lifespan

21 Psychopharmacology

Psychopharmacologic advances continue to expand the parameters of psychiatric treatments dramatically. Our increasing understanding of the brain has led to more effective, less toxic, better-tolerated, and more specific therapeutic agents. With the ever-increasing sophistication and array of treatment options, clinicians, however, must remain aware of potential adverse effects, drug–drug (and drug–food or drug–supplement) interactions, and how to manage the emergence of unwanted or unintended consequences. Newer drugs often cause side effects that are not recognized initially. Keeping up with the latest research findings is important as these findings proliferate. A thorough understanding of the management of medication-induced side effects (either through treating the effect with another agent or substituting another primary agent) is necessary.

Medications used to treat psychiatric disorders are sometimes referred to as *psychotropic drugs*. These drugs are commonly described by their primary clinical application, for example, *antidepressants, antipsychotics, mood stabilizers, anxiolytics, hypnotics, cognitive enhancers,* and *stimulants*. A problem with this approach is that, in many instances, drugs have multiple indications. For example, drugs such as the selective serotonin reuptake inhibitors (SSRIs) are both antidepressants and anxiolytics, and the serotonin-dopamine antagonists (SDAs) are both antipsychotics and mood stabilizers. The term is largely synonymous with simply “psychiatric drugs” and we use both terms synonymously in this book.

Psychotropic drugs have also been organized according to structure (e.g., tricyclic), mechanism (e.g., monoamine oxidase inhibitor [MAOI]), history (e.g., first-generation, traditional), uniqueness (e.g., atypical), or indication (e.g., antidepressant). A further source of confusion is that many drugs used

to treat medical and neurologic conditions are routinely used to treat psychiatric disorders.

Also, psychotropic drug terminology can be confusing. The first pharmaceutical agents used to treat schizophrenia were termed *tranquilizers*. When newer drugs emerged as therapies for anxiety, a distinction was drawn between *major* and *minor tranquilizers*. At first, antidepressants were tricyclic antidepressants (TCAs) or MAOIs. In the 1970s and 1980s, as newer antidepressant drugs emerged, they were labeled as *second-* or *third-generation antidepressants*. More recently, older agents used as treatments for psychosis became known as *typical, conventional,* or first-generation *traditional* neuroleptics. Newer ones became *atypical neuroleptics* or second-generation antipsychotics.

In this chapter, we still start with a general review of psychopharmacology, as it applies to psychotropic medications. We will then review the major classes of drugs. For the purposes here, we will use the first system of organization described above; that is, we will classify them by their primary application. Also, we will divert from our usual practice of mainly using generic names of the drugs to, in many cases, include brand names as well. However, in practice, most psychotropic medications are now available through generic preparations, and few patients receive the brand version of a medication. Also, the brand names here reflect US brands. Drug companies in other countries may produce medications under a different brand name.

DRUG SELECTION

Although all U.S. Food and Drug Administration (FDA)-approved psychotropics are similar in overall effectiveness for their indicated disorder, they differ considerably in their pharmacology and their efficacy and adverse effects on individual patients. The ability of a drug to prove effective, thus, is only partially predictable and is dependent on poorly understood patient variables. Nevertheless, some drugs may have a niche in which they can be uniquely helpful for a subgroup of patients, without demonstrating any overall superiority in efficacy. No drug is universally effective, and no evidence indicates the unambiguous superiority of any single agent as a treatment for any major psychiatric disorders. The only exception, clozapine (Clozaril), has been approved by the FDA as a treatment for cases of

treatment-refractory schizophrenia.

Decisions about drug selection and use are made on a case-by-case basis, relying on individual judgment by the physician. Other factors in drug selection are the characteristics of the drug and the nature of the patient's illness. Each of these components affects the probability of a successful outcome.

DRUG FACTORS

Pharmacodynamics

Both genetic and environmental factors influence individual response to and tolerability of psychotropic agents. Thus, a drug that may not prove effective in many patients with a disorder can dramatically improve symptoms in others. In these cases, identification of characteristics that might predict potential candidates for that drug becomes important but often remains elusive.

Drugs, even within the same class, are distinguished from one another by often subtle differences in molecular structure, types of interactions with neurotransmitter systems, differences in pharmacokinetics, the presence or absence of active metabolites, and protein binding. These differences, along with patient biochemical variations, account for the profile of efficacy, tolerability, and safety and the risk-to-benefit ratio for the individual. These multiple variables, some poorly understood, make it difficult to predict a drug's effect with certainty. Nevertheless, knowledge of the nature of each property increases the likelihood of successful treatment. The clinical effects of drugs are best understood in terms of *pharmacokinetics* and *pharmacodynamics*. Pharmacokinetics describes *what the body does to a drug*, whereas pharmacodynamics is *what the drug does to the body*.

Pharmacokinetics and pharmacodynamics need to be seen in the context of the underlying variability among patients for how drug effects are expressed clinically. Patients differ in their therapeutic response to a drug, and the experience of side effects. It is increasingly clear that these differences have a strong genetic basis. Pharmacogenetics research is attempting to identify the role of genetics in drug response.

Primary pharmacodynamic considerations include receptor mechanisms,

the dose–response curve, the therapeutic index, and the development of tolerance, dependence, and withdrawal phenomena. The drug's mechanism of action is subsumed under pharmacodynamics. The clinical response to a drug, including adverse reactions, results from an interaction between that drug and a patient's susceptibility to those actions. Pharmacogenetic studies are beginning to identify genetic polymorphisms linked to individual differences in treatment response and sensitivity to side effects.

Mechanisms

The mechanisms through which most psychotropic drugs produce their therapeutic effects remain poorly understood. Standard explanations focus on ways that drugs alter synaptic concentrations of dopamine, serotonin, norepinephrine, histamine, γ-aminobutyric acid (GABA), or acetylcholine. These changes are said to result from receptor antagonists or agonists, interference with neurotransmitter reuptake, enhancement of neurotransmitter release, or inhibition of enzymes. Specific drugs are associated with permutations or combinations of these actions. For example, a drug can be an agonist for a receptor, thus stimulating the specific biologic activity of the receptor, or an antagonist, thus inhibiting the biologic activity. Some drugs are partial agonists because they are not capable of fully activating a specific receptor. Some psychotropic drugs also produce clinical effects through mechanisms other than receptor interactions. For example, lithium (Eskalith) can act by directly inhibiting the enzyme inositol-1-phosphatase. Some effects are closely linked to a specific synaptic effect. For example, most medications that treat psychosis share the ability to block the dopamine type 2 (D_2) receptor. Similarly, benzodiazepine agonists bind a receptor complex that contains benzodiazepine and GABA receptors.

Additionally, illustrating the fact that the mechanisms of action of psychotropic drugs remain only partially understood are observations that medications that do not directly target monoamine neurotransmitters can be remarkably effective in treating some psychiatric disorders. For example, ketamine (Ketalar), an anesthetic agent that targets glutamate, can rapidly and dramatically alleviate symptoms of depression when given as a slow infusion. Another example involves the antibiotic minocycline (Solodyn), which has been shown to have antidepressant effects. Along with other findings, this

suggests that the immune system and inflammatory responses may underlie some mood disorders.

Accounts of the so-called mechanisms of action should nevertheless be kept in perspective. Explanations of how psychotropic drugs work that focus on synaptic elements represent an oversimplification of a complex series of events. If merely raising or lowering levels of neurotransmitter activity is associated with the clinical effects of a drug, then all drugs that cause these changes should produce equivalent benefits. This predictability is not the case. Multiple obscure actions, several steps removed from events at neuronal receptor sites, are probably responsible for the therapeutic effects of psychotropic drugs. These *downstream* elements are postulated to represent the actual reasons that these drugs produce clinical improvement. A glossary of terms related to receptor drug interactions is given in Table 21-1.

SIDE EFFECTS

Side effects are an unavoidable risk of medication treatment. Although it is impossible to have an encyclopedic knowledge of all possible adverse drug effects, prescribing clinicians should be familiar with the more common adverse effects, as well as those with serious medical consequences. No single text or document, including the product information, contains a complete list of possible treatment-emergent events.

Side effect considerations include the probability of its occurrence, its impact on a patient's quality of life, its time course, and its cause. Just as no one drug is sure to produce clinical improvement in all patients, no side effect, no matter how common, occurs in every patient. When concurrent medical disorders or a history of a similar adverse reaction puts a patient at increased risk for a side effect, it is logical to consider prescribing a compound not typically associated with that adverse reaction.

Side effects can result from the same pharmacologic action that is responsible for a drug's therapeutic activity or from an unrelated property. In examples of the latter, some of the most common adverse effects of the TCAs are caused by blockade of muscarinic acetylcholine receptors or histamine receptors. If a patient is sensitive to these effects, alternative agents without these properties should be prescribed. When side effects are manifestations of the drug's presumed mechanism of action, side effects may be unavoidable.

Thus, blockade of serotonin reuptake by SSRIs can cause nausea and sexual dysfunction. The D_2 blockade of drugs used to treat psychosis can cause extrapyramidal side effects. Agonist action of benzodiazepine receptors can cause ataxia and daytime sleepiness. In these cases, additional medications are frequently used to make the primary agent better tolerated.

Time Course

Adverse effects differ in terms of their onset and duration. Some side effects appear at the outset of treatment and then rapidly diminish. Nausea occurring with SSRIs or venlafaxine (Effexor) and sedation occurring with mirtazapine (Remeron) are good examples of early, time-limited side effects. Early-onset, but persistent, side effects include a dry mouth that is associated with noradrenergic reuptake inhibition or antimuscarinic activity. Some side effects appear later in treatment (*late-appearing side effects*) and, sometimes may be just the opposite of adverse events early in treatment. For example, patients may typically lose weight during early treatment with SSRIs, only to find, over time, a reversal occurs, so that they gain weight.

Similarly, early activation or agitation may be followed by constant fatigue or apathy. Because most data about new drugs come from short-term studies, generally 8 weeks in duration, early-onset side effects are overrepresented in product information and descriptions of newly marketed information. Clinicians must follow the letters to the editor sections of journals and other sources of information to update their understanding of the real side effect profile of a drug.

Adverse effects differ in their impact on compliance and the potential to cause harm. Depending on a patient's threshold of tolerance for a side effect and the impact on the quality of life, side effects can lead to drug discontinuation. Examples of serious side effects include agranulocytosis (clozapine), Stevens–Johnson syndrome (lamotrigine [Lamictal]), hepatic failure (nefazodone [Serzone]), stroke (phenelzine [Nardil]), and heart block (thioridazine [Mellaril]). Overall, the risk of life-threatening side effects with psychotropics is low. Drugs that carry such a risk should be monitored more closely, and the prescribing physician should take into account whether the potential clinical benefits justify the additional risk. Any drug with a serious risk, as reflected in a black box warning, is generally used less extensively

than would otherwise be the case.

Table 21-1
Glossary of Receptor Drug Interactions

Receptor Interaction	Definition	Examples and Comments
Agonist (full agonist)	A drug or medication that binds to a specific receptor producing an effect identical to that usually produced by the neurotransmitter affecting that receptor. Drugs are often designed as receptor agonists to treat a variety of diseases and disorders in which the original neurotransmitter is missing or diminished.	Full agonists include opioids such as morphine, methadone, oxycodone, hydrocodone, heroin, codeine, meperidine, propoxyphene, and fentanyl. Benzodiazepines act as agonists at the GABA receptor complex.
Antagonist	A compound that binds to a receptor that blocks or reduces the action of another substance (agonist) at the receptor site involved. Antagonists that compete with an agonist for a receptor are *competitive antagonists* Those that antagonize by other means are *noncompetitive antagonists*	Flumazenil is a competitive benzodiazepine receptor antagonist. It competitively inhibits the activity at the benzodiazepine recognition site on the GABA/benzodiazepine receptor complex. It is the purest antagonist synthesized. Drugs used in the treatment of schizophrenia block dopamine 2 receptors. Examples of opioid

		antagonists include naltrexone and naloxone.
Partial agonist (mixed agonist)	A compound that (even when fully occupying a receptor) possesses affinity for a receptor, but elicits a partial pharmacologic response at the receptor involved. Partial agonists are often structural analogs of agonist molecules. If neurotransmitter concentrations are low, partial agonists may behave as an agonist. This is why these medications are sometimes called mixed agonists.	Buprenorphine is a partial agonist that produces typical opioid agonist effects and side effects, such as euphoria and respiratory depression, but its maximal effects are less than those of full agonists like heroin and methadone. When used at low doses buprenorphine produces sufficient agonist effect to enable opioid-addicted individuals to discontinue the drugs with fewer withdrawal symptoms.
Inverse agonist	An inverse agonist is an agent that binds to the same receptor as an agonist for that receptor but produces the opposite pharmacologic effect.	Several inverse agonists are currently in clinical development. One particular example is R015-4513, which is the inverse agonist of the benzodiazepine class of drugs. R015-4513 and the benzodiazepines both utilize the same GABA binding site on neurons, yet R015-4513 has the opposite effect, producing severe anxiety rather than the sedative and anxiolytic

	effects associated with benzodiazepines.
	Cannabinoid inverse agonists have been found to reduce appetite, the opposite of the craving effect associated with cannabis.

GABA, γ-aminobutyric acid.
Table by Norman Sussman, M.D.

In the case of haloperidol (Haldol) and other dopamine receptor antagonists (DRAs), long-term complications, such as tardive dyskinesia, have been well documented. Emerging evidence also suggests that the use of dopamine antagonists is associated with a small increase in the risk of breast cancer and that this is related to larger cumulative doses. In cases in which serious risk is associated with a drug, closer medical monitoring of medication treatment is warranted. Because the most widely used psychotropics, such as the SSRIs and SDAs, have only been in use since the 1980s or 1990s, there is less certainty about long-term effects, but no evidence indicates that side effects are not merely extensions of those already evident during initial therapy. It should also be kept in mind that most drugs used in the treatment of chronic medical disorders have not been in use sufficiently long to provide assurances about unintended long-term adverse effects.

Suicidal Ideation and Antidepressant Treatment

The issue of antidepressant-associated suicide has become front-page news, the result of an analysis suggesting a link between medication use and suicidal ideation among children, adolescents, and adults up to age 24 in short-term (4 to 16 weeks), placebo-controlled trials of nine newer antidepressant drugs. The data from trials involving more than 4,400 patients suggested that the average risk of suicidal thinking or behavior (suicidality) during the first few months of treatment in those receiving antidepressants was 4 percent, twice the placebo risk of 2 percent. No suicides occurred in

these trials. The analysis also showed no increase in suicide risk among the 25- to 65-age group. Antidepressants reduced suicidality among those over age 65.

Following public hearings on the subject, in October 2004, the FDA requested the addition of black box warnings—the most severe warning placed on the labeling of prescription medication—to all antidepressant drugs, old and new. This action raised the alarm among parents and physicians and prompted an explosion of advertisements by malpractice attorneys. Most important, antidepressant prescriptions written for adolescents declined, whereas those for adults flattened, after years of growth.

A large study of real-world patients published in the January 2006 issue of the *American Journal of Psychiatry* raised severe doubt about antidepressants and actual suicidality and about the wisdom of the FDA's decision to change the labeling. The study examined suicides and hospitalizations for suicide attempts in the medical records of 65,103 members of a nonprofit insurer in the Pacific Northwest that covers about 500,000 people who received antidepressants from 1992 to 2003. It found that (1) newer antidepressants were associated with a more rapid and more significant reduction in risk than older types of antidepressants, and (2) patients were significantly more likely to attempt or commit suicide in the month before they began drug therapy than in the 6 months after starting it.

This controversy is not the first time credible evidence has contradicted a significant link between antidepressant use and increased risk of suicide. At the hearings that led to the black box warning, John Mann of Columbia University presented population data showing that since 1987, the year before fluoxetine (Prozac) became the first marketed SSRI, suicide rates in the United States began dropping and that areas in the United States with the highest SSRI prescription rates had the most significant decline in suicides. For every 10 percent increase in prescription rates, the US suicide rate declined 3 percent.

Another study, a review of 588 case files of patients aged 10 to 19, found that a 1 percent increase in antidepressant use was associated with a decrease of 0.23 suicides per 100,000 adolescents per year.

A more critical question, given how slight the risk may be, if indeed it exists, is whether as a result of the FDA's ill-considered actions, some

depressed patients are not getting potentially life-saving treatment. Epidemiologic findings from several countries, including the United States, have shown that decreased prescribing of antidepressants for depressed children and adolescents resulted in an increase in suicide rates in those populations.

Medication-Induced Movement Disorders

Medication-induced movement disorders are commonly associated with the use of psychotropic drugs. Although most frequently associated with drugs that block dopamine type 2 (D_2) receptors, abnormal motor activity may occur with other types of medications as well. Sometimes it can be challenging to determine if abnormal motor movements are an adverse event or a symptom of an underlying disorder. For example, anxiety can resemble akathisia, and alcohol or benzodiazepine withdrawal can cause tremors. The American Psychiatric Association has decided to retain the term *neuroleptic* when discussing side effects associated with drugs used to treat psychosis—the DRAs and second-generation antipsychotics (SGAs). The rationale for continued use of the term is that it was initially used to describe the tendency of these drugs to cause abnormal movements. Note that SGA and SDA are often used interchangeably when referring to the second-generation antipsychotics.

The most common neuroleptic-related movement disorders are parkinsonism, acute dystonia, and acute akathisia. The neuroleptic malignant syndrome is a life-threatening and often misdiagnosed condition. Neuroleptic-induced tardive dyskinesia is a late-appearing adverse effect of neuroleptic drugs and can be irreversible; recent data, however, indicate that the syndrome, although still severe and potentially disabling, is less pernicious than was previously thought in patients taking DRAs. The newer antipsychotics, the SDAs, block binding to dopamine receptors to a much lesser degree and thereby are presumed to be less likely to produce such movement disorders. Nevertheless, this risk remains, and vigilance is still required when these drugs are prescribed.

Table 21-2 lists the selected medications associated with movement disorders and their impact on relevant neuroreceptors.

Neuroleptic-Induced Parkinsonism and Other Medication-Induced Parkinsonism

DIAGNOSIS, SIGNS, AND SYMPTOMS. Symptoms of neuroleptic-induced parkinsonism and other medication-induced parkinsonism include muscle stiffness (lead pipe rigidity), cogwheel rigidity, shuffling gait, stooped posture, and drooling. The pill-
rolling tremor of idiopathic parkinsonism is rare, but a regular, coarse tremor similar to essential tremor may be present. The so-called *rabbit syndrome*, a tremor affecting the lips and perioral muscles, is another parkinsonian effect seen with antipsychotics, although perioral tremor is more likely than other tremors to occur late in the course of treatment.

EPIDEMIOLOGY. Parkinsonian adverse effects typically occur within 5 to 90 days of the initiation of treatment. Patients who are elderly and female are at the highest risk for neuroleptic-induced parkinsonism, although the disorder can occur at all ages.

ETIOLOGY. The blockade of D_2 receptors causes neuroleptic-induced parkinsonism in the caudate at the termination of the nigrostriatal dopamine neurons. All antipsychotics can cause the symptoms, especially high-potency drugs with low levels of anticholinergic activity, most notably haloperidol (Haldol).

DIFFERENTIAL DIAGNOSIS. Included in the differential diagnosis are idiopathic parkinsonism, other organic causes of parkinsonism, and depression, which can also be associated with parkinsonian symptoms. Decreased psychomotor activity and blunted facial expression are symptoms of depression and idiopathic parkinsonism.

TREATMENT. Parkinsonism can be treated with anticholinergic agents, benztropine (Cogentin), amantadine (Symmetrel), or diphenhydramine (Benadryl) (Table 21-3). Anticholinergics should be withdrawn after 4 to 6 weeks to assess whether tolerance to the parkinsonian effects has developed; about half of patients with neuroleptic-induced parkinsonism require continued treatment. Even after the antipsychotics are withdrawn, parkinsonian symptoms can last up to 2 weeks. In elderly patients, this may

last as long as 3 months. With such patients, the clinician may continue the anticholinergic drug after the antipsychotic has been stopped until the parkinsonian symptoms resolve completely.

Neuroleptic Malignant Syndrome

DIAGNOSIS, SIGNS, AND SYMPTOMS. *Neuroleptic malignant syndrome* is a life-threatening complication that can occur anytime during antipsychotic treatment. The motor and behavioral symptoms include muscular rigidity and dystonia, akinesia, mutism, obtundation, and agitation. The autonomic symptoms include hyperthermia, diaphoresis, and increased pulse and blood pressure (BP). Laboratory findings include an increased white blood cell (WBC) count and increased levels of creatinine phosphokinase, liver enzymes, plasma myoglobin, and myoglobinuria, occasionally associated with renal failure.

Table 21-2
Selected Medications Associated with Movement Disorders: Impact on Relevant Neuroreceptors

Type (Subtype)	Name (Brand)	D_2 Blockade	5-HT_2 Blockade	mACh Blockade
Antipsychotics				
Phenothiazine (Aliphatic)	Chlorpromazine (Thorazine)	Low	High	High
Phenothiazine (Piperidines)	Thioridazine (Mellaril)	Low	Med	High
	Mesoridazine (Serentil)	Low	Med	High
Phenothiazine (Piperazines)	Trifluoperazine (Stelazine)	Med	Med	Med
	Fluphenazine (Prolixin)	High	Low	Low
	Perphenazine (Trilafon)	High	Med	Low
Thioxanthenes	Thiothixene (Navane)	High	Med	Low
	Chlorprothivene (Taractan)	Med	High	Med
Dibenzoxazepines	Loxapine (Loxitane)	Med	High	Low
Butyrophenones	Haloperidol (Haldol)	High	Low	Low
	Droperidol (Inapsine)	High	Med	—
Diphenyl-butylpiperidines	Pimozide (Orap)	High	Med	Low
Dihydroindolones	Molindone (Moban)	Med	Low	Low
Dibenzodiazepines	Clozapine (Clozaril)	Low	High	High
Benzisoxazole	Risperidone (Risperdal)	High	High	Low
Thienobenzodiazepines	Olanzapine (Zyprexa)	Low	High	High
Dibenzothiazepines	Quetiapine (Seroquel)	Low/med	Low/med	Low
Benzisothiazolvils	Ziprasidone (Geodon)	Med	High	Low
Quinolones	Aripiprazole (Abilify)	High (as partial agonist)	High	Low
Nonantipsychotic psychotropics	Lithium (Eskalith)	N/A	N/A	N/A
Anticonvulsants		Low	Low	Low
Antidepressants		Low (except amoxapine)	(Varies)	(Varies)
Nonpsychotropics	Prochlorperazine (Compazine)	High	Med	Low
	Metoclopramide (Reglan)	High	High	—

D_2, dopamine type 2; 5-HT_2, 5-hydroxytryptomine type 2; mACh, muscarinic acetylcholine; N/A, not applicable.
Adapted from Janicak PG, Davis JM, Preskorn SH, Ayd FJ Jr. *Principles and Practice of Psychopharmacotherapy*. 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2001, with permission.

EPIDEMIOLOGY. About 0.01 to 0.02 percent of patients treated with antipsychotics develop neuroleptic malignant syndrome. Men are affected more frequently than women, and young patients are affected more commonly than elderly patients. The mortality rate can reach 10 to 20 percent or even higher when depot antipsychotic medications are involved.

COURSE AND PROGNOSIS. The symptoms usually evolve over 24 to 72 hours, and the untreated syndrome lasts 10 to 14 days. The diagnosis is often missed in the early stages, and the withdrawal or agitation may mistakenly be considered to reflect an exacerbation of the psychosis.

TREATMENT. In addition to supportive medical treatment, the most commonly used medications for the condition are dantrolene (Dantrium) and bromocriptine (Parlodel), although amantadine (Symmetrel) is sometimes used (Table 21-4). Bromocriptine and amantadine pose direct DRA effects and may overcome the antipsychotic-induced dopamine receptor blockade.

We should reduce the antipsychotic dose to the lowest effective dose possible. High-potency drugs, such as haloperidol, pose the greatest risk. Antipsychotic drugs with anticholinergic effects seem less likely to cause neuroleptic malignant syndrome. Electroconvulsive therapy (ECT) has been used.

Medication-Induced Acute Dystonia

DIAGNOSIS, SIGNS, AND SYMPTOMS. *Dystonias* are brief or prolonged contractions of muscles that result in obviously abnormal movements or postures, including oculogyric crises, tongue protrusion, trismus, torticollis, laryngeal–pharyngeal dystonias, and dystonic postures of the limbs and trunk. Other dystonias include blepharospasm and glossopharyngeal dystonia; the latter results in dysarthria, dysphagia, and even difficulty in breathing, which can cause cyanosis. Children are particularly likely to evidence opisthotonos, scoliosis, lordosis, and writhing movements. Dystonia can be painful and frightening and often results in noncompliance with future drug treatment regimens.

EPIDEMIOLOGY. Their early-onset characterizes the development of acute dystonic symptoms during treatment with neuroleptics. There is a higher incidence of acute dystonia in men, in patients younger than age 30 years, and patients who were given high dosages of high-potency medications.

ETIOLOGY. Although it is most frequent with intramuscular doses of high-potency antipsychotics, dystonia can occur with any antipsychotic. The mechanism of action is thought to be dopaminergic hyperactivity in the basal ganglia that occurs when the central nervous system (CNS) levels of the antipsychotic drug begin to fall between doses.

Table 21-3
Drug Treatment of Extrapyramidal Disorders

Generic Name	Trade Name	Usual Daily Dosage	Indications
Anticholinergics			

Benztropine	Cogentin	PO 0.5–2 mg tid; IM or IV 1–2 mg	Acute dystonia, parkinsonism, akinesia, akathisia
Biperiden	Akineton	PO 2–6 mg tid; IM or IV 2 mg	
Procyclidine	Kemadrin	PO 2.5–5 mg bid-qid	
Trihexyphenidyl	Artane, Tremin	PO 2–5 mg tid	
Orphenadrine	Norflex, Disipal	PO 50–100 mg bid-qid; IV 60 mg	Rabbit syndrome
Antihistamine			
Diphenhydramine	Benadryl	PO 25 mg qid; IM or IV 25 mg	Acute dystonia, parkinsonism, akinesia, rabbit syndrome
Amantadine	Symmetrel	PO 100–200 mg bid	Parkinsonism, akinesia, rabbit syndrome
β-Adrenergic Antagonist			
Propranolol	Inderal	PO 20–40 mg tid	Akathisia, tremor
α-Adrenergic Antagonist			
Clonidine	Catapres	PO 0.1 mg tid	Akathisia

Benzodiazepines			
Clonazepam	Klonopin	PO 1 mg bid	Akathisia, acute dystonia
Lorazepam	Ativan	PO 1 mg tid	
Buspirone	BuSpar	PO 20–40 mg qid	Tardive dyskinesia
Vitamin E	—	PO 1,200–1,600 IU/day	Tardive dyskinesia

PO, orally; IM, intramuscularly; IV, intravenously; bid, twice a day; tid, three times a day; qid; four times a day.

DIFFERENTIAL DIAGNOSIS. The differential diagnosis includes seizures and tardive dyskinesia.

COURSE AND PROGNOSIS. Dystonia can fluctuate spontaneously and respond to reassurance, so the clinician gets the false impression that the movement is hysterical or entirely under conscious control.

Table 21-4
Treatment of Neuroleptic Malignant Syndrome

Intervention	Dosing	Effectiveness
Amantadine	200–400 mg PO/day in divided doses	Beneficial as monotherapy or in combination; decrease in death rate
Bromocriptine	2.5 mg PO bid or tid, may increase to a total of 45 mg/day	Mortality reduced as a single or combined agent
Levodopa/carbidopa	Levodopa 50–100 mg/day	Case reports of

	IV as continuous infusion	dramatic improvement
Electroconvulsive therapy	Reports of good outcome with both unilateral and bilateral treatments; response may occur in as few as three treatments	Effective when medications have failed; also may treat underlying psychiatric disorder
Dantrolene	1 mg/kg/day for 8 days, then continue as PO for 7 additional days	Benefits may occur in minutes or hours as a single agent or in combination
Benzodiazepines	1–2 mg IM as test dose; if effective, switch to PO; consider use if underlying disorder has catatonic symptoms	Has been reported effective when other agents have failed
Supportive measures	IV hydration, cooling blankets, ice packs, ice-water enema, oxygenation, antipyretics	Often effective as initial approach early in the episode

PO, orally; bid, twice a day; tid, three times a day; IV, intravenously; IM, intramuscularly.
Adapted from Davis JM, Caroif SN, Mann SC. Treatment of neuroleptic malignant syndrome. *Psychiatr Ann*. 2000;30:325–331, with permission.

TREATMENT. Prophylaxis with anticholinergics or related drugs (outlined in Table 21-3) usually prevents dystonia, although the risks of prophylactic treatment weigh against that benefit. Treatment with intramuscular anticholinergics or intravenous or intramuscular diphenhydramine (Benadryl) (50 mg) almost always relieves the symptoms. Diazepam (Valium) (10 mg intravenously), amobarbital (Amytal), caffeine sodium benzoate, and hypnosis have also been reported to be effective. Although tolerance for the

adverse effects usually develops, it is prudent to change the antipsychotic if the patient is particularly concerned that the reaction may recur.

Medication-Induced Acute Akathisia

DIAGNOSIS, SIGNS, AND SYMPTOMS. *Akathisia* is subjective feelings of restlessness, objective signs of restlessness, or both. Examples include a sense of anxiety, inability to relax, jitteriness, pacing, rocking motions while sitting, and rapid alternation of sitting and standing. Akathisia has been associated with the use of a wide range of psychiatric drugs, including antipsychotics, antidepressants, and sympathomimetics. Once akathisia is recognized and diagnosed, the antipsychotic dose should be reduced to a minimally adequate level. Akathisia may be associated with a poor treatment outcome.

EPIDEMIOLOGY. Middle-aged women are at increased risk of akathisia, and the time course is similar to that for neuroleptic-induced parkinsonism.

TREATMENT. Three necessary steps in the treatment of akathisia are reducing medication dosage, attempting treatment with appropriate drugs, and considering changing the neuroleptic. The most efficacious drugs are β-adrenergic receptor antagonists, although anticholinergic drugs, benzodiazepines, and cyproheptadine (Periactin) may benefit some patients. In some cases of akathisia, no treatment seems to be effective.

Tardive Dyskinesia

DIAGNOSIS, SIGNS, AND SYMPTOMS. *Tardive dyskinesia* is a delayed effect of antipsychotics; it rarely occurs until after 6 months of treatment. The disorder consists of abnormal, involuntary, irregular choreoathetoid movements of the muscles of the head, limbs, and trunk. The severity of the movements ranges from minimal—often missed by patients and their families—to grossly incapacitating. Perioral movements are the most common and include darting, twisting, and protruding movements of the tongue; chewing and lateral jaw movements; lip-puckering; and facial grimacing. Finger movements and hand clenching are also typical. Torticollis, retrocollis, trunk twisting, and pelvic thrusting occur in severe cases. In the most severe cases,

patients may have breathing and swallowing irregularities that result in aerophagia, belching, and grunting. Respiratory dyskinesia has also been reported. Dyskinesia is exacerbated by stress and disappears during sleep.

Table 21-5
Abnormal Involuntary Movement Scale (AIMS) Examination Procedure

Patient Identification	Date

Rated by

Either before or after completing the examination procedure, observe the patient unobtrusively at rest (e.g., in waiting room).

The chair to be used in this examination should be a hard, firm one without arms.

After observing the patient, rate him or her on a scale of 0 (none), 1 (minimal), 2 (mild), 3 (moderate), and 4 (severe), according to the severity of the symptoms.

Ask patient whether there is anything in his or her mouth (e.g., gum, candy) and, if so, to remove it.

Ask patient about the current condition of his or her teeth. Ask patient if he or she wears dentures. Do teeth or dentures bother patient now?

Ask patient whether he or she notices movement in mouth, face, hands, or feet. If yes, ask patient to describe and indicate to what extent movements currently bother patient or interfere with his or her activities.

0 1 2 3 4 Have patient sit in chair with hands on knees, legs slightly apart, and feet flat on floor. (Look at entire body for movement while in this position.)

0 1 2 3 4 Ask patient to sit with hands hanging unsupported—If male, between legs; if female and wearing a dress, hanging over knees. (Observe hands and other body areas.)

0 1 2 3 4 Ask patient to open mouth. (Observe tongue at rest within mouth.) Do this twice.

0 1 2 3 4 Ask patient to protrude tongue. (Observe abnormalities of tongue movement.) Do this twice.
0 1 2 3 4 Ask patient to tap thumb, with each finger, as rapidly as possible for 10–15 seconds; separately with right hand, then with left hand. (Observe facial and leg movements.)
0 1 2 3 4 Flex and extend patient's left and right arms. (One at a time.)
0 1 2 3 4 Ask patient to stand up. (Observe in profile. Observe all body areas again, hips included.)
0 1 2 3 4 [a]Ask patient to extend both arms outstretched in front with palms down. (Observe trunk, legs, and mouth.)
0 1 2 3 4 [a]Have patient walk a few paces, turn, and walk back to chair. (Observe hands and gait.)
Do this twice.

[a]Activated movements.

EPIDEMIOLOGY. Tardive dyskinesia develops in about 10 to 20 percent of patients who are treated for more than a year. About 20 to 40 percent of patients who require long-term hospitalization have tardive dyskinesia. Women are more likely to be affected than men. Children, patients who are more than 50 years of age, and patients with brain damage or mood disorders are also at high risk.

COURSE AND PROGNOSIS. Between 5 and 40 percent of all cases of tardive dyskinesia eventually remit, and between 50 and 90 percent of all mild cases remit. Tardive dyskinesia is less likely to remit in elderly patients than in young patients, however.

TREATMENT. The three basic approaches to tardive dyskinesia are prevention, diagnosis, and management. Prevention is best achieved by using antipsychotic medications only when indicated and in the lowest effective doses. The atypical antipsychotics are associated with less tardive dyskinesia than the older antipsychotics. Clozapine (Clozaril) is the only antipsychotic to have minimal risk of tardive dyskinesia and can even help improve preexisting symptoms of tardive dyskinesia. This quality of the drug may be

due to its low affinity for D_2 receptors and high affinity for 5-hydroxytryptamine (5-HT) receptor antagonism. Patients who are receiving antipsychotics should be examined regularly for the appearance of abnormal movements, preferably with the use of a standardized rating scale (Table 21-5). Patients frequently experience an exacerbation of their symptoms when the DRA is withheld, whereas substitution of an SDA may limit the abnormal movements without worsening the progression of the dyskinesia.

Once tardive dyskinesia is recognized, the clinician should consider reducing the dose of the antipsychotic or even stopping the medication altogether. Alternatively, the clinician may switch the patient to clozapine or one of the new SDAs. In patients who cannot continue taking any antipsychotic medication, lithium (Eskalith), carbamazepine (Tegretol), or benzodiazepines may effectively reduce the symptoms of both the movement disorder and the psychosis. In 2017, the FDA-approved valbenazine (Ingrezza) for the treatment of adults with tardive dyskinesia, making this the first approved medication for tardive dyskinesia.

Tardive Dystonia and Tardive Akathisia. On occasion, dystonia and akathisia emerge late in the course of treatment. These symptoms may persist for months or years despite drug discontinuation or dose reduction.

Medication-Induced Postural Tremor

DIAGNOSIS, SIGNS, AND SYMPTOMS. *Tremor* is a rhythmic alteration in a movement that is usually faster than one beat per second. Fine tremor (8 to 12 Hz) is most common.

EPIDEMIOLOGY. Typically, tremors decrease during periods of relaxation and sleep and increase with stress or anxiety.

ETIOLOGY. Whereas all the above diagnoses specifically include an association with a neuroleptic, a range of psychiatric medications can produce tremors—most notably, lithium, stimulants, antidepressants, caffeine, and valproate (Depakene).

TREATMENT. The treatment involves four principles:

1. The lowest possible dose of the psychiatric drug should be taken.
2. Patients should minimize caffeine consumption.
3. The psychiatric drug should be taken at bedtime to minimize the amount of daytime tremor.
4. β-Adrenergic receptor antagonists (e.g., propranolol [Inderal]) can be given to treat drug-induced tremors.

Other Medication-Induced Movement Disorders

NOCTURNAL MYOCLONUS. *Nocturnal myoclonus* consists of highly stereotyped, abrupt contractions of specific leg muscles during sleep. Patients lack any subjective awareness of the leg jerks. The condition may be present in about 40 percent of persons over 65 years of age. The cause is unknown, but it is a rare side effect of SSRIs.

The repetitive leg movements occur every 20 to 60 seconds, with extensions of the large toe and flexion of the ankle, the knee, and the hips. Frequent awakenings, unrefreshing sleep, and daytime sleepiness are significant symptoms. No treatment for nocturnal myoclonus is universally effective. Benzodiazepines, levodopa (Larodopa), quinine, and, in rare cases, opioids may be useful.

RESTLESS LEG SYNDROME. In *restless leg syndrome*, persons feel deep sensations of creeping inside the calves whenever sitting or lying down. The dysesthesias are rarely painful but are agonizingly relentless and cause an almost irresistible urge to move the legs; thus, this syndrome interferes with sleep and with falling asleep. It peaks in middle age and occurs in 5 percent of the population. The cause is unknown, but it is a rare side effect of SSRIs.

Symptoms are relieved by movement and by leg massage. The dopamine receptor agonists ropinirole (Requip) and pramipexole (Mirapex) are effective in treating this syndrome. Other treatments include the benzodiazepines, levodopa, quinine, opioids, propranolol, valproate, and carbamazepine.

Hyperthermic Syndromes. All the medication-induced movement disorders may be associated with hyperthermia. Table 21-6 lists the various conditions associated with hyperthermia.

Side Effects Associated with Newer Medications

All medications are associated with side effects. The clinician should be aware of these, be able to recognize them, and take appropriate measures to treat them.

Somnolence. Sedation is often an intended effect of many psychotropic drugs, mainly when used to treat insomnia, anxiety, or agitation. Daytime sleepiness, or somnolence, is also an unwanted adverse event, however. It is essential for the clinician to alert patients to the possibility of sedation and to document that the person was advised to exercise caution when operating any type of vehicle or mechanical equipment. Some somnolence results from a carryover of nighttime use of drugs as hypnotics. Even with drugs such as the SSRIs, which are activating for many patients, somnolence can be problematic. In some instances, it results from impairment of sleep quality. Chronic use of SSRIs can cause some patients to experience a subjective sense of fatigue, exhaustion, or yawning, even with adequate amounts of sleep. Management of unwanted somnolence includes adjustment of dose or timing of administration, switching to alternative medications, the addition of small doses of stimulants, or the addition of modafinil (Provigil).

Gastrointestinal Disturbances. The significant gastrointestinal (GI) side effects of the older antidepressant and antipsychotic drugs consisted primarily of constipation and dry mouth, a consequence of their antimuscarinic activity. Most of the newer drugs have little antimuscarinic activity but do have effects on the serotonin system. Most of the body's serotonin is in the GI tract, and serotonergic drugs often cause varying degrees of stomach pain, nausea, flatulence, and diarrhea. In most cases, these side effects are transient, but some persons never accommodate and must switch to another class of drugs. The initial use of lower doses or the use of delayed-release preparations are the most effective strategies for minimizing GI side effects.

Movement Disorders. The introduction of SDAs has dramatically reduced the incidence of medication-induced movement disorders, but varying degrees of dose-related parkinsonism, akathisia, and dystonia still occur. Risperidone (Risperdal) most closely resembles the older agents in terms of these side effects. Olanzapine (Zyprexa) also causes more extrapyramidal

effects than clinical trials suggested. Aripiprazole (Abilify) causes severe akathisia. There have been rare reports of SSRI-induced movement disorders, ranging from akathisia to tardive dyskinesia.

Sexual Dysfunction. The use of psychiatric drugs can be associated with sexual dysfunction—decreased libido, impaired ejaculation and erection, and inhibition of female orgasm. In clinical trials with the SSRIs, the extent of sexual side effects was grossly underestimated because data were based on spontaneous reports by patients. The rate of sexual dysfunction in the original fluoxetine product information, for example, was less than 5 percent. In subsequent studies in which specific questions elicited information about sexual side effects, the rate of SSRI-associated sexual dysfunction was found to be between 35 and 75 percent. In clinical practice, patients are not likely to report sexual dysfunction spontaneously to the physician, so it is essential to ask about this side effect. Also, some sexual dysfunctions may be related to the primary psychiatric disorder.

Table 21-6
Drug-Induced Central Hyperthermic Syndromes[a]

Condition (and Mechanism)	Common Drug Causes	Frequent Symptoms	Possible Treatment[a]	Clinical Course
Hyperthermia (↓ heat dissipation, ↑ heat production)	Atropine, lidocaine, meperidine NSAID toxicity, pheochromocytoma, thyrotoxicosis	Hyperthermia, diaphoresis, malaise	Acetaminophen per rectum (325 mg every 4 hr), diazepam oral or per rectum (5 mg every 8 hr) for febrile seizures	Benign, febrile seizures in children
Malignant hyperthermia (↑ heat production)	NMJ blockers (succinylcholine), halothane	Hyperthermia, muscle rigidity, arrhythmias, ischemia,[c] hypotension, rhabdomyolysis; disseminated intravascular coagulation	Dantrolene sodium (1–2 mg/kg/min IV infusion)[d]	Familial, 10% mortality if untreated
Tricyclic overdose (↑ heat production)	Tricyclic antidepressants, cocaine	Hyperthermia, confusion, visual hallucinations, agitation, hyperreflexia, muscle relaxation, anticholinergic effects (dry skin, pupil dilation), arrhythmias	Sodium bicarbonate (1 mEq/kg IV bolus) if arrhythmia is present, physostigmine (1–3 mg IV) with cardiac monitoring	Fatalities have occurred if untreated
Autonomic hyperreflexia (↑ heat production)	CNS stimulants (amphetamines)	Hyperthermia, excitement, hyperreflexia	Trimethaphan (0.3–7 mg/min IV infusion)	Reversible
Lethal catatonia (↓ heat dissipation)	Lead poisoning	Hyperthermia, intense anxiety, destructive behavior, psychosis	Lorazepam (1–2 mg IV every 4 hr), antipsychotics may be contraindicated	High mortality if untreated
Neuroleptic malignant syndrome (mixed; hypothalamic, ↓ heat dissipation, ↑ heat production)	Antipsychotics (neuroleptics), methyldopa, reserpine	Hyperthermia, muscle rigidity, diaphoresis (60%), leukocytosis, delirium, rhabdomyolysis, elevated CPK, autonomic deregulation, extrapyramidal symptoms	Bromocriptine (2–10 mg every 8 hr orally or nasogastric tube), lysuride (0.02–0.1 mg/hr IV infusion), carbidopa-levodopa (Sinemet) (25/100 PO every 8 hr), dantrolene sodium (0.3–1 mg/kg IV every 6 hr)	Rapid onset, 20% mortality if untreated

NSAID, nonsteroidal anti-inflammatory drug; MAOI, monoamine oxidase inhibitor; NMJ, neuromuscular junction; CNS, central nervous system; CPK, creatine phosphokinase; PO, orally; IV, intravenously.
[a]Boldface indicates features that may be used to distinguish one syndrome from another.
[b]Gastric lavage and supportive measures, including cooling, are required in most cases.
[c]Oxygen consumption increases by 7% for every 1°F increase in body temperature.
[d]Has been associated with idiosyncratic hepatocellular injury, as well as severe hypotension in one case.
From Theoharides TC, Harris RS, Weckstein D. Neuroleptic malignant-like syndrome due to cyclobenzaprine? [letter]. *J Clin Psychopharmacol.* 1995;15:80, with permission.

Nevertheless, if sexual dysfunction emerges after pharmacotherapy has begun and the primary response to treatment has been positive, it may be worthwhile to attempt to treat the symptoms. Long lists of possible antidotes to these side effects have evolved, but few interventions are consistently effective, and few have more than anecdotal evidence to support their use. The clinician and patient should consider the possibility of sexual side effects when selecting a drug and switching treatment to another drug that is less or not at all associated with sexual dysfunction if this adverse effect is not acceptable to the patient.

Weight Gain. Weight gain accompanies the use of many psychotropic drugs as a result of retained fluid, increased caloric intake, decreased exercise, or altered metabolism. Weight gain can also occur as a symptom of a disorder, as in bulimia or atypical depression. In these cases, it may be a sign of

recovery. Treatment-emergent increase in body weight is a common reason for noncompliance with a drug regimen. No specific mechanisms have been identified as causing weight gain, and it appears that the histamine and serotonin systems mediate changes in weight associated with many drugs used to treat depression and psychosis. Metformin (Glucophage) has been reported to facilitate weight loss among patients whose weight gain is attributed to the use of serotonin-dopamine reuptake inhibitors and valproic acid (Depakene). Valproate (Depacon), as well as olanzapine, has been linked to the development of insulin resistance, which could induce appetite increase, with the subsequent weight increase. Weight gain is a noteworthy side effect of clozapine (Clozaril) and olanzapine. Genetic factors that regulate body weight, as well as the related problem of diabetes mellitus, seem to involve the 5-HT_{2C} receptor. There is a genetic polymorphism of the promoter region of this receptor, and patients with a variant allele have less weight gain. Drugs with a strong 5-HT_{2C} affinity would be expected to have a more significant impact on body weight of patients with a polymorphism of the 5-HT_{2C} receptor promoter region.

Weight Loss. Initial weight loss is associated with SSRI treatment but is usually transient, with most weight being regained within the first few months. Bupropion (Wellbutrin) has been shown to cause modest weight loss that is sustained. When combined with diet and lifestyle changes, bupropion can facilitate more significant weight loss. Topiramate (Topamax) and zonisamide (Zonegran), marketed as treatments for epilepsy, sometimes produce substantial, sustained loss of weight.

Glucose Changes. Increased risk of glucose abnormalities, including diabetes mellitus, is associated with weight increase during psychotropic drug therapy. Clozapine and olanzapine are associated with a greater risk than other SDAs of abnormalities in fasting glucose levels, as well as hyperosmolar diabetes and ketoacidosis. This dysregulation of glucose homeostasis appears to be drug-induced and increases glucagon.

Hyponatremia. Hyponatremia is associated with oxcarbazepine (Trileptal) and SSRI treatment, especially in elderly patients. Confusion, agitation, and lethargy are common symptoms.

Cognitive Impairment. Cognitive impairment means a disturbance in the capacity to think. Some agents, such as the benzodiazepine agonists, are recognized as causes of cognitive impairment. Other widely used psychotropics, such as the SSRIs, lamotrigine (Lamictal), topiramate (Topamax), gabapentin (Neurontin), lithium, TCAs, and bupropion, however, are also associated with varying degrees of memory impairment and word-finding difficulties. In contrast to the benzodiazepine-induced anterograde amnesia, these agents cause a more subtle type of absent-mindedness. Drugs with anticholinergic properties are likely to worsen memory performance.

Sweating. Severe perspiration unrelated to ambient temperature is associated with TCAs, SSRIs, and venlafaxine. This side effect is often socially disabling. Attempts can be made to treat this side effect with alpha agents, such as terazosin (Hytrin) and oxybutynin (Ditropan).

Cardiovascular Disturbances. Newer agents are less likely to have direct cardiac effects. Many older agents, such as TCAs and phenothiazines, affected BP and cardiac conduction. Thioridazine (Mellaril), which has been in use for decades, has been shown to prolong the QTc interval in a dose-related manner and may increase the risk of sudden death by delaying ventricular repolarization and causing torsades de pointes. Newer drugs are now routinely scrutinized for evidence of cardiac effects. A promising treatment for psychosis, sertindole (Serlect), was not marketed because the FDA would have required a black box warning. Slight QTc effects noted with ziprasidone (Geodon) delayed the marketing of that drug. Clozapine can cause myocarditis in rare cases.

Rash. Any medication is a potential source of a drug rash. Some psychotropics, such as carbamazepine (Equetro, Tegretol) and lamotrigine, have been linked to an increased risk of severe exfoliative dermatitis. Commonly referred to as Stevens–Johnson syndrome, this condition is a systemic, immune-mediated reaction that can prove fatal or result in permanent scarring or blindness. All patients should be informed about the potential seriousness of widespread lesions that occur above the neck, that involve the mucous membranes, and that may be associated with fever and

lymphadenopathy. If such symptoms manifest, a patient should be instructed at the time that the medication is prescribed to go immediately to an emergency department.

Idiosyncratic and Paradoxical Drug Responses

Idiosyncratic reactions occur in a tiny percentage of patients taking a drug. The reactions are not related to the known pharmacologic properties, and most likely represent a genetically based abnormal sensitivity to a drug. A paradoxical response represents the manifestation of a clinical effect the opposite of what is expected. In March 2007, the FDA reported dissociative-like states associated with certain sedative-hypnotics. These included behaviors such as sleepwalking, binge eating, aggressive outbursts, and night driving, of which the patient was unaware. Table 21-7 lists the drugs required to have warning labels for that effect.

Therapeutic Index

The therapeutic index is a relative measure of the toxicity or safety of a drug and is defined as the ratio of the median toxic dose to the median effective dose. The median toxic dose is the dose at which 50 percent of patients experience a specific toxic effect, and the median effective dose is the dose at which 50 percent of patients have a specified therapeutic effect. When the therapeutic index is high, as it is for haloperidol, it is reflected by the wide range of dosages in which that drug is prescribed. Conversely, the therapeutic index for lithium is relatively low, thus requiring careful monitoring of serum lithium levels in patients for whom the drug is prescribed.

Overdose

Safety in overdose is always a consideration in drug selection. Almost all of the newer agents, however, have a wide margin of safety when taken in overdose. By contrast, a 1-month supply of TCAs could be fatal. The depressed patients they were used to treat are the group most at risk of attempting suicide. Because even the safest drugs can sometimes produce severe medical complications, especially when combined with other agents, clinicians must recognize that the prescribed medication can be used in an attempt to commit suicide. Although it is prudent to write nonrefillable

prescriptions for small quantities, this practice passes along increased copay costs to the patient. Many pharmacy benefit management programs encourage the prescribing of a 3-month supply of medication.

Table 21-7
Sedative-Hypnotics Cited by the U.S. Food and Drug Administration

Drug	Manufacturer
Zolpidem (Ambien/Ambien CR)	Sanofi Aventis
Butabarbital (Butisol Sodium)	MedPointe Pharmaceuticals
Pentobarbital and carbromal (Carbrital)	Parke-Davis
Flurazepam (Dalmane)	Valeant Pharmaceuticals
Quazepam (Doral)	Questcor Pharmaceuticals
Triazolam (Halcion)	Pfizer
Eszopiclone (Lunesta)	Sepracor
Ethchlorvynol (Placidyl)	Abbott
Estazolam (Prosom)	Abbott
Temazepam (Restoril)	Tyco Healthcare
Ramelteon (Rozerem)	Takeda
Secobarbital (Seconal)	Lilly
Zaleplon (Sonata)	King Pharmaceuticals

In cases in which suicide is a significant concern, an attempt should be made to verify that the medication is not being hoarded for a later overdose attempt. Random pill counts or asking a family member to dispense daily doses may be helpful. Some patients attempt suicide just as they are beginning to recover. Large quantities of medications with a low therapeutic index should be prescribed judiciously. Another reason to limit the number of

pills prescribed is the possibility of accidental ingestion of medications by children in the household. Psychotherapeutic medications should be kept in a safe place.

Physicians who work in emergency departments should know which drugs can be hemodialyzed. The issues involved are complex and are not based on any single chemical property of the drug. For example, it is generally presumed that drugs with low protein binding are good candidates for dialysis. Venlafaxine, however, is only 27 percent protein-bound and is too large as a molecule dialyzed. Hemodialysis is useful for treating overdose of lithium and valproic acid.

Pharmacokinetics

Pharmacokinetic drug interactions are the effects of drugs on the plasma concentrations of each other, and *pharmacodynamic drug interactions* are the effects of drugs on the biologic activities of each other. Pharmacokinetic concepts are used to describe and predict the time course of drug concentrations in different parts of the body, such as plasma, adipose tissue, and the CNS. From a clinical perspective, pharmacokinetic methods help explain or predict the onset and duration of drug activity and interactions between drugs that alter their metabolism or excretion.

Pharmacogenetic research focuses on finding variant alleles that alter drug pharmacokinetics and pharmacodynamics. Researchers are attempting to identify genetic differences in how enzymes metabolize psychotropics, as well as CNS proteins directly involved in drug action. Likely, identification of patient genotypes will facilitate the prediction of clinical response to different types of drugs.

Most clinicians need to consult charts or computer programs to determine when potential interactions may occur and, if so, how clinically relevant they may be. Whenever possible, it is preferable to use a medication that produces the minimal risk of drug interactions. Also, it is recommended that prescribers know the interaction profiles of the drugs they most commonly prescribe.

Examples of pharmacokinetic interactions include one drug increasing or decreasing the concentrations of a coadministered compound. These types of interactions can also lead to altered concentrations of metabolites. In some

cases, there may also be interference with the conversion of a drug to its active metabolite. Enormous variability exists among patients concerning pharmacokinetic parameters, such as drug absorption and metabolism. Another type of interaction is represented by interactions involving the kidney. Commonly used medications, such as angiotensin-converting enzyme inhibitors (ACEIs), nonsteroidal anti-inflammatory drugs (NSAIDs), and thiazides, decrease the renal clearance of lithium, increasing the likelihood of severe elevations of lithium. Drug interactions can occur pharmacokinetically or pharmacodynamically.

Pharmacogenetics is being used to study why patients differ in the way they metabolize drugs. In patients who are ultrarapid or extensive metabolizers, the concentrations of a drug may be lower than expected.

PATIENT-RELATED FACTORS

Response to medication and sensitivity to side effects are influenced by factors related to the patient. This response is why there is no one-size-fits-all approach to pharmacologic treatment. Patient-related variables include diagnosis, genetic factors, lifestyle, overall medical status, concurrent disorders, and history of drug response. A patient's attitude toward medication in general, aversion to certain types of side effects, and preference for a specific agent also need to be considered.

Diagnosis

Failure to correctly diagnose a disorder diminishes the likelihood of optimal drug selection. Misdiagnosis not only can result in a missed opportunity, but it also can, at times, produce worsening of symptoms. Inadvertently diagnosing a patient in the depressed phase of bipolar disorder as having unipolar depression can induce mania or rapid cycling. Treatment failure or exacerbation of symptoms should prompt a reassessment of the working diagnosis.

Past Treatment Response

A specific drug should be selected according to the patient's history of drug response (compliance, therapeutic response, adverse effects), the patient's

family history of drug response, the profile of adverse effects for that drug concerning the particular patient, and the prescribing clinician's usual practice. If a drug has previously been effective in treating a patient or a family member, the same drug should be used again. For reasons that are not understood, however, some patients fail to respond to a previously effective agent when it is resumed. A history of severe adverse effects from a specific drug is a strong indicator that the patient would not be compliant with that particular drug.

It is helpful if patients can recall the details of past psychotropic drug treatment: the drugs prescribed, in what dosages, for how long, and in what combinations. Because of their psychiatric disorders, many patients, however, are poor historians. If possible, patients' medical records should be obtained to confirm their reports. Family members are a good source of collateral information.

Response in Family Members

It is widely held that drug responses cluster in families. Response to a drug in a relative may predict a patient's response. Although no conclusive evidence supports this as a consideration in drug selection, existing studies do confirm that a history of positive response to treatment with a drug should be considered in making treatment decisions. Of course, certain drugs may not have been available to a family member depending on the era in which they were treated.

Concurrent Medical or Psychiatric Disorders

The initial assessment should elicit information about coexisting medical disorders. In some cases, a medical disorder may be responsible for the symptoms. Patients with thyroid disease who are not adequately treated may appear depressed. Sleep apnea produces depression and cognitive impairment. Rare conditions, such as Kleine–Levin syndrome, can mimic bipolar disorder. A drug should be selected that minimally exacerbates any preexisting medical problems that a particular patient may have.

Recreational drug use, excessive consumption of alcohol, and frequent ingestion of caffeine-containing beverages can complicate and even undermine psychotropic drug treatment. These compounds possess

significant psychoactive properties and, in some cases, may represent the source of the patient's symptoms. It is reasonable to ask patients to abstain from the use of these substances, at least until the benefits of psychotropic drug treatment have been unequivocally established. Gradual reintroduction of moderate amounts of alcohol, tea, and coffee can then take place. Patients can then observe for themselves whether there are any untoward effects on their clinical status.

INFORMED CONSENT AND PATIENT EDUCATION

Establishing trust and motivating the patient to comply with the medication regimen are essential components of successful treatment. Patients should be informed about treatment options and the probable side effects and unique benefits of each treatment. Patient preference should be respected unless a compelling advantage exists involving efficacy, tolerability, or safety with an alternative agent. If a particular medication is being recommended, the reasons for this recommendation should be explained. Patients are more likely to continue taking their medication if they fully understand the reasons why it is being prescribed.

A strong therapeutic alliance between a clinician and a patient is always helpful. Given the unpredictability of medication response, the frequent occurrence of side effects, and underlying ambivalence about, or fear of taking, medication, a constructive, trusting relationship serves to improve patient compliance. Repeated failed trials may be needed before a response is seen. A patient's confidence in the physician's knowledge and judgment enables medication trials and more complex regimens, such as the use of multiple medications.

Discussions about drug selection should be documented in notes, but a signed informed consent is not needed. Surprisingly, patients who are informed of potential adverse effects report a higher incidence of side effects but do not have higher rates of premature discontinuation.

How the patient and family are engaged in the treatment plan can determine the success of treatment. The psychodynamic meaning of pharmacotherapy to the patient and family and environmental influences, psychosocial stressors, and support should be explored. Some patients may view drug treatment as a panacea, and others may view it as the enemy. With

the patient's consent, relatives and other clinicians should be instructed about the reasons for the drug treatment, as well as the expected benefits and potential risks.

DOSING, DURATION, AND MONITORING

Dosing

The clinically effective dose for treatment depends on the characteristics of the drug and patient factors, such as inherited sensitivity and ability to metabolize a drug, concurrent medical disorders, use of concurrent medications, and history of exposure to previous medications.

Plasma concentrations of many psychotropics can vary up to 10-fold. Thus, to some extent, the optimal dose for an individual is ultimately determined by trial and error, guided by the empirical evidence of the usual dose range for that drug. In some cases, it may prove helpful to test patients for genetic polymorphisms involving hepatic enzymes. Patients who are ultrarapid metabolizers of certain drugs may require higher than standard dosing. Slow metabolizers might demonstrate side effects and even toxicity at very low doses.

Some drugs demonstrate a clear relationship between increases in the dose and clinical response. This dose–response curve plots the drug concentration against the effects of the drug.

The *potency* of a drug refers to the relative dose required to achieve specific effects, not to its efficacy. Haloperidol, for example, is more potent than chlorpromazine (Thorazine) because approximately 5 mg of haloperidol is required to achieve the same therapeutic effect as 100 mg of chlorpromazine. These drugs, however, are equal in their clinical efficacy—that is, the maximal clinical response achievable by the administration of a drug.

Drugs must be used in effective dosages for sufficient periods. Although drug tolerability and safety are always considerations, subtherapeutic doses and incomplete therapeutic trials should be avoided. The use of inadequate doses merely exposes the patient to the risk of side effects without providing the probability of therapeutic benefit. Because of the wide margin of safety associated with most currently prescribed medications, more risk exists in

underdosing than in overshooting the recommended dose range.

The time of dosing is usually based on the plasma half-life of a drug and its side effect profile. Sedating drugs are given all at night or with disproportionate daily doses at night. The opposite is true with activating drugs. The frequency of dosing is not as straightforward as with sedating drugs. Most dosing regimens of psychotropic drugs, such as once-a-day versus divided doses, are based on measurements of plasma concentrations rather than receptor occupancy in the brain. Evidence suggests a significant dissociation exists between the brain and plasma kinetics. Reliance on plasma kinetics as the basis for dosing regimens leads to a misunderstanding of necessary schedules.

As a rule, psychotropic drugs should be used continuously. There are some possible exceptions, such as when treating insomnia, agitation, or situational anxiety. A common mistake is the use of high-potency benzodiazepines, such as alprazolam (Xanax) and clonazepam (Klonopin), only after an attack has begun. These drugs should be used as part of a regular schedule to prevent attacks.

Some patients who experience sexual dysfunction while being treated with SSRIs take a drug holiday; that is, they skip a daily dose from time to time to facilitate sexual performance.

Intermittent dosing regimens of SSRIs are effective as a treatment for premenstrual dysphoric disorder (PMDD). The drugs are taken daily during the 2-week luteal phase of the menstrual cycle.

Duration of Treatment

A common question from a patient is, “How long do I need to take the medication?” The answer depends on multiple variables. These include the specific disorder, the symptom duration, and family history. We should also consider the patient’s tolerance of and benefit from the medication. Patients can be given a reasonable explanation of the probabilities but should be told that it is first best to see if the medication works for them and whether any side effects are acceptable. Any more definitive discussion of treatment duration can be held once we can assess the degree of success. Even patients with a philosophical aversion to the use of psychotropic drugs may elect to stay on the medication indefinitely if the magnitude of improvement is

excellent. Most psychiatric disorders have high rates of chronicity and relapse. Because of this, long-term treatment is often needed to prevent a recurrence. Nevertheless, the fact remains that psychotropic drugs are not said to cure the disorders they treat but rather to help control the symptoms.

Treatment is conceptually broken down into three phases: the initial therapeutic trial, the continuation, and the maintenance phase. The initial period of treatment should last at least several weeks because of the delay in therapeutic effects that characterize most classes of psychotropic drugs. The required duration of a *therapeutic trial* of a drug should be discussed at the outset of treatment so that the patient does not have unrealistic expectations of an immediate improvement in symptoms. Patients are more likely to experience side effects early in the course of pharmacotherapy than any relief from their disorder. In some cases, medication may even exacerbate some symptoms. Patients should be counseled that a meager initial reaction to medication is not an indicator of the outcome of treatment. For instance, many patients with panic disorder develop jitteriness or an increase in panic attacks after starting on tricyclic or SSRI treatment. Benzodiazepine agonists are an exception to the rule that clinical onset is delayed. In most cases, their hypnotic and antianxiety effects are evident immediately.

Ongoing use of medication, however, does not provide absolute protection against relapse. Continuation therapy provides clinically and statistically significant protective effects against relapse. The optimal duration of continuation or maintenance therapy is variable and dependent on the clinical history of the patient. Early-onset chronic major depression, for example, has a more severe course and more significant comorbidity than late-onset chronic major depression. In addition to early-onset, a history of multiple past episodes and the severity and length of a current episode would suggest that longer, even indefinite, treatment is appropriate.

Frequency of Visits

Until an unequivocal response to treatment occurs, patients should be seen as frequently as circumstances warrant. The frequency of follow-up or monitoring visits is determined by clinical judgment. In severely ill patients, this might mean several times a week. Patients on maintenance therapy, even when stable, need monitoring, but no consensus exists on the frequency of

follow-up therapy. Three months is a reasonable interval between visits, but 6 months may be adequate after long-standing treatment.

LABORATORY TESTS AND THERAPEUTIC BLOOD MONITORING

Laboratory testing and therapeutic blood monitoring should be based on clinical circumstances and the drugs being used. For most commonly used psychotropic drugs, routine testing is not required.

Pretreatment tests are routine as part of a workup to establish baseline values and to rule out underlying medical problems that may be causing the psychiatric symptoms or that might complicate treatment with drugs. Results of recently performed tests should be obtained. With agents known to cause cardiac conduction changes, a pretreatment electrocardiogram (ECG) should be obtained before initiating treatment. With lithium and clozapine, the possibility of severe changes in thyroid, renal, hepatic, or hematologic functions requires pretreatment and ongoing monitoring with appropriate laboratory tests.

As a result of both anecdotal and research findings of sometimes severe glucose dysregulation during treatment primarily with SDAs, the FDA has suggested that patients being treated with any atypical antipsychotic be monitored for the emergence of diabetes.

Certain circumstances present in which it is necessary or useful to use plasma concentrations to monitor a patient’s condition. The most common is the monitoring of drugs with narrow therapeutic indexes, such as lithium. Also, we may monitor drugs with a therapeutic window, which is the optimal dose range for a therapeutic response; drug combinations that can lead to interactions that raise drug concentrations of medications or their metabolites, which can cause toxicity; unexplained toxicity at average therapeutic doses; and failure to respond in a patient who may be noncompliant. A clinician should have no reservations about requesting random urine toxicologic tests in a patient who abuses substances.

TREATMENT OUTCOMES

The goal of psychotropic treatment is to eliminate all manifestations of a

disorder, thus enabling the patient to regain the ability to function as well and to enjoy life as fully as before they became ill. This degree of improvement to below the syndromal threshold is defined as *remission*.

Response and Remission

Remission is the preferred outcome of treatment, not only because of the immediate impact on functioning and state of mind but also because emerging evidence suggests that patients in remission are less likely to experience relapse and recurrence of their disorder.

Patients who improve but do not experience a full resolution are considered to be responders. They may exhibit significant improvement but continue to experience symptoms. In depression studies, the *response* is usually defined as a 50 percent or more significant decrease from baseline on a standard rating scale, such as the Hamilton Depression (HAM-D) Scale or the Montgomery-Asberg Depression Rating Scale (MADRS). The scales define r*emission* as an absolute score of 7 or less on the HAM-D or 10 or less on the MADRS.

Our expectations around improvement derive from what we know about the disorder and its response to treatment. Obsessive-compulsive disorder (OCD) and schizophrenia, for example, are more likely to be associated with residual manifestations of illness than major depression or panic disorder. The probability of full remission from OCD with SSRI treatment alone over 2 years is less than 12 percent, and the probability of partial remission is approximately 47 percent.

Treatment Failure

The initial treatment plan should anticipate that the medication may be ineffective. A next-step strategy should be in place at the initiation of treatment. Repeated drug failures should prompt a reassessment of the patient. First, was the original diagnosis correct? In answering this question, the clinician should include the possibility of an undiagnosed medical condition or recreational drug use as the cause of the psychiatric symptoms.

Second, are the observed symptoms related to the original disorder, or are they adverse effects of the drug treatment? Some antipsychotic drugs, for example, can produce akinesia, which resembles psychotic withdrawal, or

akathisia and neuroleptic malignant syndrome, which resemble increased psychotic agitation. Long-term use of SSRIs can produce emotional blunting, which can mimic depression. Intolerance of side effects may be the most common reason for treatment failure.

Third, was the drug administered at an appropriate dosage for a sufficient length of time? Because absorption and metabolism of drugs can vary significantly in patients, the clinician may need to measure plasma levels of a drug to ensure a sufficient dose of the drug.

Fourth, did a pharmacokinetic or pharmacodynamic interaction with another drug that the patient was taking reduce the efficacy of the newly prescribed drug?

Fifth, did the patient take the drug as directed? Drug noncompliance is a common clinical problem that arises as a result of complicated drug regimens (more than one drug in more than one daily dosage), adverse effects (mainly if unnoticed by the clinician), and poor patient education about the drug treatment plan. Patients may discontinue medication when they recover, thinking that they are cured and no longer benefiting from the medication.

Treatment Resistance

Some patients fail to respond to repeated trials of medication. No single factor can explain the ineffectiveness of the various interventions in these cases. Strategies in these cases include the use of drug combinations, high-dose therapy, and the use of unconventional drugs. Limited evidence is available on the comparative success rates associated with any given strategy.

Tolerance

The development of tolerance is marked by a need, over time, to use increased doses of a drug for it to maintain a clinical effect. This decreased responsiveness to a drug occurs after repeated doses. Tolerance also describes decreased sensitivity to adverse effects of the drug, such as nausea. This phenomenon is used as the basis for starting some drugs at subtherapeutic doses, with the plan to adjust the schedule once the patient can tolerate higher doses. Clinical tolerance appears to represent changes in the CNS, such as altered receptor configuration or density. Drugs with similar pharmacologic actions often exhibit cross-tolerance.

Sensitization

Clinically manifested as the reverse of tolerance, sensitization is said to occur when sensitivity to a drug effect increases over time. In these cases, the same dose typically produces more pronounced effects as treatment progresses.

Withdrawal

The development of physiologic adaptation to a drug, with a subsequent risk of withdrawal symptoms, has been reported for many classes of psychotropic drugs. Technically, withdrawal should be considered a side effect. The probability and severity of these reactions are remote with most drugs and more frequent with others. As a general rule, the more abruptly a drug is stopped and the shorter its elimination half-life, the more likely it is that clinically significant withdrawal symptoms will occur. When using some short-acting drugs, withdrawal reactions can result from missed doses and during daily intervals between doses. Gradual tapering of medications after prolonged use is recommended whenever possible. Although this reduces the risk of withdrawal reactions, it does not ensure they will not occur. The so-called sedative-hypnotics and opiates are the agents most often associated with mentally and physically distressing discontinuation reactions. In some cases, such as barbiturate use, withdrawal can be fatal.

Marked differences are found among agents, even within a given class, concerning the probability and severity of discontinuation effects. For example, the benzodiazepines alprazolam and triazolam (Halcion) commonly produce more immediate and intense withdrawal symptoms than other compounds. Among the SSRIs, there is a well-described withdrawal syndrome that appears to be more frequent and severe with paroxetine (Paxil). It can, however, occur with any SSRI. Even fluoxetine can be associated with discontinuation symptoms, but the symptoms may be delayed and attenuated because of the long elimination half-life of its active metabolite. These manifestations are subtle and are delayed for weeks after the last dose. Venlafaxine also produces severe SSRI-like withdrawal syndrome.

In addition to half-life, many variables can influence the likelihood and degree of discontinuation symptoms. Changes in the rate of drug metabolism, as an example, can play a role. Paroxetine is primarily metabolized by the

cytochrome P450 (CYP) 2D6 isoenzyme. However, it is also a potent inhibitor of CYP 2D6. This results in *autoinhibition,* dose-dependent inhibition of its metabolism, with a subsequent increase in plasma concentrations of paroxetine. If the dose of paroxetine is decreased or the drug is stopped, the decline in its plasma concentrations can be steep, causing withdrawal to occur. Withdrawal can occur in rare cases in which the dose of a drug is not decreased, but a second agent, which had been inhibiting its metabolism, was stopped. For example, alprazolam is metabolized via the CYP 3A3/4 enzyme system. Nefazodone inhibits that enzyme. If a patient taking both agents for several weeks discontinues the nefazodone, it could result in a rapid increase in the rate of alprazolam metabolism and a consequent drop in plasma concentrations.

The development of sustained-release versions of drugs, such as alprazolam, paroxetine, and venlafaxine, has not reduced the severity of their withdrawal reactions. The prolonged half-life of those agents results from delayed absorption rather than prolongation of the elimination phase. The frequency of drug dosing is reduced but not the rate of the falloff in plasma concentrations.

Low bioavailability with a generic agent may account for the unexpected loss of clinical effect in the emergence of withdrawal symptoms. The occurrence of these events soon after refilling a prescription should prompt examination of the new medication. It should be confirmed whether the dispensed medication and dose are both correct. It is difficult to ascertain whether generic medications are genuinely equivalent, so the possibility exists that differences in potency may underlie adverse changes in clinical status.

Withdrawal symptoms invariably occur hours or days after dose reduction or discontinuation. Symptoms resolve within a few weeks, so the persistence of symptoms argues against withdrawal. Although depletion studies have been shown to provoke the rapid return of symptoms, in clinical practice, psychotic and mood symptoms do not usually reappear abruptly after long-term treatment.

COMBINATION OF DRUGS

According to the American Psychiatric Association Practice Guidelines for

the Treatment of Psychiatric Disorders, “the use of multiple agents should be avoided if possible” in the treatment of psychiatric disorders. Although *monotherapy* represents the ideal, *polypharmacy*, the simultaneous use of psychotropic medications, has been commonplace since chlorpromazine was combined with reserpine (Diupres) in the early 1950s. The practice of combining drugs and the merits of various *augmentation* or *combination* strategies are routinely discussed in the literature and at scientific meetings. The mean number of simultaneously prescribed medications has increased in recent decades. Among psychiatric inpatients, the mean number of psychotropics prescribed is approximately three. Fixed combinations—drugs that contain more than one active ingredient—have been successfully marketed in the past, and research on new combinations is ongoing. A fluoxetine-olanzapine fixed combination has been approved as a treatment for bipolar disorder. The use of such drugs may increase the patients’ compliance by simplifying the drug regimen. A problem with combination drugs, however, is that the clinician has less flexibility in adjusting the dosage of one of the components; that is, the use of combination drugs can cause two drugs to be administered when only one drug continues to be necessary for therapeutic efficacy (Table 21-8).

Table 21-8
Selected Combination Drugs Used in Psychiatry

Ingredients	Preparation	Amount of Each	Recommended Dosage	Indications
Perphenazine and amitriptyline	—	Tablet: 2:25, 4:25, 4:50, 2:10, 4:10	Initial therapy: tablet of 2:25 or 4:25 qid Maintenance therapy: tablet 2:25 or 4:25 bid or qid.	Depression and associated anxiety
Dextroamphetamine and amphetamine	Adderall	Tablet: 5, 7.5, 10.0, 12.5, 15.0, 20.0, 30.0 mg	3–5 yr: 2.5 mg/day; 6 yr and older: 5 mg/day	Attention-deficit/hyperactivity disorder
	Adderall XR	Capsule: 5, 10, 15, 20, 25, 30 mg	—	—
Chlordiazepoxide and clidinium bromide	—	Capsule: 5:25	One or two capsules tid or qid before meals and at bedtime	Peptic ulcer, gastritis, duodenitis, irritable bowel syndrome, spastic colitis, and mild ulcerative colitis
Chlordiazepoxide and amitriptyline	—	Tablet: 5.0:12.5, 10:25	Tablet of 5:12.5 tid or qid; tablet of 10:25 tid or qid, initially, then may increase to six tablets daily as required	Depression and associated anxiety
Olanzapine and fluoxetine	Symbyax	Capsule: 6:25, 6:50, 12:25, 12:50	Once daily in the evening in a dose range of olanzapine 6–12 mg and fluoxetine 25–50 mg	Depressive episodes associated with bipolar I disorder

qid, four times daily; bid, twice daily; tid, three times daily.

Sometimes distinctions are made between augmentation and combination

therapy. When two psychotropics with the same approved indications are used concurrently, this is termed *combination therapy*. Adding a drug with another indication is termed *augmentation*. Augmentation often entails the use of a drug that is not primarily considered a psychotropic. For example, in treating depression, it is not common to add thyroid hormone to an approved antidepressant.

Almost all patients with bipolar disorder are taking more than one psychotropic agent. Combination treatment with drugs that treat depression and DRA or SDA has long been held as preferable in patients with psychotic depression. Similarly, SSRIs typically produce partial improvement in patients with OCD, so the addition of an SDA may be helpful.

Medications also can be combined to counteract side effects, to treat specific symptoms, and as a temporary measure to transition from one drug to another. It is common practice to add a new medication without the discontinuation of a prior drug, mainly when the first drug has provided partial benefit. This addition can be part of a plan to transition from an agent that is not producing a satisfactory response or an attempt to maintain the patient on combined therapy.

The advantages of combining drugs include building on the existing response, which may be less demoralizing, and the possibility that combinations produce new mechanisms that no single agent can provide. One limitation is that noncompliance and adverse effects increase, and the clinician may not be able to determine whether it was the second drug alone or the combination of drugs that resulted in a therapeutic success or a particular adverse effect. Combining drugs can create a broad spectrum effect and also changes the ratio of metabolites.

COMBINED PSYCHOTHERAPY AND PHARMACOTHERAPY

Many psychiatrists believe that patients are best treated with a combination of medication and psychotherapy. Studies have demonstrated that the results of combined therapy are superior to those of either type of therapy alone. When pharmacotherapy and psychotherapy are used together, the approach should be coordinated, integrated, and synergistic. If two separate clinicians direct psychotherapy and pharmacotherapy, the clinicians must communicate with

each other clearly and often.

SPECIAL POPULATIONS

Although every patient brings a unique combination of demographic and clinical variables to the clinical setting, specific patient populations require special consideration. When treating the young, the elderly, those with medical disorders, and women who want to conceive or are pregnant or nursing, awareness of risks associated with medication assumes increased importance. Data derived from clinical trials are of limited value in guiding many decisions because populations in these studies consisted of healthy young adults and, until recently, excluded many women of child-bearing age. Studies of children and adolescents have become more common, so understanding of treatment effects in this population has grown.

Children

Understanding of the safety and efficacy of most psychotropic drugs, when used to treat children, is based more on clinical experience than on evidence from extensive clinical trial data. Often, so results from adult studies are extrapolated to children. This extrapolation is not necessarily appropriate because of developmental differences in pharmacokinetics and pharmacodynamics. Dosing is another special consideration in drug use with children. Although the small volume of distribution suggests the use of lower doses than those used in adults, a child's higher rate of metabolism suggests that a higher ratio of milligrams of a drug to kilograms of body weight should be used. In practice, beginning with a small dose is best, then increasing it until clinical effects are observed. The clinician should not hesitate, however, to use adult dosages in children if these dosages are effective and the adverse effects are acceptable.

The paucity of research data is a legacy of many years in which manufacturers avoided conducting trials in children because of liability concerns, small market share, and, hence, limited profit potential represented by this population. To correct this problem, the FDA Modernization Act (FDAMA) of 1997 provided for special encouragement and incentives to study drugs for pediatric use.

Pregnant and Nursing Women

No definitive assurances exist that any drug is entirely without risk during pregnancy and lactation. No psychotropic medication is absolutely contraindicated during pregnancy, although drugs with known risks of congenital disabilities, premature birth, or neonatal complications should be avoided if acceptable alternatives are available.

Women who are pregnant or lactating are excluded from clinical trials, and it is only recently that women of child-bearing age have been able to participate in these studies. As a result, there are large gaps in knowledge of the effects of psychotropic agents on the developing fetus and the neonate. Most of what is known are the result of anecdotal reports or data from registries. The basic rule is to avoid administering any drug to a woman who is pregnant (particularly during the first trimester) or who is breastfeeding a child unless the mother's psychiatric disorder is severe, and the therapeutic value of the drug outweighs the theoretical adverse effects on the fetus or newborn. A woman may elect to continue on medication because she does not want to chance a possible recurrence of painful or disabling symptoms.

Among the newer antidepressants, paroxetine is the only one to carry a warning from the FDA, the result of an increased risk of cardiac malformation. The agents with the most well-documented risk of specific congenital disabilities are lithium, carbamazepine, and valproate. Lithium administration during pregnancy is associated with Ebstein anomaly, a severe abnormality of cardiac development, although recent evidence suggests that the risk is not as significant as previously believed. Carbamazepine and valproic acid are associated with neural tube defects, which can be prevented by the use of folate during pregnancy. Lamotrigine may cause oral clefts when used during the first trimester. Some experts advise that all women of child-bearing age who are treated with psychotropics take supplemental folate.

The administration of psychotherapeutic drugs at or near delivery can cause the baby to be overly sedated at delivery and require a respirator. They may also be physically dependent on the drug, requiring detoxification and the treatment of a withdrawal syndrome. Reports exist of a neonatal withdrawal syndrome associated with third-trimester use of SSRIs in pregnant women. They have also been implicated in producing pulmonary

hypertension in newborns.

Virtually all psychiatric drugs are secreted in the milk of a nursing mother; therefore, mothers on those agents should be advised not to breastfeed their infants.

Elderly Patients

The two major concerns when treating geriatric patients with psychotherapeutic drugs are that elderly persons may be more susceptible to adverse effects (particularly cardiac effects) and may metabolize and excrete drugs more slowly, thus requiring lower dosages of medication. In practice, clinicians should begin treating geriatric patients with a small dose, usually approximately half of the usual starting dose. The dose should be raised in small increments, more slowly than for middle-aged adults, until a clinical benefit is achieved or unacceptable adverse effects appear. Although many geriatric patients require a small dose of medication, many others require a full therapeutic dose.

Elderly patients account for approximately one-third of all prescription drug use and a substantial percentage of over-the-counter preparations as well. Even more significant is the incidence of polypharmacy. Recent surveys have found that elderly patients in the community are taking between three and five medications, and that hospitalized elderly patients are treated with an average of ten drugs. Nearly half of all patients in long-term care facilities are prescribed one or more psychotropic agents. Because of these statistics, clinicians need to consider potential types and likelihood of drug interactions when selecting medications.

Psychotropic drugs are causally related to falls in the elderly. Discontinuation of psychotropic drugs results in an estimated 40 percent risk reduction for falls. This association between psychotropics and falls and hip fractures may weaken as newer agents become widely used. As a rule, new-generation compounds produce less unwanted sedation, dizziness, parkinsonism, and postural hypotension.

Age-related changes in renal clearance and hepatic metabolism make it more important to be conservative with the starting doses of medication as well as the rate of dose titration. Within any class of psychotropic agents, those with potentially serious consequences, such as hypotension, cardiac

conduction abnormalities, anticholinergic activity, and respiratory depression, are not suitable choices. Drugs that cause cognitive impairment, such as benzodiazepines and anticholinergics, can mimic or exacerbate symptoms of dementia. Similarly, DRAs can worsen or induce Parkinson disease, another age-related disorder. Some side effects, such as SSRI-associated syndrome of inappropriate secretion of antidiuretic hormone (SIADH) and oxcarbazepine-associated hyponatremia, occur more commonly in older patients.

A common ethical dilemma with the medically ill elderly or those with dementia is the question of their capacity to give informed consent before treatment with psychotropic drugs or ECT.

Medically Ill Patients

There are special considerations, diagnostic and therapeutic, when administering psychiatric drugs to medically ill patients. The medical disorder should be ruled out as a cause of psychiatric symptoms. For example, patients with neurologic or endocrine disorders or those infected with human immunodeficiency virus (HIV) may experience disturbances of mood and cognition. Common medications, such as corticosteroids and L-dopa, are associated with the induction of mania.

A patient with diabetes mellitus is better treated with an agent without the risk of weight gain or glucose dysregulation. Depending on the diagnosis, drugs that might treat the primary psychiatric disorder and also cause weight loss, drugs such as bupropion, topiramate, and zonisamide, should be prescribed for these patients. Patients with obstructive pulmonary disease should not be given sedating drugs, which raise the arousal threshold and suppress respiration. Patients with medical disorders are also taking other medications, which can result in pharmacodynamic and pharmacokinetic interactions. Combined treatment with an inducer of multiple CYP enzymes and a drug that is a substrate for those enzymes could result in subtherapeutic levels, leading to inadequate symptom control. The use of the tuberculosis treatment rifampicin (Rifadin) with carbamazepine is an example of this. The use of drugs that inhibit CYP 2D6, agents such as paroxetine and fluoxetine, can prevent the conversion of hydrocodone (Robidone) and other opiates into an active analgesic form. NSAIDs are also a rare cause of perceptual

disturbances and psychotic symptoms.

Other issues include a potentially increased sensitivity to adverse effects, including increased or decreased metabolism and excretion of the drug, and interactions with other medications. Drug interactions are an obvious concern when drugs with a narrow therapeutic range are being used. Any change in the rate of metabolism or interference with the formation and elimination of metabolites can profoundly influence the activity of that drug. Similarly, interactions that interfere with drug metabolism can produce an increase in side effects and toxicity.

As with children and geriatric patients, the most reasonable clinical practice is to begin with a small dosage, to increase it slowly, and to watch for clinical benefit and adverse effects. Determining the plasma drug concentrations may be helpful for such patients, but therapeutic blood concentrations for most psychotropic drugs are neither necessary nor routinely available.

Substance Abuse

Many patients who seek or need treatment for a psychiatric disorder chronically use illicit substances or drink excessive amounts of alcohol. Discontinuation of chronic drug or alcohol use can result not only in craving but also in clinically significant psychiatric and physiologic withdrawal symptoms. For many patients, successful treatment of their underlying psychiatric disorder may not be possible in the presence of ongoing marijuana, cocaine, and alcohol use. If several trials of medications fail, hospitalization for detoxification may be necessary. Little research and no consensus exist about how to use psychotropic agents in patients who are regular users of cocaine, marijuana, or other recreational drugs.

REGULATORY ISSUES

The FDA has the authority to approve a drug for clinical use and to ensure that product labeling is truthful and contains all information pertinent to the safe and effective use of that drug.

Product information that is FDA approved for marketed drugs appears as a package insert that lists potential side effects, drug interactions, the need for special monitoring, and restrictions for use. In some cases, these adverse

reactions and potential safety hazards warrant a warning label called a *black box label*. The FDA typically negotiates final labeling language with the company; however, in cases where a company refuses to satisfy the FDA, the agency may initiate proceedings to remove the drug from clinical use. In recent years, warning labels have been applied to entire classes of psychotropic drugs, including the SDAs and antidepressants such as the SSRIs.

The product information may also contain a "Contraindications" heading. This section describes instances in which the drug should not be used because the risk of using it outweighs the benefit. If no contraindications are known, this section of the labeling will state "None known."

A Precautions section may contain precautions for most individuals taking the drug, as well as for specific groups, such as pregnant women, nursing mothers, or children. In this section, one will find recommendations for patients to ensure the safe and effective use of the drug. For example, there may be precautions about driving when taking the medication or using substances such as other drugs, food, or alcohol that may have harmful effects if taken while using the medication. The precautions section also provides information about laboratory tests needed to track responses or to identify adverse reactions to the drug or about known interactions with other drugs, foods, or ingredients.

Every product label has an Adverse Reaction section that lists the frequency of undesirable effects that may be associated with the use of a drug. Causes of adverse reactions can include medication errors, such as overdosage, or interactions between different drugs or between drugs and certain foods.

NONAPPROVED DOSAGES AND USES

It is now common practice to treat psychiatric disorders with drugs that are approved for nonpsychiatric conditions. Some examples include propranolol (Inderal) for social anxiety and treatment of lithium-induced tremor; verapamil (Calan, Isoptin) for mania and treatment of MAOI-induced hypertensive crisis; levothyroxine (Levoxyl) for antidepressant augmentation; clonidine (Catapres) and guanfacine (Tenex) for posttraumatic stress disorder (PTSD); dextroamphetamine (Dexedrine) for antidepressant augmentation;

and riluzole (Rilutek) for self-injurious behavior. Off-label use of a drug is not a violation of law or a departure from good medical practice. The FDA does not limit how a physician may use an approved drug. Medications can be prescribed for any reason shown to be medically indicated for the welfare of the patient. Once a drug is approved for commercial use, a physician can, as part of the practice of medicine, lawfully prescribe a different dosage for a patient or may otherwise vary the conditions of use from what is approved in the package labeling without notifying the FDA or obtaining its approval.

Failure to follow the information on the drug label does not in itself impose liability and should not preclude a physician from using sound clinical judgment in the service of the patient. Physicians are permitted to use a drug for indications not included on the drug's official labeling without violating the FDA rules. This fact, however, does not absolve the physician of responsibility for an untoward result from treatment. Patients can still sue for possible medical malpractice with the reasoning that the failure to follow the FDA-approved label can be interpreted as deviating from the prevailing standard of care.

When using a drug off-label or in doses outside the usual range, we should explain to the patient the reasons for this approach. We should also document it in the chart. When doubting the plan to use a drug off label, a consultation with a colleague should be obtained.

In some cases, a drug has obtained limited approval for an indication. Divalproex (Depakote) and risperidone, for example, are approved by the FDA for the acute, but not long-term, treatment of mania. Nevertheless, these drugs are routinely used for long-term prevention of recurrences of mania and bipolar disorder. In the case of lamotrigine, it was accepted as a first-choice agent for the treatment of bipolar disorder long before the FDA approved that indication.

PLACEBOS

Pharmacologically inactive substances have long been known sometimes to produce significant clinical benefits. A patient who believes that a compound is helpful may often derive considerable benefit from taking that substance, whether it is known to be pharmacologically active or not. For many psychiatric disorders, including mild to moderate depression and some

anxiety disorders, well over 30 percent of patients can exhibit significant improvement or remission of symptoms on a placebo. For other conditions, such as schizophrenia, manic episodes, and psychotic depression, the placebo response rate is meager. Whereas suggestion is undoubtedly crucial in the efficacy of placebos (and active drugs), placebos can produce biologic effects. For example, placebo-induced analgesia may sometimes be blocked by naloxone (Narcan), which suggests that endorphins may mediate the analgesia derived from taking a placebo. It is conceivable that placebos may also stimulate endogenous anxiolytic and antidepressant factors, resulting in clinical improvement in patients with depression and anxiety disorders.

Just as placebos can produce benefits, they can also have adverse effects. In many studies, some adverse effects are likely to be more frequent with placebos than with the active drug. Some patients will not tolerate placebos, although they are supposedly inert, and they exhibit adverse effects (called the *nocebo phenomenon*). It is easy to discount such patients as overly suggestible; however, if placebos can stimulate beneficial endogenous factors, perhaps toxic endogenous factors can also be produced.

Prudence is needed in contemplating the use of a placebo in clinical practice. Treating a patient with a placebo without consent can seriously undermine a patient's confidence in the physician if, and when, it is discovered.

21.1 Antipsychotics

SEROTONIN–DOPAMINE ANTAGONISTS AND SIMILARLY ACTING DRUGS (SECOND-GENERATION OR ATYPICAL ANTIPSYCHOTICS)

The SGAs, also known as second-generation or atypical antipsychotic drugs, are a group of pharmacologically diverse drugs that have largely supplanted the older DRAs. The term *atypical* is used because these drugs differ in their side effect profiles, most notably lower risk of extrapyramidal side effects (EPS), and have spectra of action that are broader than those of the DRAs. However, this term is becoming something of a misnomer, as the drugs are

now more commonly used than the “typical” antipsychotics. In contrast to the earlier antipsychotic drugs, the SGAs have significant effects on both the dopamine and serotonin systems. Their pharmacology is complex, with individual drugs in this group having multiple neurotransmitter effects. All SGAs are indicated for the treatment of schizophrenia. Most of these SGA drugs have also received approval as monotherapy or adjunctive therapy in the treatment of bipolar disorder. Some have also been approved as adjuncts for the treatment of major depression.

As of 2020, 13 SGA drugs were approved by the FDA. These include the following:

Aripiprazole (marketed as Abilify)
Asenapine Maleate (marketed as Saphris)
Brexpiprazole (marketed as Rexulti)
Cariprazine (marketed as Vraylar)
Clozapine (marketed as Clozaril)
Iloperidone (marketed as Fanapt)
Lumateperone (marketed as Caplyta)
Lurasidone (marketed as Latuda)
Olanzapine (marketed as Zyprexa, and as Symbyax in combination with fluoxetine)
Paliperidone (marketed as Invega)
Quetiapine (marketed as Seroquel)
Risperidone (marketed as Risperdal)
Ziprasidone (marketed as Geodon)

It is arguable whether the SGAs represent an improvement in overall tolerability than the DRAs. Although there is an improvement concerning a lowered, not absent, risk of EPS, most of the drugs in this group often produce substantial weight gain, which in turn increases the potential for the development of diabetes mellitus. Olanzapine and clozapine appear to account for most cases of weight gain and drug-induced diabetes mellitus. The other agents pose a smaller risk of these side effects; nevertheless, the FDA has requested that all SGAs carry a warning label that patients taking the drugs need to be monitored closely, and has recommended the following factors be considered for all patients prescribed SGAs:

1. Personal and family history of obesity, diabetes, dyslipidemia, hypertension, and cardiovascular disease
2. Weight and height (so that body mass index can be calculated)
3. Waist circumference (at the level of the umbilicus)
4. BP
5. Fasting plasma glucose level
6. Fasting lipid profile

Patients with preexisting diabetes should have regular monitoring, including hemoglobin A1C (HbA1C) and, in some cases, insulin levels. Among these drugs, clozapine sits apart. It is not considered a first-line agent because of side effects (hematologic) and the need for weekly blood tests. Although highly effective in treating both mania and depression, clozapine does not have an FDA indication for these conditions.

Mechanisms of Action

The presumed antipsychotic effects of the SDAs are blockade of D_2 dopamine receptors. Where the SDAs differ from older antipsychotic drugs is their higher ratio interactions with serotonin receptor subtypes, most notably the 5-HT_{2A} subtype, as well as with other neurotransmitter systems. It is hypothesized that these properties account for the distinct tolerability profiles associated with each of the SDAs. All SDAs have different chemical structures, receptor affinities, and side effect profiles. No SDA is identical in its combination of receptor affinities, and the relative contribution of each receptor interaction to the clinical effects is unknown.

Therapeutic Indications

Although initially approved for the treatment of schizophrenia and acute mania, some of these drugs have also been approved as adjunctive therapy in treatment-resistant depression and as adjunctive therapy in major depressive disorder (MDD). They are also useful in PTSD and anxiety disorders. Although clinicians tend to use them in behavioral disturbances associated with dementia, all SDAs carry an FDA boxed warning regarding adverse effects when used in elderly persons with dementia-related psychoses, because elderly patients with dementia-related psychoses are at an increased

risk (1.6 to 1.7 times) of death compared with placebo. All of these agents are considered first-line drugs for schizophrenia except clozapine, which may cause adverse hematologic effects that require weekly blood sampling.

Schizophrenia and Schizoaffective Disorder. The SDAs are useful for treating acute and chronic psychoses such as schizophrenia and schizoaffective disorder, in both adults and adolescents. SDAs are as good as or better than typical antipsychotics (DRAs) for the treatment of positive symptoms in schizophrenia and superior to DRAs for the treatment of negative symptoms. Compared with persons treated with DRAs, persons treated with SDAs have fewer relapses and require less frequent hospitalization, fewer emergency department visits, less phone contact with mental health professionals, and less treatment in day programs.

Because clozapine has potentially life-threatening adverse effects, it is appropriate only for patients with schizophrenia who are resistant to all other antipsychotics. Other indications for clozapine include treatment of persons with severe tardive dyskinesia—which can be reversed with high dosages in some cases—and those with a low threshold for EPS. Persons who tolerate clozapine have done well on long-term therapy. The effectiveness of clozapine may be increased by augmentation with risperidone, which raises clozapine concentrations and sometimes results in dramatic clinical improvement.

Mood Disorders. Most of the SDAs (clozapine being a notable exception) are FDA approved for the treatment of acute mania. Some of these agents, including aripiprazole, olanzapine, quetiapine, and quetiapine XR, are also approved for the maintenance treatment in bipolar disorder as monotherapy or adjunctive therapy. The SDAs improve depressive symptoms in schizophrenia, and both clinical experience and clinical trials show that all of the SDAs augment antidepressants in the acute management of major depression. At this time, olanzapine, in combination with fluoxetine, has been approved for treatment-resistant depression, and aripiprazole and quetiapine XR are indicated for adjunctive therapy to antidepressants in MDDs. Quetiapine and quetiapine XR are also approved in bipolar depression. A fixed combination of olanzapine and fluoxetine (Symbyax) is approved as a treatment for acute bipolar depression.

Other Indications. About 10 percent of patients with schizophrenia exhibit outwardly aggressive or violent behavior, and the SDAs are effective for the treatment of such aggression. Other off-label indications include acquired immunodeficiency syndrome (AIDS) dementia, autism spectrum disorders, Tourette disorder, Huntington disease, and Lesch–Nyhan syndrome. Risperidone and olanzapine have been used to control aggression and self-injury in children. These drugs are sometimes coadministered with stimulants to children with ADHD who are comorbid for either oppositional–defiant disorder or conduct disorder. SDAs—especially olanzapine, quetiapine, and clozapine—are useful in persons who have severe tardive dyskinesia. The SDAs are also effective for treating psychotic depression and for psychosis secondary to head trauma, dementia, or treatment drugs.

Treatment with SDAs decreases the risk of suicide and water intoxication in patients with schizophrenia. Patients with treatment-resistant OCD have responded to the SDAs; however, a few persons treated with the SDAs have been noted to develop treatment-emergent symptoms of OCD. Some patients with borderline personality disorder may improve with the SDAs.

Some data suggest that treatment with conventional DRAs has protective effects against the progression of schizophrenia when used during the first episode of psychosis. Ongoing studies are looking at whether the use of SDAs in at-risk patients with early evidence of disease prevents deterioration, thus improving long-term outcomes.

Adverse Effects

The SDAs share a similar spectrum of adverse reactions but differ considerably in terms of frequency or severity of their occurrence. Specific side effects that are more common with an individual SDA are emphasized in the discussion of each drug in subsequent text.

Risperidone (Risperdal)

Indications. Risperidone is indicated for the acute and maintenance treatment of schizophrenia in adults and the treatment of schizophrenia in adolescents ages 13 to 17 years. Risperidone is also indicated for the short-term treatment of acute manic or mixed episodes associated with bipolar I disorder in adults and children and adolescents ages 10 to 17 years. The

combination of risperidone with lithium or valproate is indicated for the short-term treatment of acute manic or mixed episodes associated with bipolar I disorder.

Risperidone is also indicated for the treatment of irritability associated with an autistic spectrum disorder in children and adolescents ages 5 to 16 years, including symptoms of aggression toward others, deliberate self-injuriousness, temper tantrums, and quickly changing moods.

Pharmacology. Risperidone is a benzisoxazole. It undergoes extensive first-pass hepatic metabolism to 9-hydroxy risperidone, a metabolite with equivalent antipsychotic activity. Peak plasma levels of the parent compound occur within 1 hour for the parent compound and 3 hours for the metabolite. Risperidone has bioactivity of 70 percent. The combined half-life of risperidone and 9-hydroxy risperidone averages 20 hours, so it is useful in once-daily dosing. Risperidone is an antagonist of the serotonin 5-HT_{2A}, dopamine D_2, α_1-adrenergic and α_2-adrenergic, and histamine H_1 receptors. It has a low affinity for α-adrenergic and muscarinic cholinergic receptors. Risperidone is a potent antagonist of D_2 receptors, as potent as haloperidol, however unlike haloperidol it causes less EPS.

Dosages. The recommended dose range and frequency of risperidone dosing have changed since the drug first came into clinical use. Risperidone is available in 0.25-, 0.5-, 1-, 2-, 3-, and 4-mg tablets and a 1-mg/mL oral solution. The initial dosage is usually 1 to 2 mg at night, which can then be increased to 4 mg/day. Positron emission tomography (PET) studies have shown that dosages of 1 to 4 mg/day provide the required D_2 blockade for a therapeutic effect. At first, it was believed that because of its short elimination half-life, risperidone should be given twice a day, but studies have shown equal efficacy with once-a-day dosing. Dosages above 6 mg a day are associated with a higher incidence of adverse effects, particularly EPS. There is no correlation between plasma concentrations and therapeutic effects. Dosing guidelines for adolescents and children are different from those for adults, requiring lower starting dosages; higher dosages are associated with more adverse effects.

Side Effects. The EPS of risperidone is largely dosage dependent, and there has been a trend to using lower doses than initially recommended. Weight gain, anxiety, nausea and vomiting, rhinitis, erectile dysfunction, orgasmic dysfunction, and increased pigmentation are associated with risperidone use. The most common drug-related reasons for discontinuation of risperidone use are EPS, dizziness, hyperkinesias, somnolence, and nausea. Marked elevation of prolactin may occur. Weight gain occurs more commonly with risperidone use in children than in adults.

Risperidone is also available as an orally disintegrating tablet (Risperdal M-Tab), which is available in 0.5, 1, and 2 mg strengths, and in a depot formulation (Risperdal Consta), which is given as an intramuscular (IM) injection formulation every 2 weeks. The dose may be 25, 50, or 75 mg. Oral risperidone should be coadministered with Risperdal Consta for the first 3 weeks before being discontinued.

Drug Interactions. Inhibition of CYP2D6 by drugs such as paroxetine and fluoxetine can block the formation of risperidone's active metabolite. Risperidone is a weak inhibitor of CYP2D6 and has little effect on other drugs. Combined use of risperidone and SSRIs may result in significant elevation of prolactin, with associated galactorrhea and breast enlargement.

Paliperidone (Invega)

Indications. Paliperidone is indicated for the acute and maintenance treatment of schizophrenia. Paliperidone is also indicated for the acute treatment of schizoaffective disorder as monotherapy or as an adjunct to mood stabilizers or antidepressants.

Pharmacology. Paliperidone is a benzisoxazole derivative and is the primary active metabolite of risperidone. Peak plasma concentrations (C_{max}) are achieved approximately 24 hours after dosing, and steady-state concentrations of paliperidone are attained within 4 or 5 days. The hepatic isoenzymes CYP2D6 and CYP3A4 play a limited role in the metabolism and elimination of paliperidone, so no dose adjustment is required in patients with mild or moderate hepatic impairment.

Dosage. Paliperidone is available in 3-, 6-, and 9-mg tablets. The recommended dosage is 6 mg once daily administered in the morning. It can be taken with or without food. It is also available as extended-release tablets, which are also available in 3-, 6-, and 9-mg tablets administered once daily. It is recommended that no more than 12 mg should be administered per day. A long-acting formulation of paliperidone (Invega Sustenna) is given by injection once a month. Invega Sustenna is available as a white to off-white sterile aqueous extended-release suspension for intramuscular injection in dose strengths of 39-, 78-, 117-, 156-, and 234-mg paliperidone palmitate. The drug product hydrolyzes to the active moiety, paliperidone, resulting in dose strengths of 25, 50, 75, 100, and 150 mg of paliperidone, respectively.

Invega Sustenna is provided in a prefilled syringe with a plunger stopper and tip cap. The kit also contains two safety needles (a 1½-in 22-gauge safety needle and a 1-in 23-gauge safety needle). It has a half-life of 25 to 49 days. Monthly injections of 117 mg are recommended, although higher or lower dosages can be used depending on the clinical situation. The first two injections should be in the deltoid muscle because plasma concentrations are 28 percent higher with deltoid versus gluteal administration. Subsequent injections can alternate between gluteal and deltoid sites.

Side Effects. The dose of paliperidone should be reduced in patients with renal impairment. It may cause more sensitivity to temperature extremes, such as very hot or cold conditions. Paliperidone may cause an increase in QT (QTc) interval and should be avoided in combination with other drugs that cause prolongation of QT interval. It may cause orthostatic hypotension, tachycardia, somnolence, akathisia, dystonia, EPS, and parkinsonism.

Olanzapine (Zyprexa)

Indications. Olanzapine is indicated for the treatment of schizophrenia. Oral olanzapine is indicated for use as monotherapy for the acute treatment of manic or mixed episodes associated with bipolar I disorder and maintenance treatment of bipolar I disorder. Oral olanzapine is also indicated for the treatment of manic or mixed episodes associated with bipolar I disorder as an adjunct to lithium or valproate, and olanzapine can also be used in combination with fluoxetine (Symbyax) for the treatment of depressive

episodes associated with bipolar I disorder.

Oral olanzapine and fluoxetine in combination (Symbyax) is indicated for the treatment of treatment-resistant depression. Olanzapine monotherapy is not indicated for the treatment of treatment-resistant depression.

Pharmacology. Approximately 85 percent of olanzapine is absorbed from the GI tract, and about 40 percent of the dosage is inactivated by first-pass hepatic metabolism. Peak concentrations are reached in 5 hours, and the half-life averages 31 hours (range 21 to 54 hours). It is given in once-daily dosing. In addition to 5-HT_{2A} and D_2 antagonism, olanzapine is an antagonist of the D_1, D_4, α_1, 5-HT_{1A}, muscarinic M_1 to M_5, and H_1 receptors.

Dosages. Olanzapine is available in 2.5-, 5-, 7.5-, 10-, 15-, and 20-mg oral and Zydis form (orally disintegrating) tablets. The initial dosage for the treatment of psychosis is usually 5 or 10 mg. For acute mania, it is usually 10 or 15 mg given once daily. It is also available as 5-, 10-, 15-, and 20-mg orally disintegrating tablets that might be useful for patients who have difficulty swallowing pills or who “cheek” their medication.

A starting daily dose of 5 to 10 mg is recommended. After 1 week, the dosage can be raised to 10 mg a day. Given the long half-life, 1 week must be allowed to achieve each new steady-state blood level. Dosages in clinical use ranges vary, with 5 to 20 mg a day is most commonly used, but 30 to 40 mg a day is needed in treatment-resistant patients. A word of caution, however, is that the higher dosages are associated with increased EPS and other adverse effects, and dosages above 20 mg a day were not studied in the pivotal trials that led to the approval of olanzapine. The parenteral form of olanzapine is indicated for the treatment of acute agitation associated with schizophrenia and bipolar disorder, and the IM dosage is 10 mg. Coadministration with benzodiazepines is not approved.

Other Formulations. Olanzapine is available as an extended-release injectable suspension (Relprevv), which is a long-acting atypical IM injection indicated for the treatment of schizophrenia. It is injected deep in the gluteal region and should not be administered intravenously or subcutaneously, nor is it approved for deltoid administration. Before administering the injection, the administrator should aspirate the syringe for several seconds to ensure

that no blood is visible. It carries a boxed warning for postinjection delirium sedation syndrome (PDSS). Patients are at risk for severe sedation (including coma) and must be observed for 3 hours after each injection in a registered facility. In controlled studies, all patients with PDSS recovered, and there were no deaths reported. It is postulated that PDSS is secondary to increased levels of olanzapine secondary to accidental rupture of a blood vessel, causing extreme sedation or delirium. Patients should be managed as clinically appropriate and, if necessary, monitored in a facility capable of resuscitation. The injection can be given every 2 or 4 weeks, depending on the dosing guidelines.

Drug Interactions. Fluvoxamine (Luvox) and cimetidine (Tagamet) increase, and carbamazepine and phenytoin decrease, serum concentrations of olanzapine. Ethanol increases olanzapine absorption by more than 25 percent, leading to increased sedation. Olanzapine has little effect on the metabolism of other drugs.

Side Effects. Other than clozapine, olanzapine consistently causes a more significant amount and more frequent weight gain than other atypicals. This effect is not dose-related and continues over time. Clinical trial data suggest it peaks after 9 months, after which it may continue to increase more slowly. Somnolence, dry mouth, dizziness, constipation, dyspepsia, increased appetite, akathisia, and tremor are associated with olanzapine use. A small number of patients (2 percent) may need to discontinue the use of the drug because of transaminase elevation. There is a dose-related risk of EPS. The manufacturer recommends a “periodic” assessment of blood sugar and transaminases during treatment with olanzapine. There is an FDA-mandated warning about an increased risk of stroke among patients with dementia treated with SDAs, but this risk is small and is outweighed by improved behavioral control that treatment may produce.

Quetiapine (Seroquel)

Indications. Quetiapine is indicated for the treatment of schizophrenia. It is also indicated for the acute treatment of manic episodes associated with bipolar I disorder, both as monotherapy and as an adjunct to lithium or

sodium valproate. It is also indicated as monotherapy for the acute treatment of depressive episodes associated with bipolar disorder and maintenance treatment of bipolar I disorder as an adjunct to lithium or divalproex. It also is indicated as adjunctive therapy to antidepressants for the treatment of MDD.

Pharmacology. Quetiapine is a dibenzothiazepine structurally related to clozapine, but it differs markedly from that agent in biochemical effects. It is rapidly absorbed from the GI tract, with peak plasma concentrations reached in 1 to 2 hours. The steady-state half-life is about 7 hours, and optimal dosing is two or three times per day. Quetiapine, in addition to being an antagonist of D_2 and 5-HT_2, also blocks 5-HT_6, D_1 and H_1, and α_1 and α_2 receptors. It does not block muscarinic or benzodiazepine receptors. The receptor antagonism for quetiapine is generally lower than that for other antipsychotic drugs, and it is not associated with EPS.

Dosages. Quetiapine is available in 25-, 50-, 100-, 200-, 300-, and 400-mg tablets. Quetiapine dosing should begin at 25 mg twice daily, with doses then increased by 25 to 50 mg/dose every 2 to 3 days, up to a target of 300 to 400 mg a day. Studies have shown efficacy in the range of 300 to 800 mg a day. In reality, more aggressive dosing is both tolerated and more effective. It has become evident that the target dose can be achieved more rapidly and that some patients benefit from dosages of as much as 1,200 to 1,600 mg a day. When used at higher doses, serial ECG studies are required. Despite its short elimination half-life, quetiapine can be given to many patients once a day. This dosing is consistent with the observation that quetiapine receptor occupancy remains even when concentrations in the blood have markedly declined. Quetiapine in doses of 25 to 300 mg at night has been used for insomnia.

Other Formulations. Quetiapine XR has comparable bioavailability to an equivalent dose of quetiapine administered two or three times daily. Quetiapine XR is given once daily, preferably in the evening, 3 to 4 hours before bedtime without food or a light meal to prevent an increase in C_{max}. The usual starting dose is 300 mg, and it may be increased to 400 to 800 mg.

Drug Interactions. The potential interactions between quetiapine and other

drugs have been well studied. Phenytoin increases quetiapine clearance fivefold; no significant pharmacokinetic interactions have been noted. Avoid the use of quetiapine with drugs that increase the QT interval and in patients with risk factors for prolonged QT interval. The FDA has added a new warning about quetiapine, cautioning prescribers about potential prolongation of the QT interval when above-recommended amounts of quetiapine are combined with specific drugs. Quetiapine should not be combined with other drugs that are known to prolong QTc. This includes class 1A antiarrhythmics (e.g., quinidine, procainamide) or class III antiarrhythmics (e.g., amiodarone, sotalol), antipsychotic medications (e.g., ziprasidone, chlorpromazine, thioridazine), antibiotics (e.g., gatifloxacin, moxifloxacin), or any other class of medications known to prolong the QTc interval (e.g., pentamidine, levomethadyl acetate, methadone). Quetiapine should also be avoided in circumstances that may increase the risk of occurrence of torsade de pointes or sudden death, including (1) a history of cardiac arrhythmias such as bradycardia; (2) hypokalemia or hypomagnesemia; (3) concomitant use of other drugs that prolong the QTc interval; and (4) presence of congenital prolongation of the QT interval. Postmarketing cases also show increases in QT interval in patients who overdose on quetiapine.

Side Effects. Somnolence, postural hypotension, and dizziness are the most common adverse effects of quetiapine. These are usually transient and are best managed with initial gradual upward titration of the dosage. Quetiapine is the SDA least likely to cause EPS, regardless of dose. This makes it particularly useful in treating patients with Parkinson disease who develop dopamine agonist-induced psychosis. Prolactin elevation is rare and both transient and mild when it occurs. Quetiapine is associated with modest transient weight gain in some persons, but some patients occasionally gain a considerable amount of weight. The relationship between quetiapine and the development of diabetes is not as clearly established as are the cases involving the use of olanzapine. Small increases in heart rate, constipation, and a transient increase in liver transaminases may also occur. Initial concerns about cataract formation, based on animal studies, have not been borne out since the drug has been in clinical use. Nevertheless, it might be prudent to test for lens abnormalities early in treatment and periodically after that.

Ziprasidone (Geodon)

Indications. Ziprasidone is indicated for the treatment of schizophrenia. Ziprasidone is also indicated as monotherapy for the acute treatment of manic or mixed episodes associated with bipolar I disorder and as an adjunct to lithium or valproate for the maintenance treatment of bipolar I disorder.

Pharmacology. Ziprasidone is a benzisothiazole piperazine. Peak plasma concentrations of ziprasidone are reached in 2 to 6 hours. Steady-state levels ranging from 5 to 10 hours are reached between the first and the third days of treatment. The mean terminal half-life at steady state ranges from 5 to 10 hours, which accounts for the recommendation that twice-daily dosing is necessary. Bioavailability doubles when ziprasidone is taken with food, and therefore it should be taken with food.

Peak serum concentrations of IM ziprasidone occur after approximately 1 hour, with a half-life of 2 to 5 hours.

Ziprasidone, similar to the other SDAs, blocks 5-HT_{2A} and D_2 receptors. It is also an antagonist of 5-HT_{1D}, 5-HT_{2C}, D_3, D_4, α_1, and H_1 receptors. It has a very low affinity for D_1, M_1, and α_2 receptors. Also, ziprasidone has agonist activity at the serotonin 5-HT_{1A} receptors and is an SSRI and a norepinephrine reuptake inhibitor. This action is consistent with clinical reports that ziprasidone has antidepressant-like effects in nonschizophrenic patients.

Dosages. Ziprasidone is available in 20-, 40-, 60-, and 80-mg capsules. Ziprasidone for IM use comes as a single-use 20 mg/mL vial. Oral ziprasidone dosing should be initiated at 40 mg a day, divided into two daily doses. Studies have shown efficacy in the range of 80 to 160 mg a day, divided twice daily. In clinical practice, doses as high as 240 mg a day are being used. The recommended IM dosage is 10 to 20 mg every 2 hours for the 10-mg dose and every 4 hours for the 20-mg dose. The maximum total daily dose of IM ziprasidone is 40 mg.

Other than interactions with other drugs that prolong the QTc complex, ziprasidone appears to have a low potential for clinically significant drug interactions.

Side Effects. Somnolence, headache, dizziness, nausea, and lightheadedness are the most common adverse effects in patients taking ziprasidone. The drug has almost no significant effects outside the CNS, is associated with almost no weight gain, and does not cause sustained prolactin elevation. Concerns about prolongation of the QTc complex have deterred some clinicians from using ziprasidone as a first choice. The QTc interval has been shown to increase in patients treated with 40 and 120 mg/day. Ziprasidone is contraindicated in combination with other drugs known to prolong the QTc interval. These include, but are not limited to, dofetilide, sotalol, quinidine, other class IA and III antiarrhythmics, mesoridazine, thioridazine, chlorpromazine, droperidol, pimozide, sparfloxacin, gatifloxacin, moxifloxacin, halofantrine, mefloquine, pentamidine, arsenic trioxide, levomethadyl acetate, dolasetron mesylate, probucol, and tacrolimus. Ziprasidone should be avoided in patients with congenital long QT syndrome and patients with a history of cardiac arrhythmias.

Aripiprazole (Abilify)

Aripiprazole is a potent 5-HT_{2A} antagonist and is indicated for the treatment of both schizophrenia and acute mania. It is also approved for the augmentation of antidepressant agents in MDD. Aripiprazole is a D_2 antagonist, but can also act as a partial D_2 agonist. Partial D_2 agonists compete at D_2 receptors for endogenous dopamine, thereby producing a functional reduction of dopamine activity.

Indications. Aripiprazole is indicated for the treatment of schizophrenia. Short-term, 4- to 6-week studies comparing aripiprazole with haloperidol and risperidone in patients with schizophrenia and schizoaffective disorder have shown comparable efficacy. Dosages of 15, 20, and 30 mg a day were found to be effective. Long-term studies suggest that aripiprazole is effective as a maintenance treatment at a daily dose of 15 to 30 mg.

Aripiprazole is also indicated for the acute and maintenance treatment of manic and mixed episodes associated with bipolar I disorder. It is also used as adjunctive therapy to either lithium or valproate for the acute treatment of manic and mixed episodes associated with bipolar I disorder.

Aripiprazole is indicated for use as adjunctive therapy to antidepressants

for the treatment of MDD. Aripiprazole is also indicated for the treatment of irritability associated with autistic disorder.

Pharmacology. Aripiprazole is well absorbed, reaching peak plasma concentrations after 3 to 5 hours. Absorption is not affected by food. The mean elimination half-life of aripiprazole is about 75 hours. It has a weakly active metabolite with a half-life of 96 hours. These relatively long half-lives make aripiprazole suitable for once-daily dosing. Clearance is reduced in elderly persons. Aripiprazole exhibits linear pharmacokinetics and is primarily metabolized by CYP3A4 and CYP2D6 enzymes. It is 99 percent protein-bound. Aripiprazole is excreted in breast milk in lactating rats.

Mechanistically, aripiprazole acts as a modulator, rather than a blocker, and acts on both postsynaptic D_2 receptors and presynaptic autoreceptors. In theory, this mechanism addresses excessive limbic dopamine (hyperdopaminergic) activity and decreased dopamine (hypodopaminergic) activity in frontal and prefrontal areas—abnormalities that are thought to be present in schizophrenia. The absence of a complete D_2 blockade in the striatal areas would be expected to minimize EPS. Aripiprazole is an α_1-adrenergic receptor antagonist, which may cause some patients to experience orthostatic hypotension. Similar to the so-called atypical antipsychotic agents, aripiprazole is a 5-HT_{2A} antagonist.

Other Uses. A study of aggressive children and adolescents with oppositional defiant disorder or conduct disorder found that there was a positive response in about 60 percent of the subjects. In this study, vomiting and somnolence led to a reduction in initial aripiprazole dosage.

Drug Interactions. Whereas carbamazepine and valproate reduce serum concentrations, ketoconazole, fluoxetine, paroxetine, and quinidine increase aripiprazole serum concentrations. Lithium and valproic acid, two drugs likely to be combined with aripiprazole when treating bipolar disorder, do not affect the steady-state concentrations of aripiprazole. Combined use with antihypertensives may cause hypotension. Drugs that inhibit CYP2D6 activity reduce aripiprazole elimination.

Dosage and Clinical Guidelines. Aripiprazole is available as 5-, 10-, 15-

, 20-, and 30-mg tablets. The effective dosage range is 10 to 30 mg/day. Although the starting dosage is 10 to 15 mg/day, problems with nausea, insomnia, and akathisia have led to the use of lower than recommended starting dosages of aripiprazole. Many clinicians find that an initial dose of 5 mg increases tolerability.

Side Effects. The most commonly reported side effects of aripiprazole are headache, somnolence, agitation, dyspepsia, anxiety, and nausea. Although it is not a frequent cause of EPS, aripiprazole does cause akathisia-like activation. Described as restlessness or agitation, it can be highly distressing and often leads to discontinuation of the medication. Insomnia is another common complaint. Data so far do not indicate that weight gain or diabetes mellitus have an increased incidence with aripiprazole. Prolactin elevation does not typically occur. Aripiprazole does not cause significant QTc interval changes. There have been reports of seizures.

Asenapine (Saphris)

Indications. Asenapine is approved for the acute treatment of adults with schizophrenia and acute treatment of manic or mixed episodes associated with bipolar I disorder with or without psychotic features in adults.

Pharmacology. Asenapine has an affinity for several receptors, including serotonin (5-HT_{2A} and 5-HT_{2C}), noradrenergic (α_2, and α_1), dopaminergic (D_3 and D_4 receptors is higher than its affinity for D_2 receptors), and histamine (H_1). It has a negligible affinity for muscarinic-1 cholinergic receptors and hence less incidence of dry mouth, blurred vision, constipation, and urinary retention. The bioavailability is 35 percent via the sublingual (preferred) route, and it achieves peak plasma concentration in 1 hour. Asenapine is metabolized through glucuronidation and oxidative metabolism by CYP1A2, so coadministration with fluvoxamine and other CYP1A2 inhibitors should be done cautiously.

Dosage. Asenapine is available as 5- and 10-mg sublingual tablets and should be placed under the tongue. This method is because the bioavailability of asenapine is less than 2 percent when swallowed, but is 35 percent when

absorbed sublingually. The agent dissolves in saliva within seconds and is absorbed through the oral mucosa. Sublingual administration avoids first-pass hepatic metabolism. Patients should be advised to avoid drinking or eating for 10 minutes after taking asenapine because this may lower the blood levels. The recommended starting and target dose for schizophrenia is 5 mg twice a day. In bipolar disorder, the patient may be started on 10 mg twice a day, and if necessary, the dosage may be lowered to 5 mg twice a day, depending on the tolerability issues. In acute schizophrenia treatment, there is no evidence of added benefit with a 10 mg twice-daily dose, but there is an apparent increase in specific adverse reactions. In both bipolar I disorder and schizophrenia, the maximum dose should not exceed 10 mg two times a day. The safety of doses above 10 mg twice a day has not been evaluated in clinical studies.

Side Effects. The most common side effects observed in schizophrenic and bipolar disorders are somnolence, dizziness, EPS other than akathisia, and increased weight. In clinical trials, the mean weight gain after 52 weeks is 0.9 kg, and there were no clinically relevant differences in lipid profile and blood glucose after 52 weeks. In clinical trials, asenapine was found to increase the QTc interval in a range of 2 to 5 milliseconds compared to placebo. No patients treated with asenapine experienced QTc increases 60 milliseconds or greater from baseline measurements, nor did any experience a QTc of 500 milliseconds or more. Nevertheless, asenapine should be avoided in combination with other drugs known to prolong QTc interval in patients with congenital prolongation of QT interval or a history of cardiac arrhythmias, and in circumstances that may increase the occurrence of torsades de pointes. Asenapine can elevate prolactin levels, and the elevation can persist during chronic administration. Galactorrhea, amenorrhea, gynecomastia, and impotence may occur.

Clozapine (Clozaril)

Indications. In addition to being the most effective drug treatment for patients who have failed to respond to standard therapies, clozapine has been shown to benefit patients with severe tardive dyskinesia. Clozapine suppresses these dyskinesias, but the abnormal movements return when

clozapine is discontinued. This suppression is true even though clozapine, on rare occasions, may cause tardive dyskinesia. Other clinical situations in which clozapine may be used include the treatment of psychotic patients intolerant of EPS caused by other agents, treatment-resistant mania, severe psychotic depression, idiopathic Parkinson disease, Huntington disease, and suicidal patients with schizophrenia or schizoaffective disorder. Other treatment-resistant disorders that have demonstrated response to clozapine include pervasive developmental disorder, autism of childhood, and OCD (either alone or in combination with an SSRI). Used by itself, clozapine may very rarely induce obsessive-compulsive symptoms.

Pharmacology. Clozapine is a dibenzothiazepine. It is rapidly absorbed, with peak plasma levels reached in about 2 hours. Steady state is achieved in less than 1 week if twice-daily dosing is used. The elimination half-life is about 12 hours. Clozapine has two significant metabolites, one of which, *N*-dimethyl clozapine, may have some pharmacologic activities. Clozapine is an antagonist of 5-HT_{2A}, D_1, D_3, D_4, and α (especially α_1) receptors. It has relatively low potency as a D_2 receptor antagonist. Data from PET scanning show that whereas 10 mg of haloperidol produces 80 percent occupancy of striatal D_2 receptors, clinically significant dosages of clozapine occupy only 40 to 50 percent of striatal D_2 receptors. This difference in D_2 receptor occupancy is probably why clozapine does not cause EPS. It has also been postulated that clozapine and other SDAs bind more loosely to the D_2 receptor, and because of this "fast dissociation," more normal dopamine neurotransmission is possible.

Dosages. Clozapine is available in 25- and 100-mg tablets. The initial dosage is usually 25 mg one or two times daily, although a conservative initial dosage is 12.5 mg twice daily. The dosage can then be increased gradually (25 mg a day every 2 or 3 days) to 300 mg a day in divided doses, usually two or three times a day. Dosages up to 900 mg a day can be used. Testing for blood concentrations of clozapine may be helpful in patients who fail to respond. Studies have found that plasma concentrations greater than 350 μg/mL are associated with a better likelihood of response.

Drug Interactions. Clozapine should not be used with any other drug that is associated with the development of agranulocytosis or bone marrow suppression. Such drugs include carbamazepine, phenytoin, propylthiouracil, sulfonamides, and captopril (Capoten). Lithium combined with clozapine may increase the risk of seizures, confusion, and movement disorders. Lithium should not be used in combination with clozapine by persons who have experienced an episode of neuroleptic malignant syndrome. Clomipramine (Anafranil) can increase the risk of seizure by lowering the seizure threshold and by increasing clozapine plasma concentrations. Risperidone, fluoxetine, paroxetine, and fluvoxamine increase serum concentrations of clozapine. The addition of paroxetine may precipitate clozapine-associated neutropenia.

Side Effects. The most common drug-related adverse effects are sedation, dizziness, syncope, tachycardia, hypotension, electrocardiography (ECG) changes, nausea, and vomiting. Other common adverse effects include fatigue, weight gain, various GI symptoms (most commonly constipation), anticholinergic effects, and subjective muscle weakness. Sialorrhea, or hypersalivation, is a side effect that begins early in treatment and is most evident at night. Patients report that their pillows are drenched with saliva. This side effect is most likely the result of impairment of swallowing. Although there are reports that clonidine or amitriptyline may help reduce hypersalivation, the most practical solution is to put a towel over the pillow.

The risk of seizures is about 4 percent in patients taking dosages greater than 600 mg a day. Leukopenia, granulocytopenia, agranulocytosis, and fever occur in about 1 percent of patients. During the first year of treatment, there is a 0.73 percent risk of clozapine-
induced agranulocytosis. The risk during the second year is 0.07 percent. For neutropenia, the risk is 2.32 percent and 0.69 percent, respectively, during the first and second years of treatment. The only contraindications to the use of clozapine are a WBC count below 3,500 cells/mm^3; a previous bone marrow disorder; a history of agranulocytosis during clozapine treatment; or the use of another drug that is known to suppress the bone marrow, such as carbamazepine (Tegretol).

During the first 6 months of treatment, weekly WBC counts are indicated to monitor the patient for the development of agranulocytosis. If the WBC

count remains normal, the frequency of testing can be decreased to every 2 weeks. Although monitoring is expensive, an early indication of agranulocytosis can prevent a fatal outcome. Clozapine should be discontinued if the WBC count is below 3,000 cells/mm^3 or the granulocyte count is below 1,500/mm^3. Also, a hematologic consultation should be obtained, and obtaining a bone marrow sample should be considered. Persons with agranulocytosis should not be reexposed to the drug. Clozapine cannot be dispensed without proof of monitoring.

Patients exhibiting symptoms of chest pain, shortness of breath, fever, or tachypnea should be immediately evaluated for myocarditis or cardiomyopathy, an infrequent but serious adverse effect ending in death. Serial CPK-MB (creatine phosphokinase with myocardial band fractions), troponin levels, and ECG studies are recommended, with immediate discontinuation of clozapine.

Iloperidone (Fanapt)

Indications. Iloperidone (Fanapt) is indicated for the acute treatment of schizophrenia in adults. The safety and efficacy of iloperidone in children and adolescents has not been established.

Pharmacology. Iloperidone is not a derivative of another antipsychotic agent. It has complex multiple antagonist effects on several neurotransmitter systems. Iloperidone has a strong affinity for dopamine D_3 receptors, followed by decreasing affinities of α_{2c}-noradrenergic, 5-HT_{1a}, D_{2a}, and 5-HT_6 receptors. Iloperidone has a low affinity for histaminergic receptors. As with other antipsychotics, the clinical significance of this receptor binding affinity is unknown.

Iloperidone has a peak concentration of 2 to 4 hours and a half-life that is dependent on hepatic isoenzyme metabolism. It is metabolized primarily through CYP2D6 and CYP3A4, and the dosage should be reduced by half when administered concomitantly with potent inhibitors of these two isoenzymes. The half-life is 18 to 26 hours in CYP2D6 extensive metabolizers and is 31 to 37 hours in CYP2D6 poor metabolizers. Of note, approximately 7 to 10 percent of whites and 3 to 8 percent of African Americans cannot metabolize CYP2D6 substrates; hence, dosing should be

determined with this caveat in mind. Iloperidone should be used with caution in persons with severe hepatic impairment.

Side Effects. Iloperidone prolongs the QT interval and may be associated with arrhythmia and sudden death. Iloperidone prolongs the QTc interval by 9 milliseconds at dosages of 12 mg twice daily. Concurrent use with other agents that prolong the QTc interval may result in additive effects on the QTc interval. The concurrent use of iloperidone with agents that prolong the QTc interval may result in potentially life-threatening cardiac arrhythmias, including torsades de pointes. Concurrent administration of other drugs that are known to prolong the QTc interval should be avoided. Cardiovascular disease, hypokalemia, hypomagnesemia, bradycardia, congenital prolongation of the QT interval, and concurrent use of inhibitors of CYP3A4 or CYP2D6, which metabolize iloperidone, may increase the risk of QT prolongation.

The most common adverse effects reported are dizziness, dry mouth, fatigue, sedation, tachycardia, and orthostatic hypotension (depending on dosing and titration). Despite being a robust D_2 antagonist, the rates of EPS and akathisia are similar to those of placebo. The mean weight gain in short- and long-term trials is 2.1 kg. Due to its relatively limited use, there is no accurate understanding of iloperidone's effects on weight and lipids. Some patients exhibit elevated prolactin levels. Three cases of priapism have been reported in the premarketing phase.

Dosing. Iloperidone must be titrated slowly to avoid orthostatic hypotension. It is available in a titration pack, and the effective dose (12 mg) should be reached in approximately 4 days based on a twice-a-day dosing schedule. It is usually started on day 1 at 1 mg twice a day and increased daily on a twice-a-day schedule to reach 12 mg by day 4. The maximum recommended dose is 12 mg twice a day (24 mg a day), and it can be administered without regard to food.

Lurasidone HCL (Latuda)

Indications. Lurasidone hydrochloride is an oral, once-daily atypical antipsychotic indicated for the treatment of patients with schizophrenia. To

date, there has not been extensive clinical experience with lurasidone.

Side Effects. The most commonly observed adverse reactions associated with the use of lurasidone are similar to those seen with other new-generation antipsychotics. These include, but are not limited to, somnolence, akathisia, nausea, parkinsonism, and agitation. Based on clinical trial data, lurasidone appears to cause less weight gain and metabolic changes than the two other most recently approved SDAs, asenapine and iloperidone. More extensive clinical experience with the drug is required to determine whether this is, in fact, the case.

Drug Interactions. When coadministration of lurasidone with a moderate CYP3A4 inhibitor such as diltiazem is considered, the dose should not exceed 40 mg/day. Lurasidone should not be used in combination with a potent CYP3A4 inhibitor (e.g., ketoconazole). Lurasidone also should not be used in combination with a potent CYP3A4 inducer (e.g., rifampin).

Dosages. Lurasidone is available as 20-, 40-, 80-, and 120-mg tablets. Initial dose titration is not required. The recommended starting dose is 40 mg once daily, and the medication should be taken with food. It is effective in a dose range of 40 to 120 mg/day. Although there is no proven added benefit with the 120 mg/day dose, there may be a dose-related increase in adverse reactions. Still, some patients may benefit from the maximum recommended dose of 160 mg/day. Dose adjustment is recommended in patients with renal impairment. The dose in moderate to severe renal impairment should not exceed 80 mg/day. The dose in severe hepatic impairment patients should not exceed 40 mg/day.

Lumateperone (Caplyta)

Lumateperone was approved by the FDA for the treatment of schizophrenia in adults in December 2019 and became available in February 2020. It antagonizes several receptors, including 5-HT_{2A} receptor, D_1, D_2, and D_4. Although effective for schizophrenia, several studies of its effectiveness in bipolar depression had disappointing results. It is available in several doses, although the highest FDA-approved dose is 42 mg. As this is a new drug, experience with it in post study clinical samples is very limited.

Clinical Guidelines for SDAs

All SDAs are appropriate for the management of an initial psychotic episode, but clozapine is reserved for persons who are refractory to all other antipsychotic drugs. If a person does not respond to the first SDA, other SDAs should be tried. The choice of drug should be based on the patient's clinical status and history of response to medication. Recent studies have challenged the notion that SDAs require 4 to 6 weeks to reach full effectiveness, and it may take up to 8 weeks for the full clinical effects of an SDA to become apparent. The newer meta-analyses suggest that the apparent benefits may be seen as early as 2 to 3 weeks, and early response or failure is an indicator of subsequent response or failure.

Nevertheless, it is acceptable practice to augment an SDA with a high-potency DRA or benzodiazepine in the first few weeks of use. Lorazepam (Ativan) 1 to 2 mg orally or IM can be used as needed for acute agitation. Once effective, dosages can be lowered as tolerated. Clinical improvement may take 6 months of treatment with SDAs in some, particularly treatment-refractory persons.

The use of all SDAs must be initiated at low dosages and gradually tapered upward to therapeutic dosages. The potential development of adverse effects necessitates the gradual increase in dosage. If a person stops taking an SDA for more than 36 hours, drug use should be resumed at the initial titration schedule. After the decision to terminate olanzapine or clozapine use, dosages should be tapered whenever possible to avoid cholinergic rebound symptoms such as diaphoresis, flushing, diarrhea, and hyperactivity.

After assuring themselves of the appropriateness of SDA treatment, the clinician should explain the risks and benefits of SDA treatment to the person and the family. In the case of clozapine, an informed consent procedure should be documented in the person's chart. The patient's history should include information about blood disorders, epilepsy, cardiovascular disease, hepatic and renal diseases, and drug abuse. The presence of a hepatic or renal disease necessitates using low starting dosages of the drug. The physical examination should include supine and standing BP measurements to screen for orthostatic hypotension. The laboratory examination should include an ECG and several complete blood counts (CBCs) with WBC counts, which can then be averaged; and liver and renal function tests. Periodic monitoring

of blood glucose, lipids, and body weight is recommended.

Although the transition from a DRA to an SDA may be made abruptly, it is wiser to taper off the DRA slowly while titrating up the SDA. Clozapine and olanzapine both have anticholinergic effects, and the transition from one to the other can usually be accomplished with little risk of cholinergic rebound. The transition from risperidone to olanzapine is best accomplished by tapering the risperidone off over 3 weeks while simultaneously beginning olanzapine at 10 mg a day. Risperidone, quetiapine, and ziprasidone lack anticholinergic effects, and the abrupt transition from a DRA, olanzapine, or clozapine to one of these agents may cause cholinergic rebound, which consists of excessive salivation, nausea, vomiting, and diarrhea. The risk of cholinergic rebound can be mitigated by initially augmenting risperidone, quetiapine, or ziprasidone with an anticholinergic drug, which is then tapered off slowly. Any initiation and termination of SDA use should be accomplished gradually.

It is wise to overlap the administration of the new drug with the old drug. Of interest, some people have a more robust clinical response while taking the two agents during the transition and then regressing on monotherapy with the newer drug. We know little about the safety of combination antipsychotic treatment.

Persons receiving regular injections of depot formulations of a DRA who are to switch to SDA use are given the first dose of the SDA on the day the next injection is due.

Persons who developed agranulocytosis while taking clozapine can safely switch to olanzapine use, although initiation of olanzapine use amid clozapine-induced agranulocytosis can prolong the time of recovery from the usual 3 to 4 days up to 11 to 12 days. It is prudent to wait for the resolution of agranulocytosis before initiating olanzapine use. Emergence or recurrence of agranulocytosis has not been reported with olanzapine, even in persons who developed it while taking clozapine.

SDA use by pregnant women has not been studied, but consideration should be given to the potential of risperidone to raise prolactin concentrations, sometimes up to three to four times the upper limit of the normal range. Because the drugs can be excreted in breast milk, they should not be taken by nursing mothers. The dosages for selected SDAs are given in Table 21-9.

DOPAMINE RECEPTOR ANTAGONISTS (FIRST-GENERATION ANTIPSYCHOTICS)

The DRAs represent the first group of effective agents for schizophrenia and other psychotic illnesses. The first of these drugs, the phenothiazine chlorpromazine (Thorazine), was introduced in the early 1950s. Other DRAs include all of the antipsychotics in the following groups: phenothiazines, butyrophenones, thioxanthenes, dibenzoxazepines, dihydroindoles, and diphenylbutylpiperidines. Because these agents are associated with extrapyramidal side effects (EPS) at clinically effective dosages, newer antipsychotic drugs—the SDAs—have gradually replaced the older agents in the United States. The SDAs are differentiated from earlier drugs by their lower liability to cause extrapyramidal side effects. These newer drugs have other liabilities, most notably a propensity to cause weight gain, lipid elevations, and diabetes. Therefore, a reason to still consider the use of the DRAs is their lower risk of causing significant metabolic abnormalities. Intermediate-potency DRAs, such as perphenazine (Trilafon), are as effective and well tolerated as the SDAs. Manufacturing of molindone (Moban), the DRA with the lowest risk of weight gain and metabolic side effects, was discontinued in the United States.

Table 21-9
Comparison of Usual Dosing[a] for Some Available Second-Generation Antipsychotics in Schizophrenia

Antipsychotic	Typical Starting Dosage	Maintenance Therapy Dose Range	Titration	Maximum Recommended Dosage
Aripiprazole (Abilify)	10–15 mg tablets once a day	10–30 mg/day	Dosage increases should not be made before 2 wk	30 mg/day
Asenapine (Saphris)	5 mg twice a day	10 mg twice a day	Titration not necessary	20 mg/day
Clozapine (Clozaril)	12.5-mg tablets once or twice a day	150–300 mg/day in divided doses or 200 mg as a single dose in the evening	The dosage should be increased to 25–50 mg on the second day. Further increases may be made in daily increments of 25–50 mg to a target dosage of 300–450 mg/day. Subsequent dosage increases should be made no more than once or twice weekly in increments of no more than 100 mg	900 mg/day
Iloperidone (Fanapt)	1 mg twice a day	12–24 mg a day in divided dose	Start at 1 mg twice a day then move to 2, 4, 6, 8 and 12 mg twice a day. Do this over the course of 7 days	24 mg/day
Lurasidone (Latuda)	40 mg/day	40–80 mg/day	Titration not necessary	120 mg/day
Olanzapine (Zyprexa)	5–10 mg/day tablets or orally disintegrating tablets	10–20 mg/day	Dosage increments of 5 mg once a day are recommended when required at intervals of not less than 1 wk	20 mg/day
Paliperidone (Invega)	3–9 mg extended-release tablets once a day	3–6 mg/day	Plasma concentration rises to a peak approximately 24 hr after dosing	12 mg/day
Quetiapine (Seroquel)	25-mg tablets twice a day	Lowest dose needed to maintain remission	Increase in increments of 25–50 mg two or three times a day on the second and the third day, as tolerated, to a target dosage of 500 mg daily by the fourth day (given in two or three doses/day). Further dosage adjustments, if required, should be of 25–50 mg twice a day and occur at intervals of not fewer than 2 days	800 mg/day
Risperidone (Risperdal)	1-mg tablet and oral solution once a day	2–6 mg once a day	Increase to 2 mg once a day on the second day and 4 mg once a day on the third day. In some patients, a slower titration may be appropriate. When dosage adjustments are necessary, further dosage increments of 1–2 mg/day at intervals of not less than 1 wk are recommended	1–6 mg/day
Risperidone IM long-acting (Consta)	25–50 mg IM injection every 2 wk	Start with oral risperidone for 3 wk	Starting dose: 25 mg every 2 wk	50 mg for 2 wk
Ziprasidone (Geodon)	20-mg capsules twice a day with food	20–80 mg twice a day	Dosage adjustments based on individual clinical status may be made at intervals of not fewer than 2 days	80 mg twice a day
Ziprasidone (IM)	For acute agitation: 10–20 mg, as required, up to a maximum of 40 mg/day	Not applicable	For acute agitation: Doses of 10 mg may be administered every 2 hr, and doses of 20 mg may be administered every 4 hr up to a maximum of 40 mg/day	For acute agitation: 40 mg/day, for not more than 3 consecutive days

Note: Information taken from U.S. Prescribing Information for individual agents.
[a]Dosage adjustments may be required in special populations.
IM, intramuscular.

Pharmacologic Actions

All of the DRAs are well absorbed after oral administration, with liquid preparations being absorbed more efficiently than tablets or capsules. Peak plasma concentrations are usually reached 1 to 4 hours after oral administration and 30 to 60 minutes after parenteral administration. Smoking, coffee, antacids, and food interfere with the absorption of these drugs. Steady-state levels are reached in approximately 3 to 5 days. The half-lives of these drugs are approximately 24 hours. All can be given in one daily oral

dose if tolerated after the patient is in a stable condition. Most DRAs are highly protein-bound. Parenteral formulation of the DRAs results in a more rapid and more reliable onset of action. Bioavailability is also up to 10-fold higher with parenteral administration. Most DRAs are metabolized by cytochrome P450 (CYP) CYP2D6 and 3A isozymes. However, there are differences among the specific agents.

Table 21-10
Factors Influencing the Pharmacokinetics of Antipsychotics

Age	Elderly patients may demonstrate reduced clearance rates.
Medical condition	Decreased hepatic blood flow can reduce clearance.
	Hepatic disease can decrease clearance.
Enzyme inducers	Carbamazepine, phenytoin, ethambutol, barbiturates.
Clearance inhibitors	Include SSRIs, TCAs, cimetidine, β-blockers, isoniazid, methylphenidate, erythromycin, triazolobenzodiazepines, ciprofloxacin, and ketoconazole.
Changes in binding protein	Hypoalbuminemia can occur with malnutrition or hepatic failure.

SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant.

Adapted from Ereshefsky L. Pharmacokinetics and drug interactions: update for new antipsychotics. *J Clin Psychiatry*. 1996;57(Suppl 11):12–25.

Long-acting depot parenteral formulations of haloperidol (Haldol Decanoate) and fluphenazine are available in the United States. These agents are usually administered once every 1 to 4 weeks, depending on the dose and the patient. It can take up to 6 months of treatment with depot formulations to reach steady-state plasma levels, indicating that oral therapy should be

continued during the first month or so of depot antipsychotic treatment.

Antipsychotic activity derives from the inhibition of dopaminergic neurotransmission. The DRAs are effective when approximately 72 percent of dopamine D_2 receptors in the brain are occupied. The DRAs also block noradrenergic, cholinergic, and histaminergic receptors, with different drugs having different effects on these receptor systems.

Some generalizations can be made about the DRAs based on their potency. Potency refers to the amount of drug that is required to achieve therapeutic effects. Low-potency drugs such as chlorpromazine and thioridazine (Mellaril), given in doses of several 100 mg/day, typically produce more weight gain and sedation than high-potency agents such as haloperidol and fluphenazine, usually given in doses of less than 10 mg/day. High-potency agents are also more likely to cause EPS. Some factors influencing the pharmacologic actions of DRAs are listed in Table 21-10.

Therapeutic Indications

Many types of psychiatric and neurologic disorders may benefit from treatment with DRAs. Some of these indications are shown in Table 21-11.

Schizophrenia and Schizoaffective Disorder. The DRAs are useful in both the short- and long-term management of schizophrenia and schizoaffective disorder. They both reduce acute symptoms and prevent future exacerbations. These agents produce their most dramatic effects on the positive symptoms of schizophrenia (e.g., hallucinations, delusions, and agitation). Negative symptoms (e.g., emotional withdrawal and ambivalence) are less likely to improve significantly, and they may appear to worsen because these drugs produce constriction of facial expression and akinesia, side effects that mimic negative symptoms.

Table 21-11
Indications for Dopamine Receptor Antagonists

Acute psychotic episodes in schizophrenia and schizoaffective disorder
Maintenance treatment in schizophrenia and schizoaffective

disorders
Mania
Depression with psychotic symptoms
Delusional disorder
Borderline personality disorder
Substance-induced psychotic disorder
Delirium and dementia
Mental disorders caused by a medical condition
Childhood schizophrenia
Autism spectrum disorder
Tourette disorder
Huntington disease

Schizophrenia and schizoaffective disorder are characterized by remission and relapse. DRAs decrease the risk of reemergence of psychosis in patients who have recovered while on medication. After the first episode of psychosis, patients should be maintained on medication for 1 to 2 years; after multiple episodes, for 2 to 5 years.

Mania. DRAs are useful for treating psychotic symptoms of acute mania. Because antimanic agents (e.g., lithium) generally have a slower onset of action than do antipsychotics in the treatment of acute symptoms, it is standard practice to initially combine either a DRA or an SDA with lithium (Eskalith), sodium valproate (Depakote), lamotrigine (Lamictal), or carbamazepine (Tegretol) and then to withdraw the antipsychotic gradually.

Depression with Psychotic Symptoms. Combination treatment with an antipsychotic and an antidepressant is one of the treatments of choice for MDD with psychotic features; the other is ECT.

Delusional Disorder. Patients with delusional disorder often respond favorably to treatment with these drugs. Some persons with borderline personality disorder who develop paranoid thinking may respond to antipsychotic drugs.

Severe Agitation and Violent Behavior. Severely agitated and violent patients, regardless of diagnosis, may be treated with DRAs. Symptoms such as extreme irritability, lack of impulse control, severe hostility, gross hyperactivity, and agitation respond to short-term treatment with these drugs. Children with mental disabilities, especially those with profound intellectual disabilities and autistic disorder, often have associated episodes of violence, aggression, and agitation that respond to treatment with antipsychotic drugs; however, the repeated administration of antipsychotics to control disruptive behavior in children is controversial.

Tourette Disorder. DRAs are used to treat Tourette's disorder, a neurobehavioral disorder marked by motor and vocal tics. Haloperidol and pimozide (Orap) are the drugs most frequently used, but other DRAs are also useful. Some clinicians prefer to use clonidine (Catapres) for this disorder because of its lower risk of neurologic side effects.

Borderline Personality Disorder. Patients with borderline personality disorder who experience transient psychotic symptoms, such as perceptual disturbances, suspiciousness, ideas of reference, and aggression, may need to be treated with a DRA. This disorder is also associated with mood instability, so patients should be evaluated for possible treatment with mood-stabilizing agents.

Dementia and Delirium. About two-thirds of agitated, elderly patients with various forms of dementia improve when given a DRA. Low doses of high-potency drugs (e.g., 0.5 to 1 mg a day of haloperidol) are recommended. DRAs are also used to treat psychotic symptoms and agitation associated with delirium. The cause of the delirium needs to be determined because toxic deliriums caused by anticholinergic agents can be exacerbated by low-potency DRAs, which often have significant antimuscarinic activity. Orthostasis, parkinsonism, and worsened cognition are the most problematic side effects in this elderly population.

Substance-Induced Psychotic Disorder. Intoxication with cocaine, amphetamines, alcohol, phencyclidine, or other drugs can cause psychotic symptoms. Because these symptoms tend to be time-limited, it is preferable

to avoid the use of a DRA unless the patient is severely agitated and aggressive. Usually, benzodiazepines can be used to calm the patient. Benzodiazepines should be used instead of DRAs in cases of phencyclidine intoxication. When a patient is experiencing hallucinations or delusions as a result of alcohol withdrawal, DRAs may increase the risk of seizure.

Childhood Schizophrenia. Children with schizophrenia benefit from treatment with antipsychotic medication, although considerably less research has been devoted to this population. Studies are underway to determine if intervention with medication at the very earliest signs of disturbance in children genetically at risk for schizophrenia can prevent the emergence of more florid symptoms. Careful consideration needs to be given to side effects, especially those involving cognition and alertness.

Table 21-12
Dopamine Receptor Antagonists: Potency and Adverse Effects

Drug Name	Chemical Classification	Therapeutically Equivalent Oral	Side Effects		
			Sedation	Autonomic[a]	Extrapyramidal Reactions[b]
Pimozide[c]	Diphenylbutyl-piperidine	1.5	+	+	+++
Fluphenazine	Phenothiazine: piperazine compound	2	+	+	+++
Haloperidol	Butyrophenone	2	+	+	+++
Thiothixene	Thioxanthene	4	+	+	+++
Trifluoperazine	Phenothiazine: piperazine compound	5	++	+	+++
Perphenazine	Phenothiazine: piperazine compound	8	++	+	++/+++
Molindone	Dihydroindolone	10	++	+	+
Loxapine	Dibenzoxazepine	10	++	+/++	++/+++
Prochlor-perazine[c]	Phenothiazine: piperazine compound	15	++	+	+++
Aceto-phenazine	Phenothiazine: piperazine compound	20	++	+	++/+++
Triflupromazine	Phenothiazine: aliphatic compound	25	+++	++/+++	++
Mesoridazine	Phenothiazine: piperidine compound	50	+++	++	+
Chlorpromazine	Phenothiazine: aliphatic compound	100	+++	+++	++
Chlorprothixene	Thioxanthene	100	+++	+++	+/++
Thioridazine	Phenothiazine: piperidine compound	100	+++	+++	+

[a]Anti–α-adrenergic and anticholinergic effects.
[b]Excluding tardive dyskinesia, which appears to be produced to the same degree and frequency by all agents with equieffective antipsychotic dosages.
[c]Pimozide is used principally in the treatment of Tourette disorder; prochlorperazine is used rarely, if ever, as an antipsychotic agent.
Adapted from American Medical Association. *AMA Drug Evaluations: Annual 1992*. Chicago: American Medical Association, 1992.

Other Psychiatric and Nonpsychiatric Indications. The DRAs reduce the chorea in the early stages of Huntington disease. Patients with this disease

may develop hallucinations, delusions, mania, or hypomania. These and other psychiatric symptoms respond to DRAs. High-potency DRAs should be used. However, clinicians should be aware that patients with a rigid form of this disorder may experience acute EPS. The use of DRAs to treat impulse control disorders should be reserved for patients in whom other interventions have failed. Patients with autism spectrum disorder may exhibit hyperactivity, screaming, and agitation with combativeness. Some of these symptoms respond to high-potency DRAs, but there is little research evidence supporting benefits in these patients.

The rare neurologic disorders ballismus and hemiballismus (which affect only one side of the body), characterized by propulsive movements of the limbs away from the body, also respond to treatment with antipsychotic agents. Other miscellaneous indications for the use of DRAs include the treatment of nausea, emesis, intractable hiccups, and pruritus. Endocrine disorders and temporal lobe epilepsy may be associated with psychosis that responds to antipsychotic treatment.

The most common side effects of DRAs are neurologic. As a rule, low-potency drugs cause the most nonneurologic adverse effects, and high-potency drugs cause the most neurologic adverse effects.

Precautions and Adverse Reactions

Table 21-12 summarizes the most common adverse events associated with the use of DRAs.

Neuroleptic Malignant Syndrome. A potentially fatal side effect of DRA treatment, neuroleptic malignant syndrome, can occur at any time during DRA treatment. Symptoms include extreme hyperthermia, severe muscular rigidity and dystonia, akinesia, mutism, confusion, agitation, and increased pulse rate and BP. Laboratory findings include increased WBC count and levels of creatinine phosphokinase, liver enzymes, plasma myoglobin, and myoglobinuria, occasionally associated with renal failure. The symptoms usually evolve over 24 to 72 hours, and the untreated syndrome lasts 10 to 14 days. The diagnosis is often missed in the early stages, and the withdrawal or agitation may mistakenly be considered to reflect increased psychosis. Men are affected more frequently than are

women, and young persons are affected more commonly than are elderly persons. The mortality rate can reach 20 to 30 percent, or even higher, when depot medications are involved. Rates are also increased when high doses of high-potency agents are used.

If the neuroleptic malignant syndrome is suspected, the DRA should be stopped immediately, and the following done: medical support to cool the person; monitoring of vital signs, electrolytes, fluid balance, and renal output; and symptomatic treatment of fever. Antiparkinsonian medications may reduce some of the muscle rigidity. Dantrolene (Dantrium), a skeletal muscle relaxant (0.8 to 2.5 mg/kg every 6 hours, up to a total dosage of 10 mg a day), may be useful in the treatment of this disorder. When the person can take oral medications, dantrolene can be given in doses of 100 to 200 mg a day. Bromocriptine (20 to 30 mg a day in four divided doses) or amantadine can be added to the regimen. Treatment should usually be continued for 5 to 10 days. When drug treatment is restarted, the clinician should consider switching to a low-potency drug or an SDA, although these agents—including clozapine—may also cause the neuroleptic malignant syndrome.

Seizure Threshold. DRAs may lower the seizure threshold. Chlorpromazine, thioridazine, and other low-potency drugs are thought to be more epileptogenic than are high-potency drugs. The risk of inducing a seizure by drug administration warrants consideration when the person already has a seizure disorder or brain lesion.

Sedation. The blockade of histamine H_1 receptors is the usual cause of sedation associated with DRAs. Chlorpromazine is the most sedating typical antipsychotic. The relative sedative properties of the drugs are summarized in Table 21-12. Giving the entire daily dose at bedtime usually eliminates any problems from sedation, and tolerance for this adverse effect often develops.

Central Anticholinergic Effects. The symptoms of central anticholinergic activity include severe agitation; disorientation to time, person, and place; hallucinations; seizures; high fever; and dilated pupils. Stupor and coma may ensue. The treatment of anticholinergic toxicity consists of discontinuing the causal agent or agents, close medical supervision, and physostigmine (Antilirium, Eserine), 2 mg by slow

intravenous (IV) infusion, repeated within 1 hour as necessary. Too much physostigmine is dangerous, and symptoms of physostigmine toxicity include hypersalivation and sweating. Atropine sulfate (0.5 mg) can reverse the effects of physostigmine toxicity.

Cardiac Effects. The DRAs decrease cardiac contractility, disrupt enzyme contractility in cardiac cells, increase circulating levels of catecholamines, and prolong atrial and ventricular conduction time and refractory periods. Low-potency DRAs, particularly the phenothiazines, are usually more cardiotoxic than are high-potency drugs. One exception is haloperidol, which has been linked to abnormal heart rhythm, ventricular arrhythmias, torsades de pointes, and sudden death when injected IV. Pimozide, sulpiride, and droperidol (a butyrophenone) also prolong the QTc interval and have been associated with torsades de pointes and sudden death. In one study, thioridazine was responsible for 28 (61 percent) of the 46 sudden antipsychotic deaths. In 15 of these cases, it was the only drug ingested. Chlorpromazine also causes prolongation of the QT and PR intervals, blunting of the T waves, and depression of the ST segment. These drugs are thus indicated only when other agents have been ineffective.

Sudden Death. Occasional reports of sudden cardiac death during treatment with DRAs may be the result of cardiac arrhythmias. Other causes may include seizure, asphyxiation, malignant hyperthermia, heatstroke, and neuroleptic malignant syndrome. However, there does seem to be an overall increased incidence of sudden death with antipsychotics.

Orthostatic (Postural) Hypotension. Orthostatic (postural) hypotension is most frequent with low-potency drugs, particularly chlorpromazine, thioridazine, and chlorprothixene. When using intramuscular (IM) low-potency DRAs, the clinician should measure the patient’s BP (lying and standing) before and after the first dose and during the first few days of treatment.

Orthostatic hypotension is mediated by adrenergic blockade and occurs most frequently during the first few days of treatment. Tolerance often develops for this side effect, which is why the initial dosing of these drugs is lower than the usual therapeutic dose. Fainting or falls, although uncommon,

may lead to injury. Patients should be warned of this side effect and instructed to rise slowly after sitting and reclining. Patients should avoid all caffeine and alcohol; should drink at least 2 L of fluid a day; and if not under treatment for hypertension, should add liberal amounts of salt to their diet. Support hose may help some persons.

Hypotension can usually be managed by having patients lie down with their feet higher than their heads and pump their legs as if bicycling. Volume expansion or vasopressor agents, such as norepinephrine (Levophed), may be indicated in severe cases. Because hypotension is produced by α-adrenergic blockade, the drugs also block the α-adrenergic stimulating properties of epinephrine, leaving the β-adrenergic stimulating effects untouched. Therefore, the administration of epinephrine results in a paradoxical worsening of hypotension and is contraindicated in cases of antipsychotic-induced hypotension. Pure α-adrenergic pressor agents, such as metaraminol (Aramine) and norepinephrine, are the drugs of choice in the treatment of the disorder.

Hematologic Effects. Temporary leukopenia with a WBC count of about 3,500 is a common but not a serious problem. Agranulocytosis, a life-threatening hematologic problem, occurs in about 1 in 10,000 persons treated with DRAs. Thrombocytopenic or nonthrombocytopenic purpura, hemolytic anemias, and pancytopenia may rarely occur in persons treated with DRAs. Although routine CBCs are not indicated, if a person reports a sore throat and fever, a CBC should be done immediately to check for the possibility of a severe blood dyscrasia. If blood index values are low, the administration of DRAs should be stopped, and the patient should be transferred to a medical facility. The mortality rate for the complication may be as high as 30 percent.

Peripheral Anticholinergic Effects. Peripheral anticholinergic effects, such as dry mouth and nose, blurred vision, constipation, urinary retention, and mydriasis, are common. This is especially true with low-potency DRAs, for example, chlorpromazine, thioridazine, mesoridazine (Serentil). Some persons may also have nausea and vomiting.

Constipation should be treated with the usual laxative preparations, but severe constipation can progress to paralytic ileus. A decrease in the DRA dosage is warranted in such cases. Pilocarpine (Salagen) may be used to treat

paralytic ileus, although the relief is only transitory. Bethanechol (Urecholine) (20 to 40 mg a day) may be useful in some persons with urinary retention.

Weight gain is associated with increased mortality and morbidity and with medication noncompliance. Low-potency DRAs may cause significant weight gain but not as much as is seen with the SDAs olanzapine (Zyprexa) and clozapine (Clozaril). Molindone and perhaps loxapine (Loxitane) appear to be least likely to cause weight gain.

Endocrine Effects. Blockade of the dopamine receptors in the tuberoinfundibular tract results in the increased secretion of prolactin, which can result in breast enlargement, galactorrhea, amenorrhea, and inhibited orgasm in women and impotence in men. The SDAs, except risperidone (Risperdal), are not significantly associated with an increase in prolactin levels and may be the drugs of choice for persons experiencing disturbing side effects from increased prolactin release.

Sexual Adverse Effects. Both men and women taking DRAs can experience anorgasmia and decreased libido. Up to 50 percent of men who take antipsychotics report ejaculatory and erectile disturbances. Sildenafil (Viagra), vardenafil (Levitra), and tadalafil (Cialis) are often used to treat psychotropic-induced orgasmic dysfunction, but they have not been studied in combination with the DRAs. Thioridazine is mainly associated with decreased libido and retrograde ejaculation in men. Priapism and reports of painful orgasms have also been described, both possibly resulting from α_1-adrenergic antagonist activity.

Skin and Eye Effects. Allergic dermatitis and photosensitivity may occur, especially with low-potency agents. Urticarial, maculopapular, petechial, and edematous eruptions may occur early in treatment, generally in the first few weeks, and remit spontaneously. A photosensitivity reaction that resembles a severe sunburn also occurs in some persons taking chlorpromazine. Persons should be warned of this adverse effect, should spend no more than 30 to 60 minutes in the sun, and should use sunscreens. Long-term chlorpromazine use is associated with blue-gray discoloration of skin areas exposed to sunlight. The skin changes often begin with a tan or golden brown color and

progress to such colors as slate gray, metallic blue, and purple. These discolorations resolve when the patient is switched to another medication.

Irreversible retinal pigmentation is associated with the use of thioridazine at dosages above 1,000 mg a day. An early symptom of the side effect can sometimes be nocturnal confusion related to difficulty with night vision. The pigmentation can progress even after thioridazine administration is stopped, finally resulting in blindness. It is for this reason that the maximum recommended dosage of thioridazine is 800 mg/day.

Patients taking chlorpromazine may develop a relatively benign pigmentation of the eyes, characterized by whitish brown granular deposits concentrated in the anterior lens and posterior cornea and visible only by slit-lens examination. The deposits can progress to opaque white and yellow-brown granules, often stellate. Occasionally, the conjunctiva is discolored by a brown pigment. No retinal damage is seen, and vision is rarely impaired. This condition gradually resolves when chlorpromazine is discontinued.

Jaundice. Elevations of liver enzymes during treatment with a DRA tend to be transient and not clinically significant. When chlorpromazine first came into use, cases of obstructive or cholestatic jaundice were reported, usually in the first month of treatment and heralded by symptoms of upper abdominal pain, nausea, and vomiting. This adverse effect was followed by fever, rash, eosinophilia, bilirubin in the urine, and increases in levels of serum bilirubin, alkaline phosphatase, and hepatic transaminases. Reported cases are now sporadic, but if jaundice occurs, the medication should be discontinued.

Overdoses. Overdoses typically consist of exaggerated DRA side effects. Symptoms and signs include CNS depression, EPS, mydriasis, rigidity, restlessness, decreased deep tendon reflexes, tachycardia, and hypotension. The severe symptoms of overdose include delirium, coma, respiratory depression, and seizures. Haloperidol may be among the safest typical antipsychotics in overdose. After an overdose, electroencephalography (EEG) shows diffuse slowing and low voltage. An extreme overdose may lead to delirium and coma, with respiratory depression and hypotension. Life-threatening overdose usually involves the ingestion of other CNS depressants, such as alcohol or benzodiazepines.

Activated charcoal, if possible, and gastric lavage should be administered

if the overdose is recent. Emetics are not indicated because the antiemetic actions of the DRAs inhibit their efficacy. Seizures can be treated with IV diazepam or phenytoin. Hypotension can be treated with either norepinephrine or dopamine but not epinephrine.

Pregnancy and Lactation. There is a low correlation between the use of antipsychotics during pregnancy and congenital malformations. Nevertheless, antipsychotics should be avoided during pregnancy, particularly in the first trimester, unless the benefit outweighs the risk. High-potency drugs are preferable to low-potency drugs because low-potency drugs are associated with hypotension.

DRAs are secreted in the breast milk, although concentrations are low. Women taking these agents should be advised against breastfeeding.

Drug Interactions

Many pharmacokinetic and pharmacodynamic drug interactions are associated with these drugs (Table 21-13). CYP2D6 is the most common hepatic isozyme involved in DRA pharmacokinetic interactions. Other common drug interactions affect the absorption of the DRAs.

Antacids, activated charcoal, cholestyramine (Questran), kaolin, pectin, and cimetidine (Tagamet) taken within 2 hours of antipsychotic administration can reduce the absorption of these drugs. Anticholinergics may decrease the absorption of the DRAs. The additive anticholinergic activity of the DRAs, anticholinergics, and tricyclic drugs may result in anticholinergic toxicity. Digoxin (Lanoxin) and steroids, both of which decrease gastric motility, can increase DRA absorption.

Table 21-13
Antipsychotic Drug Interactions

Interacting Medication	Mechanism	Clinical Effect
Drug Interactions Assessed to Have Major Severity		
β-Adrenergic receptor	Synergistic pharmacologic effect; antipsychotic	Severe hypotension

antagonists	inhibits metabolism of propranolol; antipsychotic increases plasma concentrations	
Anticholinergics	Pharmacodynamic effects	Decreased antipsychotic effect
	Additive anticholinergic effect	Anticholinergic toxicity
Barbiturates	Phenobarbital induces antipsychotic metabolism	Decreased antipsychotic concentrations
Carbamazepine	Induces antipsychotic metabolism	Up to 50% reduction in antipsychotic concentrations
Charcoal	Reduces GI absorption of antipsychotic and adsorbs drug during enterohepatic circulation	May reduce antipsychotic effect or cause toxicity when used to treat overdose or for GI disturbances
Cigarette smoking	Induction of microsomal enzymes	Reduced plasma concentrations of antipsychotic agents
Epinephrine, norepinephrine	Antipsychotic antagonizes pressor effect	Hypotension
Ethanol	Additive CNS depression	Impaired psychomotor status

Fluvoxamine	Fluvoxamine inhibits metabolism of haloperidol and clozapine	Increased concentrations of haloperidol and clozapine
Guanethidine	Antipsychotic antagonizes guanethidine reuptake	Impaired antihypertensive effect
Lithium	Unknown	Rare reports of neurotoxicity
Meperidine	Additive CNS depression	Hypotension and sedation
Drug Interactions Assessed to Have Minor or Moderate Severity		
Amphetamines, anorexiants	Decreased pharmacologic effect of amphetamine	Diminished weight loss effect; amphetamines may exacerbate psychosis
ACEIs	Additive hypotensive crisis	Hypotension, postural intolerance
Antacids containing aluminum	Insoluble complex formed in GI tract	Possible reduced antipsychotic effect
AD nonspecific	Decreased metabolism of AD through competitive inhibition	Increased AD concentration
Benzodiazepines	Increased pharmacologic effect of the benzodiazepine	Respiratory depression, stupor, hypotension

Bromocriptine	Antipsychotic antagonizes dopamine receptor stimulation	Increased prolactin
Caffeinated beverages	Form precipitate with antipsychotic solutions	Possible diminished antipsychotic effect
Cimetidine	Reduced antipsychotic absorption and clearance	Decreased antipsychotic effect
Clonidine	Antipsychotic potentiates α-adrenergic hypotensive effect	Hypotension or hypertension
Disulfiram	Impairs antipsychotic metabolism	Increased antipsychotic concentrations
Methyldopa	Unknown	BP elevations
Phenytoin	Induction of antipsychotic metabolism; decreased phenytoin metabolism	Decreased antipsychotic concentrations: increased phenytoin levels
SSRIs	Impair antipsychotic metabolism; pharmacodynamic interaction	Sudden onset of extrapyramidal symptoms
Valproic acid	Antipsychotic inhibits valproic acid metabolism	Increased valproic acid half-life and levels

ACEI, angiotensin-converting enzyme inhibitor; AD, antidepressant; BP, blood pressure; CNS, central nervous system; GI, gastrointestinal; SSRI, selective serotonin reuptake inhibitor.

From Ereshosky L, Overman GP, Karp JK. Current psychotropic dosing and monitoring guidelines. *Prim Psychiatry*. 1996;3:21, with permission.

Phenothiazines, especially thioridazine, may decrease the metabolism of and cause toxic concentrations of phenytoin. Barbiturates may increase the metabolism of DRAs.

Tricyclic drugs and SSRIs that inhibit CYP2D6—paroxetine (Paxil), fluoxetine (Prozac), and fluvoxamine (Luvox)—interact with DRAs, resulting in increased plasma concentrations of both drugs. The anticholinergic, sedative, and hypotensive effects of the drugs may also be cumulative.

Typical antipsychotics may inhibit the hypotensive effects of α-methyldopa (Aldomet). Conversely, typical antipsychotics may have an additive effect on some hypotensive drugs. Antipsychotic drugs have a variable effect on the hypotensive effects of clonidine. Propranolol (Inderal) coadministration increases the blood concentrations of both drugs.

The DRAs potentiate the CNS-depressant effects of the sedatives, antihistamines, opiates, opioids, and alcohol, particularly in persons with impaired respiratory status. When these agents are taken with alcohol, the risk for heatstroke may be increased.

Cigarette smoking may decrease the plasma levels of the typical antipsychotic drugs. Epinephrine has a paradoxical hypotensive effect in persons taking typical antipsychotics. These drugs may decrease the blood concentration of warfarin (Coumadin), resulting in decreased bleeding time. The phenothiazines, thioridazine, and pimozide should not be coadministered with other agents that prolong the QT interval. Thioridazine is contraindicated in patients taking drugs that inhibit the CYP2D6 isoenzyme or in patients with reduced levels of CYP2D6.

Laboratory Interferences

Chlorpromazine and perphenazine (Trilafon) may cause both false-positive and false-negative results in immunologic pregnancy tests and falsely elevated bilirubin (with reagent test strips) and urobilinogen (with Ehrlich reagent test) values. These drugs are associated with an abnormal shift in the results of the glucose tolerance test. However, that shift may reflect the effects of the drugs on the glucose-regulating system. Phenothiazines have been reported to interfere with the measurement of 17-ketosteroids and 17-hydroxycorticosteroids and produce false-positive results in tests for

phenylketonuria.

Dosage and Clinical Guidelines

Contraindications to the use of DRAs include the following: (1) a history of a severe allergic response; (2) the possible ingestion of a substance that will interact with the antipsychotic to induce CNS depression (e.g., alcohol, opioids, barbiturates, and benzodiazepines) or anticholinergic delirium (e.g., scopolamine and possibly phencyclidine [PCP]); (3) the presence of a severe cardiac abnormality; (4) a high risk for seizures; (5) the presence of narrow-angle glaucoma or prostatic hypertrophy if a drug with high anticholinergic activity is to be used; and (6) the presence or a history of tardive dyskinesia. Antipsychotics should be administered with caution in persons with hepatic disease because impaired hepatic metabolism may result in high plasma concentrations. The usual assessment should include a CBC with WBC indexes, liver function tests, and electrocardiography (ECG), especially in women older than 40 years of age and men older than 30 years of age. Elderly persons and children are more sensitive to side effects than are young adults, so the dosage of the drug should be adjusted accordingly.

Various patients may respond to widely different dosages of antipsychotics; therefore, there is no set dosage for any given antipsychotic drug. Because of side effects, it is a reasonable clinical practice to begin at a low dosage and increase as necessary. It is important to remember that the maximal effects of a particular dosage may not be evident for 4 to 6 weeks. Available preparations and dosages of the DRAs are given in Table 21-14.

Short-Term Treatment. The equivalent of 5 to 20 mg of haloperidol is a reasonable dose for an adult in an acute state. An older adult may benefit from as little as 1 mg of haloperidol. The administration of more than 25 mg of chlorpromazine in one injection may result in profound hypotension. IM administration results in peak plasma levels in about 30 minutes versus 90 minutes using the oral route. Doses of drugs for IM administration are about half those given by the oral route. In a short-term treatment setting, the person should be observed for 1 hour after the first dose of medication. After that time, most clinicians administer a second dose or a sedative agent (e.g., a benzodiazepine) to achieve effective behavioral control. Possible sedatives

include lorazepam (Ativan) (2 mg IM) and amobarbital (50 to 250 mg IM).

Rapid Neuroleptization. Rapid neuroleptization (also called psychotolysis) is the practice of administering hourly IM doses of antipsychotic medications until marked sedation is achieved. However, several research studies have shown that merely waiting several more hours after one dose yields the same clinical improvement as is seen with repeated doses. Nevertheless, clinicians must be careful to keep patients from becoming violent while they are psychotic. Clinicians can help prevent violent episodes by using adjuvant sedatives or by temporarily using physical restraints until the persons can control their behavior.

Early Treatment. A full 6 weeks may be necessary to evaluate the extent of the improvement in psychotic symptoms. However, agitation and excitement usually improve quickly with antipsychotic treatment. About 75 percent of persons with a short history of illness show significant improvement in their psychosis. Psychotic symptoms, both positive and negative, usually continue to improve 3 to 12 months after the initiation of treatment.

About 5 mg of haloperidol or 300 mg of chlorpromazine is a usual effective daily dose. In the past, much higher doses were used, but evidence suggests that it resulted in more side effects without additional benefits. A single daily dose is usually given at bedtime to help induce sleep and to reduce the incidence of adverse effects. However, bedtime dosing for elderly persons may increase their risk of falling if they get out of bed during the night. The sedative effects of typical antipsychotics last only a few hours, in contrast to the antipsychotic effects, which last for 1 to 3 days.

Intermittent Medications. It is a common clinical practice to order medications to be given intermittently as needed (PRN). Although this practice may be reasonable during the first few days that a person is hospitalized, the amount of time the person takes antipsychotic drugs, rather than an increase in dosage, is what produces therapeutic improvement. Clinicians on inpatient services may feel pressured by staff members to write PRN antipsychotic orders; such orders should include specific symptoms, how often the drugs should be given, and how many doses can be given each day. Clinicians may choose to use small doses for the PRN doses (e.g., 2 mg

of haloperidol) or use a benzodiazepine instead (e.g., 2 mg of lorazepam IM). If PRN doses of an antipsychotic are necessary after the first week of treatment, the clinician may want to consider increasing the standing daily dose of the drug.

Maintenance Treatment. The first 3 to 6 months after a psychotic episode are usually considered a period of stabilization. After that time, the dosage can be decreased by about 20 percent every 6 months until the minimum effective dosage is found. A person is usually maintained on antipsychotic medications for 1 to 2 years after the first psychotic episode. Antipsychotic treatment is often continued for 5 years after a second psychotic episode, and lifetime maintenance is considered after the third psychotic episode, although attempts to reduce the daily dosage can be made every 6 to 12 months.

Table 21-14
Dopamine Receptor Antagonists

Name						Rectal Suppositories (mg)	Adult Dose Range (mg/day)	
Generic or Chemical	Trade	Tablets (mg)	Capsules (mg)	Solution	Parenteral		Acute	Maintenance
Chlorpromazine	Thorazine	10, 25, 50, 100, 200	30, 75, 150, 200, 300	10 mg/5 mL, 30 mg/mL, 100 mg/mL	25 mg/mL	25, 100	100–1,600 PO, 25–400 IM	50–400 PO
Prochlorperazine	Compazine	5, 10, 25	10, 15, 30	5 mg/5 mL	5 mg/mL	2.5, 5, 25	15–200 PO, 40–80 IM	15–60 PO
Perphenazine	Trilafon	2, 4, 8, 16	—	16 mg/5 mL	5 mg/mL	—	12–64 PO, 15–30 IM	8–24 PO
Trifluoperazine	Stelazine	1, 2, 5, 10	—	10 mg/mL	2 mg/mL	—	4–40 PO, 4–10 IM	5–20 PO
Fluphenazine	Prolixin	1, 2.5, 5, 10	—	2.5 mg/5 mL, 5 mg/mL	2.5 mg/mL (IM only)	—	2.5–40.0 PO, 5–20 IM	1.0–15.0 PO, 12.5–50.0 IM (decanoate or enanthate, weekly or biweekly)
Fluphenazine decanoate	—	—	—	—	2.5 mg/mL	—	—	—
Fluphenazine enanthate	—	—	—	2.5 mg/mL	—	—	—	—
Thioridazine	Mellaril	10, 15, 25, 50, 100, 150, 200	—	25 mg/5 mL, 100 mg/5 mL, 30 mg/mL, 100 mg/mL	—	—	200–800 PO	100–300 PO
Mesoridazine	Serentil	10, 25, 50, 100	—	25 mg/mL	25 mg/mL	—	100–400 PO, 25–200 IM	30–150 PO
Haloperidol	Haldol	0.5, 1, 2, 5, 10, 20	—	2 mg/5 mL	5 mg/mL (IM only)	—	5–20 PO, 12.5–25 IM	1–10 PO
Haloperidol decanoate		—	—	—	50 mg/mL, 100 mg/mL (IM only)	—		25–200 IM (decanoate, monthly)
Chlorprothixene	Taractan	10, 25, 50, 100	—	100 mg/5 mL (suspension)	12.5 mg/mL	—	75–600 PO, 75–200 IM	50–400 PO
Thiothixene	Navane	—	1, 2, 5, 10, 20	5 mg/mL	5 mg/mL (IM only), 20 mg/mL (IM only)	—	60–100 PO, 8–30 IM	6–30 PO
Loxapine	Loxitane	—	5, 10, 25, 50	25 mg/5 mL	50 mg/mL	—	20–250 PO, 20–75 IM	20–100 PO
Molindone	Moban	5, 10, 25, 50, 100	—	20 mg/mL	—	—	50–225 PO	5–150 PO
Pimozide	Orap	2	—	—	—	—	0.5–20 PO	0.5–5.0 PO

IM, intramuscular; PO, oral.

Antipsychotic drugs are effective in controlling psychotic symptoms, but persons may report that they prefer being off the drugs because they feel better without them. The clinician must discuss maintenance medication with

patients and take into account their wishes, the severity of their illnesses, and the quality of their support systems. The clinician needs to know enough about the patient's life to try to predict upcoming stressors that might require increasing the dosage or closely monitoring compliance.

Long-Acting Depot Medications. Long-acting depot preparations may be needed to overcome problems with compliance. IM preparations are typically given once every 1 to 4 weeks.

Two depot preparations, a decanoate and an enanthate of fluphenazine, and a decanoate preparation of haloperidol, are available in the United States. The preparations are injected IM into an area of extensive muscle tissue, from which they are absorbed slowly into the blood. Decanoate preparations can be given less frequently than enanthate preparations because they are absorbed more slowly. Although stabilizing a person on the oral preparation of the specific drugs is not necessary before initiating the depot form, it is good practice to give at least one oral dose of the drug to assess the possibility of an adverse effect, such as severe EPS or an allergic reaction.

It is reasonable to begin with either 12.5 mg (0.5 mL) of fluphenazine preparation or 25 mg (0.5 mL) of haloperidol decanoate. If symptoms emerge in the next 2 to 4 weeks, the person can be treated temporarily with additional oral medications or with additional small depot injections. After 3 to 4 weeks, the depot injection can be increased to a single dose equal to the total of the doses given during the initial period.

A good reason to initiate depot treatment with low doses is that the absorption of the preparations may be faster than usual at the onset of treatment, resulting in frightening episodes of dystonia that eventually discourage compliance with the medication. Some clinicians keep patients drug free for 3 to 7 days before initiating depot treatment and give small doses of the depot preparations (3.125 mg of fluphenazine or 6.25 mg of haloperidol) every few days to avoid those initial problems.

Plasma Concentrations

Genetic differences among persons and pharmacokinetic interactions with other drugs influence the metabolism of the antipsychotics. If a person has not improved after 4 to 6 weeks of treatment, the plasma concentration of the

drug should be determined if feasible. After a patient has been on a particular dosage for at least five times the half-life of the drug and thus approaches steady-state concentrations, blood levels may be helpful. It is standard practice to obtain plasma samples at trough levels—just before the daily dose is given, usually at least 12 hours after the previous dose, and most commonly 20 to 24 hours after the previous dose. Most antipsychotics have no well-defined dose–response curve. The best-studied drug is haloperidol, which may have a therapeutic window ranging from 2 to 15 ng/mL. Other therapeutic ranges that have been reasonably well documented are 30 to 100 ng/mL for chlorpromazine and 0.8 to 2.4 ng/mL for perphenazine.

Treatment-Resistant Persons. Unfortunately, 10 to 35 percent of persons with schizophrenia do not obtain significant benefit from the antipsychotic drugs. Treatment resistance is a failure on at least two adequate trials of antipsychotics from two pharmacologic classes. It is useful to determine plasma concentrations for such persons because it is possible that they are slow or rapid metabolizers or are not taking their medication. Clozapine has been conclusively shown to be effective when given to patients who have failed multiple trials of DRAs.

Adjunctive Medications. It is common practice to use DRAs in conjunction with other psychotropic agents, either to treat side effects or to improve symptoms further. Most commonly, this involves the use of lithium or other mood-stabilizing agents, SSRIs, or benzodiazepines. It was once held that antidepressant drugs exacerbated psychosis in patients with schizophrenia. In all likelihood, this observation involved patients with bipolar disorder who were misdiagnosed as having schizophrenia. Abundant evidence suggests that antidepressants improve symptoms of depression in patients with schizophrenia. In some cases, amphetamines can be added to DRAs if patients remain withdrawn and apathetic.

Choice of Drug

Given their proven efficacy in managing acute psychotic symptoms and the fact that prophylactic administration of antiparkinsonian medication prevents or minimizes acute motor abnormalities, DRAs are still valuable, especially for short-term therapy. There is a considerable cost advantage to a DRA

antiparkinsonian regimen compared with monotherapy with a newer antipsychotic agent. Concern about the development of DRA-induced tardive dyskinesia is the primary deterrent to long-term use of these drugs, yet it is not clear that SDAs are entirely free of this complication. Thus, DRAs still occupy an important role in psychiatric treatment. DRAs are not predictably interchangeable. For reasons that cannot be explained, some patients do better on one drug than another. The choice of a particular DRA should be based on the known adverse effect profile of the drugs. Other than a significant advantage in terms of medication cost, the choice currently would be an SDA. If a DRA is thought to be preferable, a high-potency antipsychotic is favored, even though it may be associated with more neurologic adverse effects, mainly because there is a higher incidence of other adverse effects (e.g., cardiac, hypotensive, epileptogenic, sexual, and allergic) with the low-potency drugs. If sedation is the desired goal, either a low-potency antipsychotic can be given in divided doses, or a benzodiazepine can be coadministered.

An unpleasant or dysphoric reaction (a subjective sense of restlessness, oversedation, and acute dystonia) to the first dose of an antipsychotic predicts future inadequate response and noncompliance. Prophylactic use of antiparkinsonian medications may prevent this reaction. In general, clinicians should be vigilant about serious side effects and adverse events (described above) regardless of which drug is used.

21.2 Antidepressants

SELECTIVE SEROTONIN REUPTAKE INHIBITORS

Fluoxetine (Prozac), the first SSRI marketed in the United States, rapidly captured the favor of both clinicians and the general public as reports emerged of dramatic patient responses to treatment of depression. Patients no longer experienced such side effects as dry mouth, constipation, sedation, orthostatic hypotension, and tachycardia, typical side effects associated with the earlier antidepressant drugs—the TCAs and MAOIs. It was also significantly safer when taken in overdose than any previously available antidepressant. A significant effect of fluoxetine's popularity was that it helped ameliorate the long-standing stigma of depression and its treatment.

Table 21-15
Currently Approved Indications of the Selective Serotonin Reuptake Inhibitors in the United States for Adult and Pediatric Populations

	Citalopram (Celexa)	Escitalopram (Lexapro)	Fluoxetine (Prozac)	Fluvoxamine (Luvox)	Paroxetine (Paxil)	Sertraline (Zoloft)	Vilazodone (Viibryd)
Major depressive disorder	Adult	Adult	Adult[a] and pediatric	—	Adult[b]	Adult	Adult
Generalized anxiety disorder	—	Adult	—	—	Adult	—	—
OCD	—	—	Adult and pediatric	Adult and pediatric	Adult	Adult and pediatric	—
Panic disorder	—	—	Adult	—	Adult[b]	Adult	—
PTSD	—	—	—	—	Adult	Adult	—
Social anxiety disorder	—	—	—	—	Adult[b]	Adult	—
Bulimia nervosa	—	—	Adult	—	—	—	—
Premenstrual dysphoric disorder	—	—	Adult[c]	—	Adult[d]	Adult	—

OCD, obsessive-compulsive disorder; PTSD, posttraumatic stress disorder.
[a]Weekly fluoxetine is approved for continuation and maintenance therapy in adults.
[b]Paroxetine and paroxetine controlled-release.
[c]Marketed as Sarafem.
[d]Paroxetine-controlled release is approved for premenstrual dysphoric disorder.

Other SSRIs followed fluoxetine. These include sertraline (Zoloft), paroxetine (Paxil), fluvoxamine (Luvox), citalopram (Celexa), escitalopram (Lexapro), and vilazodone (Viibryd). These drugs are all equally effective in

treating depression. However, some are approved by the U.S. FDA for multiple indications, such as major depression, OCD, PTSD, PMDD, panic disorder, and social phobia (social anxiety disorder) (Table 21-15). Note that fluvoxamine is not FDA approved as an antidepressant, a fact that is due to a marketing decision. It is considered an antidepressant in other countries.

Although all SSRIs are equally effective, there are meaningful differences in pharmacodynamics, pharmacokinetics, and side effects, differences that might affect clinical responses among individual patients. This would explain why some patients have better clinical responses to a particular SSRI than another. The SSRIs have proven more problematic in terms of some side effects than the original clinical trials suggested. Quality-of-life–associated adverse effects such as nausea, sexual dysfunction, and weight gain sometimes mitigate the therapeutic benefits of the SSRIs. There can also be distressing withdrawal symptoms when SSRIs are stopped abruptly. This withdrawal is especially true with paroxetine but also occurs when other SSRIs with short half-lives are stopped.

Pharmacologic Actions

Pharmacokinetics. A significant difference among the SSRIs is their broad range of serum half-lives. Fluoxetine has the most prolonged half-life: 4 to 6 days; its active metabolite has a half-life of 7 to 9 days. The half-life of sertraline is 26 hours, and its less active metabolite has a half-life of 3 to 5 days. The half-lives of the other three, which do not have metabolites with significant pharmacologic activity, are 35 hours for citalopram, 27 to 32 hours for escitalopram, 21 hours for paroxetine, and 15 hours for fluvoxamine. As a rule, the SSRIs are well absorbed after oral administration and have their peak effects in the range of 3 to 8 hours. Absorption of sertraline may be slightly enhanced by food.

There are also differences in plasma protein–binding percentages among the SSRIs, with sertraline, fluoxetine, and paroxetine being the most highly bound and escitalopram being the least bound.

All SSRIs are metabolized in the liver by the CYP450 enzymes. Because the SSRIs have such a broad therapeutic index, other drugs rarely produce problematic increases in SSRI concentrations. The most critical drug–drug interactions involving the SSRIs occur as a result of the SSRIs inhibiting the

metabolism of the coadministered medication. Each of the SSRIs possesses a potential for slowing or blocking the metabolism of many drugs (Table 21-16). Fluvoxamine is the most problematic of the drugs in this respect. It has a marked effect on several of the CYP enzymes. Examples of clinically significant interactions include fluvoxamine and theophylline (Slo-Bid, Theo-Dur) through CYP1A2 interaction, fluvoxamine and clozapine (Clozaril) through CYP1A2 inhibition; and fluvoxamine with alprazolam (Xanax) or clonazepam (Klonopin) through CYP3A4 inhibition. Fluoxetine and paroxetine also possess significant effects on the CYP2D6 isozyme, which may interfere with the efficacy of opiate analogs, such as codeine and hydrocodone, by blocking the conversion of these agents to their active form. Thus, coadministration of fluoxetine and paroxetine with an opiate interferes with its analgesic effects. Sertraline, citalopram, and escitalopram are least likely to complicate treatment because of interactions.

The pharmacokinetics of vilazodone (5 to 80 mg) is dose-proportional. Steady-state plasma levels are achieved in about 3 days. The elimination of vilazodone is primarily by hepatic metabolism with a terminal half-life of approximately 25 hours.

Pharmacodynamics. The SSRIs are believed to exert their therapeutic effects through serotonin reuptake inhibition. They derive their name because they have little effect on the reuptake of norepinephrine or dopamine. Often, adequate clinical activity and saturation of the 5-HT transporters are achieved at starting dosages. As a rule, higher dosages do not increase antidepressant efficacy but may increase the risk of adverse effects.

Table 21-16
CYP450 Inhibitory Potential of Commonly Prescribed Antidepressants

Relative Rank	CYP1A2	CYP2C	CYP2D6	CYP3A
Higher	Fluvoxamine (Luvox)	Fluoxetine Fluvoxamine	Bupropion Fluoxetine Paroxetine	Fluvoxamine Nefazodone Tricyclics
Moderate	Tertiary amine tricyclics Fluoxetine (Prozac)	Sertraline	Secondary amine tricyclics Citalopram (Celexa) Escitalopram (Lexapro) Sertraline	Fluoxetine Sertraline
Low or minimal	Bupropion (Wellbutrin) Mirtazapine (Remeron) Nefazodone (Serzone) Paroxetine (Paxil) Sertraline (Zoloft) Venlafaxine (Effexor)	Paroxetine Venlafaxine	Fluvoxamine Mirtazapine Nefazodone Venlafaxine	Citalopram Escitalopram Mirtazapine Paroxetine Venlafaxine

CYP, cytochrome P450.

Citalopram and escitalopram are the most selective inhibitors of serotonin reuptake, with very little inhibition of norepinephrine or dopamine reuptake and very low affinities for histamine H_1, GABA, or benzodiazepine receptors. The other SSRIs have a similar profile except that fluoxetine weakly inhibits norepinephrine reuptake and binds to 5-HT_{2C} receptors, sertraline weakly inhibits norepinephrine and dopamine reuptake, and paroxetine has significant anticholinergic activity at higher dosages and binds to nitric oxide synthase. The SSRI vilazodone has 5-HT_{1A} receptor agonist properties. The clinical implications of the 5-HT_{1A} receptor agonist effects are not yet evident.

A pharmacodynamic interaction appears to underlie the antidepressant effects of combined fluoxetine–olanzapine. When taken together, these drugs increase brain concentrations of norepinephrine. Concomitant use of SSRIs and drugs in the triptan class (sumatriptan [Imitrex], naratriptan [Amerge], rizatriptan [Maxalt], and zolmitriptan [Zomig]) may result in a severe pharmacodynamic interaction—the development of serotonin syndrome (see “Precautions and Adverse Reactions”). However, many people use triptans while taking low doses of an SSRI for headache prophylaxis without adverse reaction. A similar reaction may occur when SSRIs are combined with tramadol (Ultram).

Therapeutic Indications

Depression. In the United States, all SSRIs other than fluvoxamine have been approved by the FDA for the treatment of depression. Several studies

have found that antidepressants with serotonin-norepinephrine activity—drugs such as the MAOIs, TCAs, venlafaxine (Effexor), and mirtazapine (Remeron)—may produce higher rates of remission than SSRIs in head-to-head studies. The continued role of SSRIs as first-line treatment thus reflects their simplicity of use, safety, and a broad spectrum of action.

Direct comparisons of individual SSRIs have not revealed any to be consistently superior to another. There nevertheless can be considerable diversity in response to the various SSRIs among individuals. For example, more than 50 percent of people who respond poorly to one SSRI will respond favorably to another. Thus, before shifting to non-SSRI antidepressants, it is most reasonable to try other agents in the SSRI class for persons who did not respond to the first SSRI.

Some clinicians have attempted to select a particular SSRI for a specific person based on the drug's unique adverse effect profile. For example, thinking that fluoxetine is an activating and stimulating SSRI, they may assume it is a better choice for an abulic person than paroxetine, which is presumed to be a sedating SSRI. These differences, however, usually vary from person to person. Analyses of clinical trial data show that SSRIs are more effective in patients with more severe symptoms of major depression than those with milder symptoms.

SUICIDE. The FDA has issued a black box warning for antidepressants and suicidal thoughts and behavior in children and young adults. This warning is based on a decade-old analysis of clinical trial data. More recent, comprehensive reanalysis of data has shown that suicidal thoughts and behavior decreased over time for adult and geriatric patients treated with antidepressants as compared with placebo. No differences were found for youths. In adults, reduction in suicide ideation and attempts occurred through a reduction in depressive symptoms. In all age groups, the severity of depression improved with medication and was significantly related to suicide ideation or behavior. It appears that SSRIs, as well as serotonin-norepinephrine reuptake inhibitors (SNRIs), have a protective effect against suicide that is mediated by decreases in depressive symptoms with treatment. For youths, no significant effects of treatment on suicidal thoughts and behavior were found, although depression responded to treatment. No evidence of increased suicide risk was observed in youths receiving active

medication. It is crucial to keep in mind that SSRIs, like all antidepressants, prevent potential suicides as a result of their primary action, the shortening and prevention of depressive episodes. In clinical practice, a few patients become anxious and agitated when started on an SSRI. The appearance of these symptoms could conceivably provoke or aggravate suicidal ideation. Thus, all depressed patients should be closely monitored during the period of maximum risk, the first few days and weeks they are taking SSRIs.

DEPRESSION DURING PREGNANCY AND POSTPARTUM. Rates of relapse of major depression during pregnancy among women who discontinue, attempt to discontinue, or modify their antidepressant regimens are very high. Rates range from 68 to 100 percent of patients. Thus, many women need to continue taking their medication during pregnancy and postpartum. The impact of maternal depression on infant development is unknown. There is no significantly increased risk for major congenital malformations after exposure to SSRIs during pregnancy (with the exception of paroxetine, discussed below). Thus, the risk of relapse into depression when a newly pregnant mother is taken off SSRIs is severalfold higher than the risk to the fetus of exposure to SSRIs.

There is some evidence suggesting increased rates of special care nursery admissions after delivery for children of mothers taking SSRIs. There is also a potential for a discontinuation syndrome with paroxetine. However, there is an absence of clinically significant neonatal complications associated with SSRI use.

Studies that have followed children into their early school years have failed to find any perinatal complications, congenital fetal anomalies, decreases in global intelligence quotient (IQ), language delays, or specific behavioral problems attributable to the use of fluoxetine during pregnancy.

Postpartum depression (with or without psychotic features) affects a small percentage of mothers. Some clinicians start administering SSRIs if the postpartum blues extend beyond a few weeks or if a woman becomes depressed during pregnancy. The head start afforded by starting SSRI administration during pregnancy if a woman is at risk for postpartum depression also protects the newborn, toward whom the woman may have harmful thoughts after parturition.

Babies whose mothers are taking an SSRI in the latter part of pregnancy

may be at a slight risk of developing pulmonary hypertension. Data about the risk of this side effect are inconclusive, but it is estimated to involve 1 to 2 babies for 1,000 births. Paroxetine should be avoided during pregnancy.

The FDA classified paroxetine as a pregnancy Category D medication in the former FDA classification system. In 2005, the FDA issued an alert that paroxetine increases the risk of congenital disabilities, particularly heart defects, when women take it during the first 3 months of pregnancy. Paroxetine should usually not be taken during pregnancy, but for some women who have already been taking paroxetine, the benefits of continuing paroxetine may be greater than the potential risk to the baby. Women taking paroxetine who are pregnant, think they may be pregnant, or plan to become pregnant should talk to their physicians about the potential risks of taking paroxetine during pregnancy.

The FDA alert was based on the findings of studies that showed that women who took paroxetine during the first 3 months of pregnancy were about one-and-a-half to two times as likely to have a baby with a heart defect as women who received other antidepressants or women in the general population. Most of the heart defects in these studies were not life-threatening and happened mainly in the inside walls of the heart muscle, where repairs can be made if needed (atrial and ventricular septal defects). Sometimes these septal defects resolve without treatment. In one of the studies, the risk of heart defects in babies whose mothers had taken paroxetine early in pregnancy was 2 percent, compared with a 1 percent risk in the whole population. In the other study, the risk of heart defects in babies whose mothers had taken paroxetine in the first 3 months of pregnancy was 1.5 percent, compared with 1 percent in babies whose mothers had taken other antidepressants in the first 3 months of pregnancy. This study also showed that women who took paroxetine in the first 3 months of pregnancy were about twice as likely to have a baby with any congenital disability as women who took other antidepressants.

Minimal amounts of SSRIs are found in breast milk, and no harmful effects have been found in breastfed babies. Concentrations of sertraline and escitalopram are exceptionally low in breast milk. However, in some cases, reported concentrations might be higher than average. No decision regarding the use of an SSRI is risk-free. It is thus essential to document that communication of potential risks to the patient has taken place.

DEPRESSION IN ELDERLY AND MEDICALLY ILL PERSONS. The SSRIs are safe and well tolerated when used to treat elderly and medically ill persons. As a class, they have little or no cardiotoxic, anticholinergic, antihistaminergic, or α-adrenergic adverse effects. Paroxetine does have some anticholinergic activity, which may lead to constipation and worsening of cognition. The SSRIs can produce subtle cognitive deficits, prolonged bleeding time, and hyponatremia, all of which may impact the health of this population. The SSRIs are effective in poststroke depression and dramatically reduce the symptom of crying.

DEPRESSION IN CHILDREN. The use of SSRI antidepressants in children and adolescents has been controversial. Few studies have shown clear-cut benefits from the use of these drugs, and studies show that there may be an increase in suicidal or aggressive impulses. However, some children and adolescents do exhibit dramatic responses to these drugs in terms of depression and anxiety. Fluoxetine has most consistently demonstrated effectiveness in reducing symptoms of depressive disorder in both children and adolescents. This fact may be a function of the quality of the clinical trials involved. Sertraline is effective in treating social anxiety disorder in this population, especially when combined with cognitive-behavioral therapy. Given the potential adverse effect of untreated depression and anxiety in a young population and the uncertainty about many aspects of how children and adolescents might react to medication, any use of SSRIs should be undertaken only within the context of comprehensive management of the patient.

Anxiety Disorders

OBSESSIVE-COMPULSIVE DISORDER. Fluvoxamine, paroxetine, sertraline, and fluoxetine are indicated for the treatment of OCD in persons older than the age of 18 years. Fluvoxamine, fluoxetine, and sertraline have also been approved for the treatment of children with OCD (ages 6 to 17 years). About 50 percent of persons with OCD begin to show symptoms in childhood or adolescence, and more than half of these respond favorably to medication. Beneficial responses can be dramatic. Long-term data support the model of

OCD as a genetically determined, lifelong condition that is best treated continuously with drugs and cognitive-behavioral therapy from the onset of symptoms in childhood throughout the lifespan.

SSRI dosages for OCD may need to be higher than those required to treat depression. Although some responses can be seen in the first few weeks of treatment, it may take several months for the maximum effects to become evident. Patients who fail to obtain adequate relief of their OCD symptoms with an SSRI will usually benefit from the addition of a small dose of risperidone (Risperdal). Apart from the extrapyramidal side effects of risperidone, patients should be monitored for increases in prolactin levels when this combination is used. Clinically, hyperprolactinemia may manifest as gynecomastia and galactorrhea (in both men and women) and loss of menses.

Several disorders are now considered to be within the OCD spectrum. This spectrum includes several conditions and symptoms characterized by nonsuicidal self-mutilation, such as trichotillomania, eyebrow picking, nose picking, nail-biting, compulsive picking of skin blemishes, and cutting. Patients with these behaviors benefit from treatment with SSRIs. Other spectrum disorders include compulsive gambling, compulsive shopping, hypochondriasis, and body dysmorphic disorder.

PANIC DISORDER. Paroxetine, fluoxetine, and sertraline are indicated for the treatment of panic disorder, with or without agoraphobia. These agents work less rapidly than do benzodiazepines but are far superior to them for the treatment of panic disorder with comorbid depression. Citalopram and fluvoxamine also may reduce spontaneous or induced panic attacks. Because fluoxetine can initially heighten anxiety symptoms, persons with panic disorder must begin taking small dosages (5 mg a day) and increase the dosage slowly. Low doses of benzodiazepines may be given to manage this side effect.

SOCIAL ANXIETY DISORDER. SSRIs are effective agents in the treatment of social phobia. They reduce both symptoms and disability. The response rate is comparable to that seen with the MAOI phenelzine (Nardil), the previous standard treatment. The SSRIs are safer to use than MAOIs or benzodiazepines.

POSTTRAUMATIC STRESS DISORDER. Pharmacotherapy for PTSD must target specific symptoms in four clusters: reexperiencing, avoidance, negative changes in mood and thinking, and arousal. For long-term treatment, SSRIs appear to have a broader spectrum of therapeutic effects on specific PTSD symptom clusters than do TCAs and MAOIs. Benzodiazepine augmentation is useful in the acute symptomatic state. The SSRIs are associated with marked improvement of both intrusive and avoidant symptoms.

GENERALIZED ANXIETY DISORDER. The SSRIs may be useful for the treatment of specific phobias, generalized anxiety disorder (GAD), and separation anxiety disorder. A thorough, individualized evaluation is the first approach, with particular attention to identifying conditions amenable to drug therapy. Also, cognitive-behavioral or other psychotherapies can be added for greater efficacy.

Bulimia Nervosa and Other Eating Disorders. Fluoxetine is indicated for the treatment of bulimia, which is best done in the context of psychotherapy. Dosages of 60 mg a day are significantly more effective than 20 mg a day. In several well-controlled studies, fluoxetine in dosages of 60 mg a day was superior to placebo in reducing binge eating and induced vomiting. Some experts recommend an initial course of cognitive-behavioral therapy alone. If there is no response in 3 to 6 weeks, then fluoxetine administration is added. The appropriate duration of treatment with fluoxetine and psychotherapy has not been determined.

Fluvoxamine was not effective at a statistically significant level in one double-blind, placebo-controlled trial for inpatients with bulimia.

ANOREXIA NERVOSA. Fluoxetine has been used in inpatient treatment of anorexia nervosa to attempt to control comorbid mood disturbances and obsessive-compulsive symptoms. However, at least two careful studies, one of 7 months' and one of 24 months' duration, failed to find that fluoxetine affected the overall outcome and the maintenance of weight. Effective treatments for anorexia include cognitive-behavioral, interpersonal, psychodynamic, and family therapies in addition to a trial with SSRIs.

OBESITY. Fluoxetine, in combination with a behavioral program, is only

modestly beneficial for weight loss. A significant percentage of all persons who take SSRIs, including fluoxetine, lose weight initially but later may gain weight. However, all SSRIs may cause initial weight gain.

PREMENSTRUAL DYSPHORIC DISORDER. PMDD is characterized by debilitating mood and behavioral changes in the week preceding menstruation that interferes with normal functioning. Sertraline, paroxetine, fluoxetine, and fluvoxamine have been reported to reduce the symptoms of PMDD. Controlled trials of fluoxetine and sertraline administered either throughout the cycle or only during the luteal phase (the 2 weeks between ovulation and menstruation) showed both schedules to be equally effective.

An additional observation of unclear significance was that fluoxetine was associated with changing the duration of the menstrual period by more than 4 days, either lengthening or shortening it. The effects of SSRIs on menstrual cycle length are mostly unknown and may warrant careful monitoring in women of reproductive age.

Off-Label Uses

PREMATURE EJACULATION. The anorgasmic effects of SSRIs make them useful as a treatment for men with premature ejaculation. The SSRIs permit intercourse for a significantly more extended period and are reported to improve sexual satisfaction in couples in which the man has premature ejaculation. Fluoxetine and sertraline are useful for this purpose.

PARAPHILIAS. The SSRIs may reduce obsessive-compulsive behavior in people with paraphilias. The SSRIs diminish the average time per day spent in unconventional sexual fantasies, urges, and activities. Evidence suggests a more significant response to sexual obsessions than for paraphilic behavior.

AUTISM. Obsessive-compulsive behavior, poor social relatedness, and aggression are prominent autistic features that may respond to serotonergic agents such as SSRIs and clomipramine (Anafranil). Sertraline and fluvoxamine have been shown in controlled and open-label trials to mitigate aggressiveness, self-injurious behavior, repetitive behaviors, some degree of language delay, and (rarely) lack of social relatedness in adults with autistic

spectrum disorders. Fluoxetine has been reported to be useful for features of autism in children, adolescents, and adults.

Precautions and Adverse Reactions. SSRI side effects need to be considered in terms of their onset, duration, and severity. For example, nausea and jitteriness are early, generally mild, and time-limited side effects. Although SSRIs share similar side effect profiles, individual drugs in this class may cause a higher rate or carry a more severe risk of specific side effects depending on the patient.

Sexual Dysfunction. All SSRIs cause sexual dysfunction, and it is the most common adverse effect of SSRIs associated with long-term treatment. It has an estimated incidence of between 50 and 80 percent. The most common complaints are anorgasmia, inhibited orgasm, and decreased libido. Some studies suggest that sexual dysfunction is dose-related, but this has not been established. Unlike most of the other adverse effects of SSRIs, sexual inhibition rarely resolves in the first few weeks of use but usually continues as long as the drug is taken. In some cases, there may be an improvement over time.

Strategies to counteract SSRI-induced sexual dysfunction are numerous, and none has been proven to be very useful. Some reports suggest decreasing the dosage or adding bupropion (Wellbutrin) or amphetamine. Reports have described successful treatment of SSRI-induced sexual dysfunction with agents such as sildenafil (Viagra), which are used to treat erectile dysfunction. Ultimately, patients may need to be switched to antidepressants that do not interfere with sexual functioning, drugs such as mirtazapine or bupropion.

Gastrointestinal Adverse Effects. GI side effects are widespread and are mediated mainly through effects on the serotonin 5-HT_3 receptor. The most frequent GI complaints are nausea, diarrhea, anorexia, vomiting, flatulence, and dyspepsia. Sertraline and fluvoxamine produce the most intense GI symptoms. Delayed-release paroxetine, compared with the immediate-release preparation of paroxetine, has less intense GI side effects during the first week of treatment. However, paroxetine, because of its anticholinergic activity, frequently causes constipation. Nausea and loose

stools are usually dose-related and transient, usually resolving within a few weeks. Sometimes flatulence and diarrhea persist, especially during sertraline treatment. Initial anorexia may also occur and is most frequent with fluoxetine. SSRI-induced appetite and weight loss begin as soon as the drug is taken and peak at 20 weeks, after which weight often returns to baseline. Up to one-third of persons taking SSRIs will gain weight, sometimes more than 20 lb. This effect is mediated through a metabolic mechanism, an increase in appetite, or both. It happens gradually and is usually resistant to diet and exercise regimens. Paroxetine is associated with more frequent, rapid, and pronounced weight gain than the other SSRIs, especially among young women.

Cardiovascular Effects. All SSRIs can lengthen the QT interval in otherwise healthy people and cause drug-induced long QT syndrome, especially when taken in overdose. The risk of QTc prolongation increases when an antidepressant and an antipsychotic are used in combination, an increasingly common practice. Citalopram stands out as the SSRI with the most pronounced effect on QT intervals. A QT study to assess the effects of 20- and 60-mg doses of citalopram on the QT interval in adults, compared with placebo, found a maximum mean prolongation in the individually corrected QT intervals were 8.5 milliseconds for 20-mg citalopram and 18.5 milliseconds for 60 mg. For 40 mg, prolongation of the corrected QT interval was estimated to be 12.6 milliseconds. Based on these findings, the FDA has issued the following recommendation regarding citalopram use:

- 20 mg a day is the maximum recommended dose for patients with hepatic impairment, who are older than 60 years of age, who are CYP2C19 poor metabolizers, or who are taking concomitant cimetidine (Tagamet).
- No longer prescribe at doses greater than 40 mg a day.
- Do not use in patients with congenital long QT syndrome.
- Correct hypokalemia and hypomagnesemia before administering citalopram.
- Monitor electrolytes as clinically indicated.

Consider more frequent electrocardiograms in patients with congestive heart failure, bradyarrhythmias, or patients on concomitant medications that

prolong the QT interval.

The fact that citalopram carries a greater risk of causing fatal rhythm abnormalities was confirmed in a review of 469 SSRI poisoning admissions. Accordingly, patients should be advised to contact their prescriber immediately if they experience signs and symptoms of an abnormal heart rate or rhythm while taking citalopram.

The effect of vilazodone (20, 40, 60, and 80 mg) on the QTc interval was evaluated, and a small effect was observed. The upper bound of the 90 percent confidence interval for the largest placebo-adjusted, baseline-corrected QTc interval was below 10 milliseconds, based on the individual correction method (QTcI). This interval is below the threshold for clinical concern. However, it is unknown whether 80 mg is adequate to represent a high clinical exposure condition.

Physicians should consider whether the benefits of androgen deprivation therapy outweigh the potential risks in SSRI treated patients with prostate cancer, as reductions in androgen levels can cause QTc interval prolongation.

Dextromethorphan/Quinidine (Nuedexta) is available as a treatment for pseudobulbar affect, which is defined by involuntary, sudden, and frequent episodes of laughing or crying that are generally out of proportion or inappropriate to the situation. Quinidine can prolong the QT interval and is a potent inhibitor of CYP2D6. It should not be used with other medications that prolong the QT interval and are metabolized by CYP2D6. This drug should be used with caution with any medications that can prolong the QT interval and inhibit CYP3A4, particularly in patients with cardiac disease.

Antepartum use of SSRIs is sometimes associated with QTc interval prolongation in exposed neonates. In a review of 52 newborns exposed to SSRIs in the immediate antepartum period and 52 matched control subjects, the mean QTc was significantly longer in the group of newborns exposed to antidepressants as compared with control subjects. Five (10 percent) newborns exposed to SSRIs had a markedly prolonged QTc interval (greater than 460 milliseconds) compared with none of the unexposed newborns. The most extended QTc interval observed among exposed newborns was 543 milliseconds. All of the drug-associated repolarization abnormalities normalized in subsequent electrocardiographic tracings.

Headaches. The incidence of headache in SSRI trials was 18 to 20 percent,

only one percentage point higher than the placebo rate. Fluoxetine is the most likely to cause headaches. On the other hand, all SSRIs are effective prophylaxis against both migraine and tension-type headaches in many persons.

Central Nervous System Adverse Effects

ANXIETY. Fluoxetine may cause anxiety, particularly in the first few weeks of treatment. However, these initial effects usually give way to an overall reduction in anxiety after a few weeks. Increased anxiety is caused considerably less frequently by paroxetine and escitalopram, which may be better choices if sedation is desired, as in mixed anxiety and depressive disorders.

INSOMNIA AND SEDATION. The primary effect SSRIs exert in the area of insomnia and sedation is improved sleep resulting from the treatment of depression and anxiety. However, as many as 25 percent of persons taking SSRIs note trouble sleeping, excessive somnolence, or overwhelming fatigue. Fluoxetine is the most likely to cause insomnia, for which reason it is often taken in the morning. Sertraline and fluvoxamine are about equally likely to cause insomnia as somnolence, and citalopram and especially paroxetine often cause somnolence. Escitalopram is more likely to interfere with sleep than its isomer, citalopram. Some persons benefit from taking their SSRI dose before going to bed, but others prefer to take it the morning. SSRI-induced insomnia can be treated with benzodiazepines, trazodone (Desyrel) (clinicians must explain the risk of priapism), or other sedating medicines. Significant SSRI-induced somnolence often requires switching to the use of another SSRI or bupropion.

OTHER SLEEP EFFECTS. Many persons taking SSRIs report recalling extremely vivid dreams or nightmares. They describe sleep as “busy.” Other sleep effects of the SSRIs include bruxism, restless legs, nocturnal myoclonus, and sweating.

EMOTIONAL BLUNTING. Emotional blunting is a largely overlooked but frequent side effect associated with chronic SSRI use. Patients report an

inability to cry in response to emotional situations, a feeling of apathy or indifference, or a restriction in the intensity of emotional experiences. This side effect often leads to treatment discontinuation, even when the drugs provide relief from depression or anxiety.

YAWNING. Close clinical observation of patients taking SSRIs reveals an increase in yawning. This side effect is not a reflection of fatigue or poor nocturnal sleep but is the result of SSRI effects on the hypothalamus.

SEIZURES. Seizures have been reported in 0.1 to 0.2 percent of all patients treated with SSRIs, an incidence comparable to that reported with other antidepressants and not significantly different from that with placebo. Seizures are more frequent at the highest doses of SSRIs (e.g., fluoxetine 100 mg a day or higher) than at standard doses.

EXTRAPYRAMIDAL SYMPTOMS. The SSRIs may rarely cause akathisia, dystonia, tremor, cogwheel rigidity, torticollis, opisthotonos, gait disorders, and bradykinesia. Rare cases of tardive dyskinesia have been reported. Some people with well-controlled Parkinson disease may experience acute worsening of their motor symptoms when they take SSRIs.

Anticholinergic Effects. Paroxetine has a mild anticholinergic activity that causes dry mouth, constipation, and sedation in a dose-dependent fashion. Nevertheless, most persons taking paroxetine do not experience cholinergic adverse effects. Other SSRIs are associated with dry mouth, but this effect is not mediated by muscarinic activity.

Hematologic Adverse Effects. The SSRIs can cause functional impairment of platelet aggregation but not a reduction in platelet number. This pharmacologic effect can manifest through easy bruising and excessive or prolonged bleeding. When patients exhibit these signs, a test for bleeding time should be performed. Special monitoring is suggested when patients use SSRIs in conjunction with anticoagulants or aspirin. Concurrent use of SSRIs and NSAIDs is associated with a significantly increased risk of gastric bleeding. In cases where this combination is necessary, we should consider using proton pump inhibitors.

Electrolyte and Glucose Disturbances. The SSRIs may acutely decrease glucose concentrations; therefore, diabetic patients should be carefully monitored. Long-term use may be associated with increased glucose levels, although it remains to be proven whether this is the result of a pharmacologic effect. Antidepressant users may have other characteristics that raise their odds of developing diabetes, or may be more likely to be diagnosed with diabetes or other medical conditions as a result of being in treatment for depression.

Cases of SSRI-associated hyponatremia and the syndrome of inappropriate antidiuretic hormone have been seen in some patients, especially those who are older or treated with diuretics.

Endocrine and Allergic Reactions. The SSRIs can increase prolactin levels and cause mammoplasia and galactorrhea in both men and women. Breast changes are reversible upon discontinuation of the drug, but this may take several months to occur.

Various types of rashes appear in about 4 percent of all patients; in a small subset of these patients, the allergic reaction may generalize and involve the pulmonary system, rarely resulting in fibrotic damage and dyspnea. SSRI treatment may have to be discontinued in patients with drug-related rashes.

Serotonin Syndrome. Concurrent administration of an SSRI with an MAOI, L-tryptophan, or lithium (Eskalith) can raise plasma serotonin concentrations to toxic levels, producing a constellation of symptoms called *serotonin syndrome*. This severe and possibly fatal syndrome of serotonin overstimulation comprises, in order of appearance as the condition worsens, (1) diarrhea; (2) restlessness; (3) extreme agitation, hyperreflexia, and autonomic instability with possible rapid fluctuations in vital signs; (4) myoclonus, seizures, hyperthermia, uncontrollable shivering, and rigidity; and (5) delirium, coma, status epilepticus, cardiovascular collapse, and death.

Treatment of serotonin syndrome consists of removing the offending agents and promptly instituting comprehensive supportive care. Supportive care and treatment may include nitroglycerine, cyproheptadine (Periactin), methysergide (Sansert), cooling blankets, chlorpromazine (Thorazine), dantrolene (Dantrium), benzodiazepines, anticonvulsants, mechanical ventilation, and paralyzing agents.

Sweating. Some patients experience sweating while being treated with SSRIs. This sweating is independent of the temperature in the environment. Nocturnal sweating may drench bed sheets and require a change of nightclothes. Terazosin (Hytrin), 1 or 2 mg/day, is often dramatically effective in counteracting sweating.

Overdose. The adverse reactions associated with overdose of vilazodone at doses of 200 to 280 mg, as observed in clinical trials, included serotonin syndrome, lethargy, restlessness, hallucinations, and disorientation.

Selective Serotonin Reuptake Inhibitor Withdrawal. The abrupt discontinuance of SSRI use, especially one with a shorter half-life such as paroxetine or fluvoxamine, has been associated with a withdrawal syndrome that may include dizziness, weakness, nausea, headache, rebound depression, anxiety, insomnia, poor concentration, upper respiratory symptoms, paresthesias, and migraine-like symptoms. It usually does not appear until after at least 6 weeks of treatment and usually resolves spontaneously in 3 weeks. Persons who experienced transient adverse effects in the first weeks of taking an SSRI are more likely to experience discontinuation symptoms.

Fluoxetine is the SSRI least likely to be associated with this syndrome because the half-life of its metabolite is more than 1 week, and it effectively tapers itself. Fluoxetine has therefore been used in some cases to treat the discontinuation syndrome caused by the termination of other SSRIs. Nevertheless, a delayed and attenuated withdrawal syndrome occurs with fluoxetine as well.

Drug Interactions

The SSRIs do not interfere with most other drugs. A serotonin syndrome (Table 21-17) can develop with concurrent administration of MAOIs, L-tryptophan, lithium, or other antidepressants that inhibit the reuptake of serotonin. Fluoxetine, sertraline, and paroxetine can raise plasma concentrations of TCAs, which can cause clinical toxicity. Several potential pharmacokinetic interactions have been described based on in vitro analyses of the CYP enzymes, but clinically relevant interactions are rare. SSRIs that inhibit CYP2D6 may interfere with the analgesic effects of hydrocodone and oxycodone. These drugs can also reduce the effectiveness of tamoxifen

(Nolvadex, Soltamox). The combined use of SSRIs and NSAIDs increases the risk of gastric bleeding.

Table 21-17
Serotonin Syndrome Symptoms

Diarrhea	Myoclonus
Diaphoresis	Hyperactive reflexes
Tremor	Disorientation
Ataxia	Lability of mood

The SSRIs, particularly fluvoxamine, should not be used with clozapine because it raises clozapine concentrations, increasing the risk of seizure. The SSRIs may increase the duration and severity of zolpidem (Ambien)-induced side effects, including hallucinations.

Fluoxetine. Fluoxetine can be administered with tricyclic drugs, but the clinician should use low dosages of the tricyclic drug. Because the hepatic enzyme CYP2D6 metabolizes it, fluoxetine may interfere with the metabolism of other drugs in the 7 percent of the population who have an inefficient isoform of this enzyme, the so-called poor metabolizers. Fluoxetine may slow down the metabolism of carbamazepine (Tegretol), antineoplastic agents, diazepam (Valium), and phenytoin (Dilantin). Drug interactions have been described for fluoxetine that may affect the plasma levels of benzodiazepines, antipsychotics, and lithium. Fluoxetine and other SSRIs may interact with warfarin (Coumadin), increasing the risk of bleeding and bruising.

Sertraline. Sertraline may displace warfarin from plasma proteins and may increase the prothrombin time. The drug interaction data on sertraline support a generally similar profile to that of fluoxetine, although sertraline does not interact as strongly with the CYP2D6 enzyme.

Paroxetine. Paroxetine has a higher risk for drug interactions than does either fluoxetine or sertraline because it is a more potent inhibitor of the

CYP2D6 enzyme. Cimetidine can increase the concentration of sertraline and paroxetine, and phenobarbital (Luminal) and phenytoin can decrease the concentration of paroxetine. Because of the potential for interference with the CYP2D6 enzyme, the coadministration of paroxetine with other antidepressants, phenothiazines, and antiarrhythmic drugs should be undertaken with caution. Paroxetine may increase the anticoagulant effect of warfarin. Coadministration of paroxetine and tramadol may precipitate serotonin syndrome in elderly persons.

Fluvoxamine. Among the SSRIs, fluvoxamine appears to present the most risk for drug–drug interactions. Fluvoxamine is metabolized by the enzyme CYP3A4, which may be inhibited by ketoconazole (Nizoral). Fluvoxamine may increase the half-life of alprazolam, triazolam (Halcion), and diazepam, and it should not be coadministered with these agents. Fluvoxamine may increase theophylline levels threefold and warfarin levels twofold, with significant clinical consequences; thus, the serum levels of the latter drugs should be closely monitored, and the doses adjusted accordingly. Fluvoxamine raises concentrations and may increase the activity of clozapine, carbamazepine, methadone (Dolophine, Methadose), propranolol (Inderal), and diltiazem (Cardizem). Fluvoxamine has no significant interactions with lorazepam (Ativan) or digoxin (Lanoxin).

Citalopram. Citalopram is not a potent inhibitor of any CYP enzymes. Concurrent administration of cimetidine increases concentrations of citalopram by about 40 percent. Citalopram does not significantly affect the metabolism of, nor is its metabolism significantly affected by, digoxin, lithium, warfarin, carbamazepine, or imipramine (Tofranil). Citalopram increases the plasma concentrations of metoprolol (Lopressor) twofold, but this usually does not affect BP or heart rate. Data on coadministration of citalopram and potent inhibitors of CYP3A4 or CYP2D6 are not available.

Escitalopram. Escitalopram is a moderate inhibitor of CYP2D6 and has been shown to raise desipramine (Norpramin) and metoprolol concentrations significantly.

Vilazodone. Vilazodone dose should be reduced to 20 mg when

coadministered with CYP3A4 potent inhibitors. Concomitant use with inducers of CYP3A4 can result in inadequate drug concentrations and may diminish effectiveness. The effect of CYP3A4 inducers on the systemic exposure of vilazodone has not been evaluated.

Laboratory Interferences

In general, the SSRIs do not interfere with any laboratory tests. There have been some reports of false-positive urine toxicology for benzodiazepines in patients taking sertraline; if this is suspected, additional confirmation can be sought via gas chromatography-mass spectrometry.

Dosage and Clinical Guidelines

Fluoxetine. Fluoxetine is available in 10- and 20-mg capsules, in a scored 10-mg tablet, as a 90-mg enteric-coated capsule for once-weekly administration, and as an oral concentrate (20 mg/5 mL). Fluoxetine is also marketed as Sarafem for PMDD. For depression, the initial dosage is usually 10 or 20 mg orally each day, usually given in the morning, because insomnia is a potential adverse effect of the drug. Fluoxetine should be taken with food to minimize possible nausea. The long half-lives of the drug and its metabolite contribute to 4 weeks to reach steady-state concentrations. Twenty milligrams is often as effective as higher doses for treating depression. The maximum dosage recommended by the manufacturer is 80 mg a day. To minimize the early side effects of anxiety and restlessness, some clinicians initiate fluoxetine use at 5 to 10 mg a day, either with the scored 10-mg tablet or by using the liquid preparation. Alternatively, because of the long half-life of fluoxetine, its use can be initiated with an every-other-day administration schedule. The dosage of fluoxetine (and other SSRIs) that is effective in other indications may differ from the dosage generally used for depression.

Sertraline. Sertraline is available in scored 25-, 50-, and 100-mg tablets. For the initial treatment of depression, sertraline use should be initiated with a dosage of 50 mg once daily. To limit the GI effects, some clinicians begin at 25 mg a day and increase to 50 mg a day after 3 weeks. Patients who do not respond after 1 to 3 weeks may benefit from dosage increases of 50 mg every week up to a maximum of 200 mg given once daily. Sertraline can be

administered in the morning or in the evening. Administration after eating may reduce the GI adverse effects. Sertraline oral concentrate (1 mL = 20 mg) has 12 percent alcohol content and must be diluted before use. When used to treat panic disorder, sertraline should be initiated at 25 mg to reduce the risk of provoking a panic attack.

Paroxetine. Immediate-release paroxetine is available in scored 20-mg tablets; in unscored 10-, 30-, and 40-mg tablets; and as an orange-flavored 10-mg/5-mL oral suspension. Paroxetine use for the treatment of depression is usually initiated at a dosage of 10 or 20 mg a day. An increase in the dosage should be considered when an adequate response is not seen in 1 to 3 weeks. At that point, the clinician can initiate upward dose titration in 10-mg increments at weekly intervals to a maximum of 50 mg a day. Persons who experience GI upset may benefit from taking the drug with food. Paroxetine can be taken initially as a single daily dose in the evening; higher dosages may be divided into two doses per day.

A delayed-release formulation of paroxetine, paroxetine CR, is available in 12.5-, 25-, and 37.5-mg tablets. The starting dosages of paroxetine CR are 25 mg/day for depression and 12.5 mg/day for panic disorder.

Paroxetine is the SSRI most likely to produce a discontinuation syndrome, because plasma concentrations decrease rapidly in the absence of continuous dosing. Paroxetine use should be tapered gradually to limit the symptoms of abrupt discontinuation, with dosage reductions every 2 to 3 weeks.

Fluvoxamine. Fluvoxamine is the only SSRI not approved by the FDA as an antidepressant. It is indicated for OCD. It is available in unscored 25-mg tablets and scored 50- and 100-mg tablets. The effective daily dosage range is 50 to 300 mg a day. A usual starting dosage is 50 mg once a day at bedtime for the first week, after which the dosage can be adjusted according to the adverse effects and clinical response. Dosages above 100 mg a day may be divided into twice-daily dosing. A temporary dosage reduction or slower upward titration may be necessary if nausea develops over the first 2 weeks of therapy. Although fluvoxamine can also be administered as a single evening dose to minimize its adverse effects, its short half-life may lead to interdose withdrawal. An extended-release formulation is available in 100- and 150-mg dose strengths. All fluvoxamine formulations should be

swallowed with food without chewing the tablet. Abrupt discontinuation of fluvoxamine may cause a discontinuation syndrome owing to its short half-life.

Citalopram. Citalopram is available in 20- and 40-mg scored tablets and as a liquid (10 mg/5 mL). The usual starting dosage is 20 mg a day for the first week, after which it usually is increased to 40 mg a day. For elderly persons or persons with hepatic impairment, 20 mg a day is recommended. Tablets should be taken once daily in either the morning or the evening with or without food.

Escitalopram. Escitalopram is available as 10- and 20-mg scored tablets, as well as an oral solution at a concentration of 5 mg/5 mL. The recommended dosage of escitalopram is 10 mg/day. In clinical trials, no additional benefit was noted when 20 mg/day was used.

Vilazodone. Vilazodone is available as 10-, 20-, and 40-mg tablets. The recommended therapeutic dose of vilazodone is 40 mg once daily. Treatment should be titrated, starting with an initial dose of 10 mg once daily for 7 days, followed by 20 mg once daily for an additional 7 days, and then an increase to 40 mg once daily. Vilazodone should be taken with food. If vilazodone is taken without food, inadequate drug concentrations may result, and the drug's effectiveness may be diminished. Vilazodone is not approved for use in children. The safety and efficacy of vilazodone in pediatric patients have not been studied. The patient's age should not influence the dose, nor does mild or moderate hepatic impairment. Vilazodone has not been studied in patients with severe hepatic impairment. No dose adjustment is recommended in patients with mild, moderate, or severe renal impairment.

Pregnancy and Breastfeeding. Except for paroxetine, the SSRIs are safe to take during pregnancy when deemed necessary for the treatment of the mother. There are no controlled human data regarding vilazodone use during pregnancy, nor are there human data regarding drug concentrations in breast milk. Transient QTc prolongation has been noted in newborns whose mother was being treated with an SSRI during pregnancy.

Loss of Efficacy. Some patients report a diminished response or total loss of response to SSRIs with recurrence of depressive symptoms while remaining on a full dose of medication. The exact mechanism of this so-called “poop-out” is unknown, but the phenomenon is genuine. Potential remedies for the attenuation of the response to SSRIs include increasing or decreasing the dosage, tapering drug use, and then rechallenging with the same medication, switching to another SSRI or non-SSRI antidepressant, and augmenting with bupropion or another augmentation agent.

Vortioxetine (Trintellix). Vortioxetine works mainly as an inhibitor of serotonin (5-HT) reuptake, but it has a more complex pharmacologic profile than other SSRIs. It also acts as an agonist at 5-HT_{1A} receptors, a partial agonist at 5-HT_{1B} receptors, and an antagonist at 5-HT_3, 5-HT_{1D}, and 5-HT_7 receptors. The contribution of each of these activities to the drug’s antidepressant effect has not been established, but it is the only compound with this combination of pharmacodynamic actions.

Side effects seen during the trials include, but are not limited to, nausea, constipation, and vomiting.

The recommended starting dose is 10 mg administered orally once daily without regard to meals. The dose should then be increased to 20 mg/day, as tolerated. A dose of 5 mg/day should be considered for patients who do not tolerate higher doses.

The maximum recommended dose of vortioxetine is 10 mg/day in known CYP2D6 poor metabolizers. Reduction of the dose of vortioxetine by one-half is suggested when patients are receiving a CYP2D6 potent inhibitor (e.g., bupropion, fluoxetine, paroxetine, or quinidine) concomitantly. The dose should be increased to the original dose of vortioxetine in patients who stop taking CYP inducers (e.g., rifampin, carbamazepine, or phenytoin). This adjustment is especially essential when a potent CYP inducer is coadministered for greater than 14 days. The maximum recommended dose should not exceed three times the original dose. The dose of vortioxetine should be reduced to the original level within 14 days when the inducer is discontinued.

Although vortioxetine can be abruptly discontinued, in placebo-controlled trials, patients experienced transient adverse reactions such as headache and

muscle tension following abrupt discontinuation of vortioxetine 15 or 20 mg/day. It is recommended that the dose be decreased to 10 mg/day for 1 week before full discontinuation of vortioxetine 15 or 20 mg/day.

Vortioxetine is available in 5-, 10-, 15-, and 20-mg tablets.

SELECTIVE SEROTONIN–NOREPINEPHRINE REUPTAKE INHIBITORS

There are currently four SNRIs approved for use in the United States: venlafaxine (Effexor and Effexor XR), desvenlafaxine succinate (DVS; Pristiq), duloxetine (Cymbalta), and levomilnacipran (Fetzima). A fifth SNRI, milnacipran (Savella), available in other countries as an antidepressant, has U.S. FDA approval in the United States as a treatment for fibromyalgia. The term SNRI reflects the belief that the therapeutic effects of these medications are mediated by concomitant blockade of neuronal serotonin (5-HT) and norepinephrine uptake transporters. The SNRIs are also sometimes referred to as dual reuptake inhibitors, a broader functional class of antidepressant medications that include TCAs such as clomipramine (Anafranil) and, to a lesser extent, imipramine (Tofranil) and amitriptyline (Elavil). What distinguishes the SNRIs from TCAs is their relative lack of affinity for other receptors, especially muscarinic, histaminergic, and the families of α- and β-adrenergic receptors. This distinction is an important one because the SNRIs have a more favorable tolerability profile than the older dual reuptake inhibitors.

Venlafaxine and Desvenlafaxine

Therapeutic Indications. Venlafaxine is approved for the treatment of four disorders: MDD, GAD, social anxiety disorder, and panic disorder. MDD is currently the only FDA-approved indication for DVS.

DEPRESSION. The FDA does not recognize any class of antidepressants as being more effective than any other. This does not mean that differences do not exist, but no study to date has sufficiently demonstrated such superiority. It has been argued that direct modulation of serotonin and norepinephrine may convey more significant antidepressant effects than are exerted by

medications that selectively enhance only noradrenergic or serotoninergic neurotransmission. This more significant therapeutic benefit could result from an acceleration of postsynaptic adaptation to increased neuronal signaling, simultaneous activation of two pathways for intracellular signal transduction, additive effects on the activity of relevant genes such as brain-derived neurotrophic factor, or, quite simply, broader coverage of depressive symptoms. Clinical evidence supporting this hypothesis first emerged in a pair of studies conducted by the Danish University Antidepressant Group, which found an advantage for the dual reuptake inhibitor clomipramine compared with SSRIs citalopram (Celexa) and paroxetine (Paxil). Another report, which compared the results of a group of patients prospectively treated with the combination of desipramine (Norpramin) and fluoxetine (Prozac) with a historical comparison group treated with desipramine alone, provided additional support. A meta-analysis of 25 inpatient studies comparing the efficacy of TCAs and SSRIs yielded the most substantial evidence. Specifically, although the TCAs were found to have a modest overall advantage, superiority versus SSRIs was almost entirely explained by the studies that used the TCAs that are considered to be dual reuptake inhibitors—clomipramine, amitriptyline, and imipramine. Meta-analyses of head-to-head studies suggest that venlafaxine has the potential to induce higher rates of remission in depressed patients than do the SSRIs. This difference in the venlafaxine advantage is about 6 percent. DVS has not been extensively compared with other classes of antidepressants concerning efficacy.

GENERALIZED ANXIETY DISORDER. The extended-release formulation of venlafaxine is approved for the treatment of GAD. In clinical trials lasting 6 months, dosages of 75 to 225 mg a day were effective in treating insomnia, poor concentration, restlessness, irritability, and excessive muscle tension related to GAD.

SOCIAL ANXIETY DISORDER. The extended-release formulation of venlafaxine is approved for the treatment of social anxiety disorder. Its efficacy was established in 12-week studies.

OTHER INDICATIONS. Case reports and uncontrolled studies have indicated that

venlafaxine may be beneficial in the treatment of obsessive-compulsive disorder, panic disorder, agoraphobia, social phobia, ADHD, and patients with a dual diagnosis of depression and cocaine dependence. It has also been used in chronic pain syndromes with good effect.

Precautions and Adverse Reactions. Venlafaxine has a safety and tolerability profile similar to that of the more widely prescribed SSRI class. Nausea is the most frequently reported treatment-emergent adverse effect associated with venlafaxine and DVS therapy. Initiating therapy at lower dosages may also attenuate nausea. When extremely problematic, treatment-induced nausea can be controlled by prescribing a selective 5-HT_3 antagonist or mirtazapine (Remeron).

Venlafaxine and DVS therapy is associated with sexual side effects, predominantly decreased libido and a delay to orgasm or ejaculation. The incidence of these side effects may exceed 30 to 40 percent when there is a direct, detailed assessment of sexual function.

Other common side effects include headache, insomnia, somnolence, dry mouth, dizziness, constipation, asthenia, sweating, and nervousness. Although several side effects are suggestive of anticholinergic effects, these drugs have no affinity for muscarinic or nicotinic receptors. Thus, noradrenergic agonism is likely to be the culprit.

Higher-dose venlafaxine therapy is associated with an increased risk of sustained elevations of BP. Experience with the instant-release (IR) formulation in studies of depressed patients indicated that sustained hypertension was dose-related, increasing from 3 to 7 percent at doses of 100 to 300 mg/day and 13 percent at doses greater than 300 mg/day. In this dataset, venlafaxine therapy did not adversely affect BP control of patients taking antihypertensives and lowered the mean values of patients with elevated BP readings before therapy. In controlled studies of the extended-release formulation, venlafaxine therapy resulted in only approximately 1 percent greater risk of high BP when compared with the placebo. Arbitrarily capping the upper dose of venlafaxine used in these studies, thus, significantly attenuated concerns about elevated BP. When higher doses of the extended-release formulation are used, however, monitoring of BP is recommended.

Venlafaxine and DVS are commonly associated with discontinuation

syndrome. This syndrome is characterized by the appearance of a constellation of adverse effects during a rapid taper or abrupt cessation, including dizziness, dry mouth, insomnia, nausea, nervousness, sweating, anorexia, diarrhea, somnolence, and sensory disturbances. It is recommended that, whenever possible, a slow taper schedule should be used when longer-term treatment must be stopped. On occasion, substituting a few doses of the sustained-release formulation of fluoxetine may help to bridge this transition.

There were no overdose fatalities in premarketing trials of venlafaxine, although electrocardiographic changes (e.g., prolongation of QT interval, bundle branch block, QRS interval prolongation), tachycardia, bradycardia, hypotension, hypertension, coma, serotonin syndrome, and seizures were reported. Fatal overdoses have been documented subsequently, typically involving venlafaxine ingestion in combination with other drugs, alcohol, or both.

Information concerning the use of venlafaxine and DVS by pregnant and nursing women is not available at this time. Venlafaxine and DVS are excreted in breast milk. Clinicians should carefully weigh the risks and benefits of venlafaxine use by pregnant and nursing women.

Drug Interactions. Venlafaxine is metabolized in the liver primarily by the CYP2D6 isoenzyme. Because the parent drug and principal metabolite are essentially equipotent, medications that inhibit this isoenzyme usually do not adversely affect therapy. Venlafaxine is itself a relatively weak inhibitor of CYP2D6, although it can increase levels of substrates, such as desipramine or risperidone (Risperdal). In vitro and in vivo studies have shown venlafaxine to cause little or no inhibition of CYP1A2, CYP2C9, CYP2C19, and CYP3A4.

Venlafaxine is contraindicated in patients taking MAOIs because of the risk of a pharmacodynamic interaction (i.e., serotonin syndrome). An MAOI should not be started for at least 7 days after stopping venlafaxine. Few data are available regarding the combination of venlafaxine with atypical neuroleptics, benzodiazepines, lithium (Eskalith), and anticonvulsants; therefore, clinical judgment should be exercised when combining medications.

Laboratory Interferences. Data are not currently available on laboratory

interferences with venlafaxine. There have been some reports of patients taking venlafaxine who have false-positive results on liquid chromatography testing for tramadol.

Dosage and Administration. Venlafaxine is available in 25-, 37.5-, 50-, 75-, and 100-mg tablets and 37.5-, 75-, and 150-mg extended-release capsules. The tablets and the extended-release capsules are equally potent, and persons stabilized with one can switch to an equivalent dosage of the other. Because the immediate-release tablets are rarely used due to their tendency to cause nausea and the need for multiple-daily doses, the dosage recommendations that follow refer to the use of the extended-release capsules.

In depressed persons, venlafaxine demonstrates a dose–response curve. The initial therapeutic dosage is 75 mg a day, given once a day. However, most persons are started at a dosage of 37.5 mg for 4 to 7 days to minimize adverse effects, particularly nausea. A convenient starter kit for the drug contains a 1-week supply of both the 37.5- and 75-mg strengths. If a rapid titration is preferred, the dosage can be raised to 150 mg/day after day 4. As a rule, the dosage can be raised in increments of 75 mg a day every 4 or more days. Although the recommended upper dosage of the extended-release preparation (venlafaxine XR) is 225 mg/day, it is approved by the FDA for use at dosages up to 375 mg a day. The dosage of venlafaxine should be halved in persons with significantly diminished hepatic or renal function. If discontinued, venlafaxine use should be gradually tapered over 2 to 4 weeks to avoid withdrawal symptoms.

There are minor differences in the doses used for major depression, GAD, and social anxiety disorder. In the treatment of these disorders, for example, a dose–response effect has not been found. Also, lower mean dosages are typically used, with most patients taking 75 to 150 mg/day.

DVS is available as 50- and 100-mg extended-release tablets. The therapeutic dose for most patients is 50 mg a day. Although some patients may need higher doses, in clinical trials, no more significant therapeutic benefit was noted when the dose was increased. At higher doses, adverse events and discontinuation rates were increased.

Duloxetine

Pharmacologic Actions. Duloxetine is formulated as a delayed-release capsule to reduce the risk of severe nausea associated with the drug. It is well absorbed, but there is a 2-hour delay before absorption begins. Peak plasma concentrations occur 6 hours after ingestion. Food delays the time to achieve maximum concentrations from 6 to 10 hours and reduces the extent of absorption by about 10 percent. Duloxetine has an elimination half-life of about 12 hours (range, 8 to 17 hours). Steady-state plasma concentrations occur after 3 days. Duloxetine's elimination is mainly through the isozymes CYP2D6 and CYP1A2. Duloxetine undergoes extensive hepatic metabolism to numerous metabolites. About 70 percent of the drug appears in the urine as metabolites, and about 20 percent is excreted in the feces. Duloxetine is 90 percent protein-bound.

Therapeutic Indications

DEPRESSION. In contrast to venlafaxine, a small number of studies have compared duloxetine with the SSRIs. Although these studies are suggestive of some advantage in efficacy, their findings are limited by the use of fixed, low starting doses of paroxetine and fluoxetine, but dosages of duloxetine in some studies were as high as 120 mg/day. Any inferences on whether duloxetine is superior to the SSRIs in any aspect of treatment for depression thus await more evidence from adequately designed trials.

NEUROPATHIC PAIN ASSOCIATED WITH DIABETES AND STRESS URINARY INCONTINENCE. Duloxetine is the first drug to be approved by the FDA as a treatment for neuropathic pain associated with diabetes. Its pain effects have not been compared with other agents, such as venlafaxine and the TCAs. Duloxetine is currently awaiting approval as a treatment for stress urinary incontinence, the inability to voluntarily control bladder voiding, which is the most frequent type of incontinence in women. The action of duloxetine in the treatment of stress urinary incontinence is associated with its effects in the sacral spinal cord, which in turn increases the activity of the striated urethral sphincter. Duloxetine is marketed under the name Yentreve for this indication which has not been approved for this indication in the United States but is available in the European Union and other countries.

PRECAUTIONS AND ADVERSE REACTIONS. The most common adverse reactions are nausea, dry mouth, dizziness, constipation, fatigue, decreased appetite, anorexia, somnolence, and increased sweating. Nausea was the most common side effect that led to treatment discontinuation in clinical trials. The true incidence of sexual dysfunction is unknown; the long-term effects on body weight are also unknown. In clinical trials, treatment with duloxetine was associated with mean increases in BP averaging 2 mm Hg systolic and 0.5 mm Hg diastolic versus placebo. No studies have compared the BP effects of venlafaxine and duloxetine at equivalent therapeutic doses.

Close monitoring is suggested when using duloxetine in patients who have or are at risk for diabetes. Duloxetine has been shown to increase blood sugar and hemoglobin A1C levels during long-term treatment.

Patients with substantial alcohol use should not be treated with duloxetine because of possible hepatic effects. It also should not be prescribed for patients with hepatic insufficiency and end-stage renal disease or patients with uncontrolled narrow-angle glaucoma.

Abrupt discontinuation of duloxetine should be avoided because it may produce a discontinuation syndrome similar to that of venlafaxine. A gradual dose reduction is recommended.

Clinicians should avoid the use of duloxetine by pregnant and nursing women unless the potential benefits justify the potential risks.

Drug Interactions. Duloxetine is a moderate inhibitor of CYP450 enzymes.

Laboratory Interferences. Data are not currently available on laboratory interferences with duloxetine.

Dosage and Administration. Duloxetine is available in 20-, 30-, and 60-mg tablets. The recommended therapeutic and maximum dosage is 60 mg/day. The 20- and 30-mg doses are useful for either initial therapy or for twice-daily use as strategies to reduce side effects. In clinical trials, dosages of up to 120 mg/day were studied, but no consistent advantage in efficacy was noted at doses higher than 60 mg/day. Duloxetine thus does not appear to demonstrate a dosage–response curve. However, there were difficulties in tolerability with single doses above 60 mg. Accordingly, when dosages of 80

and 120 mg/day were used, they were administered as 40 or 60 mg twice daily. It remains to be seen to what extent dosages above 60 mg/day will be necessary and whether this will require divided doses to make the drug tolerable.

Milnacipran and Levomilnacipran

Milnacipran is only FDA approved for the treatment of fibromyalgia. Although some countries have approved milnacipran for general use as an antidepressant, efficacy is not as well established. Compared with venlafaxine, milnacipran is approximately five times more potent for inhibition of norepinephrine uptake than for 5-HT reuptake inhibition. Milnacipran has a half-life of approximately 8 hours and shows linear pharmacokinetics between doses of 50 and 250 mg/day. Milnacipran has no active metabolites, and it is directly metabolized in the liver. The kidneys primarily excrete milnacipran.

Milnacipran is available as 12.5-, 25-, 50-, and 100-mg tablets. The standard recommended milnacipran dose is as follows: day 1, 12.5 mg once daily; days 2 and 3, 12.5 mg twice daily; days 4 to 7, 25 mg twice daily; and day 7 and beyond, 50 mg twice daily.

Levomilnacipran was approved in 2013 by the FDA as a treatment for MDD in adults. Levomilnacipran is an active enantiomer of the racemic drug milnacipran. In vitro studies have shown that it has greater potency for norepinephrine reuptake inhibition than for serotonin reuptake inhibition and does not directly affect the uptake of dopamine or other neurotransmitters. It is taken once daily as a sustained-release formulation. In clinical trials, doses of 40, 80, or 120 mg improved symptoms compared with placebo.

The most common adverse reactions in the placebo-controlled trials were nausea, constipation, hyperhidrosis, increased heart rate, erectile dysfunction, tachycardia, vomiting, and palpitations. Rates of adverse events were generally consistent across the 40- to 120-mg dose range. The only dose-related adverse events were urinary hesitation and erectile dysfunction.

BUPROPION

Bupropion (Wellbutrin, Wellbutrin SR, Wellbutrin XL) is an antidepressant drug that inhibits the reuptake of norepinephrine and, possibly, dopamine.

Most significantly, it does not act on the serotonin system like SSRI antidepressants. This novel action results in a side effect profile characterized by a low risk of sexual dysfunction and sedation and with modest weight loss during acute and long-term treatment. No withdrawal syndrome has been linked to discontinuation of bupropion. Although increasingly used as first-line monotherapy, a significant percentage of bupropion use occurs as add-on therapy to other antidepressants, usually SSRIs. Bupropion was marketed under the name Zyban for use in smoking cessation regimens. However, the manufacturer has discontinued that brand in the United States.

Pharmacologic Actions

Three formulations of bupropion are available: immediate-release (taken three times daily), sustained-release (taken twice daily), and extended-release (taken once daily). The different versions of the drug contain the same active ingredient but differ in their pharmacokinetics and dosing. There have been reports of inconsistencies in bioequivalence between various branded and generic versions of bupropion. If a patient experiences changes in adverse effects or efficacy, the clinician should inquire whether there has been a change of formulation.

Immediate-release bupropion is well absorbed from the GI tract. Peak plasma concentrations of bupropion are usually reached within 2 hours of oral administration, and peak levels of the sustained-release version are seen after 3 hours. The mean half-life of the compound is 12 hours, ranging from 8 to 40 hours. Peak levels of extended-release bupropion occur 5 hours after ingestion. This pharmacokinetic profile provides a longer time to maximum plasma concentration (t_{max}) but comparable peak and trough plasma concentrations. The 24-hour exposure occurring after administration of the extended-release version of 300 mg once daily is equivalent to that provided by sustained release of 150 mg twice daily. Clinically, this permits the drug to be taken once a day in the morning. Plasma levels are also reduced in the evening, making it less likely for some patients to experience treatment-related insomnia.

The mechanism of action for the antidepressant effects of bupropion is presumed to involve the inhibition of dopamine and norepinephrine reuptake. Bupropion binds to the dopamine transporter in the brain. The effects of

bupropion on smoking cessation may be related to its effects on dopamine reward pathways or inhibition of nicotinic acetylcholine receptors.

Therapeutic Indications

Depression. Although overshadowed by the SSRIs as first-line treatment for major depression, the therapeutic efficacy of bupropion in depression is well established in both outpatient and inpatient settings. Observed rates of response and remission are comparable to those seen with the SSRIs. Bupropion has been found to prevent seasonal major depressive episodes in patients with a history of seasonal patterns or affective disorder.

Smoking Cessation. Bupropion is indicated for use in combination with behavioral modification programs for smoking cessation. It is intended to be used in patients who are highly motivated and who receive some form of structured behavioral support. Bupropion is most effective when combined with nicotine substitutes (Nico-Derm, Nicotrol).

Bipolar Disorders. Bupropion is less likely than TCAs to precipitate mania in persons with bipolar I disorder and less likely than other antidepressants to exacerbate or induce rapid-cycling bipolar II disorder; however, the evidence about the use of bupropion in the treatment of patients with bipolar disorder is limited.

Attention-Deficit/Hyperactivity Disorder. Bupropion is used as a second-line agent, after the sympathomimetics, for treatment of ADHD. It has not been compared with proven ADHD medications such as methylphenidate (Ritalin) or atomoxetine (Strattera) for childhood and adult ADHD. Bupropion is an appropriate choice for persons with comorbid ADHD and depression or persons with comorbid ADHD, conduct disorder, or substance use disorder. It may also be considered for use in patients who develop tics when treated with psychostimulants.

Cocaine Detoxification. Bupropion may be associated with a euphoric feeling; thus, it may be contraindicated in persons with histories of substance abuse. However, because of its dopaminergic effects, bupropion has been explored as a treatment for cocaine cravings. Results have been inconclusive,

with some patients showing a reduction in drug craving and others finding their cravings increased.

Hypoactive Sexual Desire Disorder. Bupropion is often added to drugs such as SSRIs to counteract sexual side effects and may be helpful as a treatment for nondepressed individuals with a disorder of sexual desire. Bupropion may improve sexual arousal, orgasm completion, and sexual satisfaction.

Precautions and Adverse Reactions

Headache, insomnia, dry mouth, tremor, and nausea are the most common side effects. Restlessness, agitation, and irritability may also occur. Patients with severe anxiety or panic disorder should not be prescribed bupropion. Most likely, because of its potentiating effects on dopaminergic neurotransmission, bupropion can cause psychotic symptoms, including hallucinations, delusions, and catatonia, as well as delirium. Most notable about bupropion is the absence of significant drug-induced orthostatic hypotension, weight gain, daytime drowsiness, and anticholinergic effects. Some persons, however, may experience dry mouth or constipation and weight loss. Hypertension may occur in some patients, but bupropion causes no other significant cardiovascular or clinical laboratory changes. Bupropion exerts indirect sympathomimetic activity, producing positive inotropic effects in the human myocardium, an effect that may reflect catecholamine release. Some patients experience cognitive impairment, most notably word-finding difficulties.

Concern about seizure has deterred some physicians from prescribing bupropion. The risk of seizure is dose-dependent. Studies show that at dosages of 300 mg a day or less of sustained-
release bupropion, the incidence of seizures is 0.05 percent, which is no worse than the incidence of seizures with other antidepressants. The risk of seizures increases to about 0.1 percent with dosages of 400 mg a day.

Changes in electroencephalographic (EEG) waveforms have been reported to be associated with bupropion use. About 20 percent of individuals treated with bupropion exhibit spike waves, sharp waves, and focal slowing. The likelihood of women having sharp waves is higher than for men. The

presence of these waveforms in individuals taking a medication known to lower the seizure threshold may be a risk factor for developing seizures. Other risk factors for seizures include a history of seizures, use of alcohol, recent benzodiazepine withdrawal, organic brain disease, head trauma, or pretreatment epileptiform discharges on EEG.

The use of bupropion by pregnant women is not associated with a specific risk of an increased rate of congenital disabilities. Bupropion is secreted in breast milk, so the use of bupropion in nursing women should be based on the clinical circumstances of the patient and the judgment of the clinician.

Few deaths have been reported after overdoses of bupropion. Poor outcomes are associated with cases of massive doses and mixed-drug overdoses. Seizures occur in about one-third of all overdoses and are dose-dependent, with those having seizures ingesting a significantly higher median dose. Fatalities can involve uncontrollable seizures, sinus bradycardia, and cardiac arrest. Symptoms of poisoning most often involve seizures, sinus tachycardia, hypertension, GI symptoms, hallucinations, and agitation. All seizures are typically brief and self-limited. In general, however, bupropion is safer in overdose cases than are other antidepressants except for perhaps SSRIs.

Drug Interactions

Given the fact that bupropion is frequently combined with SSRIs or venlafaxine, potential interactions are significant. Bupropion has been found to affect the pharmacokinetics of venlafaxine. One study noted a significant increase in venlafaxine levels and a consequent decrease in its main metabolite O-desmethylvenlafaxine during combined treatment with sustained-release bupropion. Bupropion hydroxylation is weakly inhibited by venlafaxine. No significant changes in plasma levels of the SSRIs paroxetine and fluoxetine have been reported. However, few case reports indicate that the combination of bupropion and fluoxetine (Prozac) may be associated with panic, delirium, or seizures. Bupropion, in combination with lithium (Eskalith), may rarely cause CNS toxicity, including seizures.

Because of the possibility of inducing a hypertensive crisis, bupropion should not be used concurrently with MAOIs. At least 14 days should pass after the discontinuation of an MAOI before initiating treatment with

bupropion. In some cases, the addition of bupropion may permit persons taking antiparkinsonian medications to lower the doses of their dopaminergic drugs. However, delirium, psychotic symptoms, and dyskinetic movements may occur with the coadministration of bupropion and dopaminergic agents, such as antiparkinsonian meds. Sinus bradycardia may occur when bupropion is combined with metoprolol.

Carbamazepine (Tegretol) may decrease plasma concentrations of bupropion, and bupropion may increase plasma concentrations of valproic acid (Depakene).

In vitro biotransformation studies of bupropion have found that the formation of a major active metabolite, hydroxybupropion, is mediated by CYP2B6. Bupropion has a significant inhibitory effect on CYP2D6.

Laboratory Interferences

A report has appeared indicating that bupropion may give a false-positive result on urinary amphetamine screens. No other reports have appeared of laboratory interferences associated with bupropion treatment. Clinically nonsignificant changes in the electrocardiogram (premature beats and nonspecific ST-T changes) and decreases in the WBC count (by about 10 percent) have been reported in a small number of persons.

Dosage and Clinical Guidelines

Immediate-release bupropion is available in 75-, 100-, and 150-mg tablets. Sustained-release bupropion is available in 100-, 150-, 200-, and 300-mg tablets. Extended-release bupropion comes in 150- and 300-mg strengths.

There have been problems associated with one of the extended-release generic versions called Budeprion XL 300-mg tablets, which was found not to be therapeutically equivalent to Wellbutrin XL 300 mg and was removed from the market.

The initiation of immediate-release bupropion in the average adult person should be 75 mg orally twice a day. On the fourth day of treatment, the dosage can be increased to 100 mg three times a day. Because 300 mg is the recommended dose, the person should be maintained on this dose for several weeks before increasing it further. The maximum dosage, 450 mg a day, should be given as 150 mg three times a day. Because of the risk of seizures,

increases in dose should never exceed 100 mg in 3 days; a single dose of immediate-release bupropion should never exceed 150 mg, and the total daily dosage should not exceed 450 mg. The maximum of 400 mg of the sustained-release version should be used as a twice-a-day regimen of either 200 mg twice daily or 300 mg in the morning and 100 mg in the afternoon. A starting dosage of the sustained-release version, 100 mg once a day, can be increased to 100 mg twice a day after 4 days. Then 150 mg twice a day may be used. A single dose of sustained-release bupropion should never exceed 300 mg. The maximum dosage is 200 mg twice a day of the immediate-release or extended-release formulations. An advantage of the extended-release preparation is that the patient can take a single daily dose of 450 mg after proper titration.

For smoking cessation, the patient should start taking 150 mg a day of sustained-release bupropion 10 to 14 days before quitting smoking. On the fourth day, the dosage should be increased to 150 mg twice daily. Treatment generally lasts 7 to 12 weeks.

MIRTAZAPINE

Mirtazapine (Remeron) is unique among drugs used to treat major depression in that it increases both norepinephrine and serotonin through a mechanism other than reuptake blockade (as in the case of tricyclic agents or SSRIs) or monoamine oxidase inhibition (as in the case of phenelzine or tranylcypromine). Mirtazapine is also more likely to reduce rather than cause nausea and diarrhea, the result of its effects on serotonin 5-HT_3 receptors. Characteristic side effects include increased appetite and sedation.

Pharmacologic Actions

Mirtazapine is administered orally and is rapidly and completely absorbed. It has a half-life of about 30 hours. Peak concentration is achieved within 2 hours of ingestion, and steady state is reached after 6 days. Plasma clearance may be slowed up to 30 percent in persons with impaired hepatic function, up to 50 percent in those with impaired renal function, up to 40 percent slower in older men, and up to 10 percent slower in older women.

The mechanism of action of mirtazapine is the antagonism of central

presynaptic α_2-adrenergic receptors and blockade of postsynaptic serotonin 5-HT_2 and 5-HT_3 receptors. The α_2-adrenergic receptor antagonism causes the increased firing of norepinephrine and serotonin neurons. The potent antagonist of serotonin 5-HT_2 and 5-HT_3 receptors serves to decrease anxiety, relieve insomnia, and stimulate the appetite. Mirtazapine is a potent antagonist of histamine H_1 receptors and is a moderately potent antagonist at α_1-adrenergic and muscarinic-cholinergic receptors.

Therapeutic Indications

Mirtazapine is effective for the treatment of depression. It is highly sedating, making it a reasonable choice for use in depressed patients with severe or long-standing insomnia. Some patients find the residual daytime sedation associated with the initiation of treatment to be quite pronounced. However, the more extreme sedating properties of the drug generally lessen over the first week of treatment. Combined with the tendency to sometimes cause a ravenous appetite, mirtazapine is well suited for depressed patients with melancholic features such as insomnia, weight loss, and agitation. Elderly depressed patients, in particular, are good candidates for mirtazapine; young adults are more likely to object to this side effect profile.

Mirtazapine's blockade of 5-HT_3 receptors, a mechanism associated with medications used to combat the severe GI side effects of cancer chemotherapy agents, has led to the use of the drug in a similar role. In this population, sedation and stimulation of appetite clearly could be seen as being beneficial instead of unwelcome side effects.

Mirtazapine is often combined with SSRIs or venlafaxine to augment antidepressant response or counteract serotonergic side effects of those drugs, particularly nausea, agitation, and insomnia. Mirtazapine has no significant pharmacokinetic interactions with other antidepressants.

Precautions and Adverse Reactions

Somnolence, the most common adverse effect of mirtazapine, occurs in more than 50 percent of persons (Table 21-18). Persons starting mirtazapine should thus exercise caution when driving or operating dangerous machinery and even when getting out of bed at night. This adverse effect is why mirtazapine

is almost always given before sleep. Mirtazapine potentiates the sedative effects of other CNS depressants, so potentially sedating prescription or over-the-counter drugs and alcohol should be avoided during the use of mirtazapine. Mirtazapine also causes dizziness in 7 percent of persons. It does not appear to increase the risk of seizures. Mania or hypomania occurred in clinical trials at a rate similar to that of other antidepressant drugs.

Mirtazapine increases appetite in about one-third of patients. Mirtazapine may also increase serum cholesterol concentration to 20 percent or more above the upper limit of normal in 15 percent of persons and increase triglycerides to 500 mg/dL or more in 6 percent of persons. Elevations of alanine transaminase levels to more than three times the upper limit of normal were seen in 2 percent of mirtazapine-treated persons as opposed to 0.3 percent of placebo control subjects.

In limited premarketing experience, the absolute neutrophil count dropped to 500/mm^3 or less within 2 months of the onset of use in 0.3 percent of persons, some of whom developed symptomatic infections. This hematologic condition was reversible in all cases and was more likely to occur when other risk factors for neutropenia were present. Increases in the frequency of neutropenia have not, however, been reported during the extensive postmarketing period. Persons who develop fever, chills, sore throat, mucous membrane ulceration, or other signs of infection should nevertheless be evaluated medically. If a low WBC count is found, mirtazapine should be immediately discontinued, and the infectious disease status should be followed closely.

Table 21-18
Adverse Reactions Reported with Mirtazapine

Event	Patients (%)
Somnolence	54
Dry mouth	25
Increased appetite	17
Constipation	13

Weight gain	12
Dizziness	7
Myalgias	5
Disturbing dreams	4

A small number of persons experience orthostatic hypotension while taking mirtazapine. Although no data exist regarding the effects on fetal development, mirtazapine should be used with caution during pregnancy.

Mirtazapine use by pregnant women has not been studied, but because the drug may be excreted in breast milk, it should not be taken by nursing mothers. Because of the risk of agranulocytosis associated with mirtazapine use, persons should be attuned to signs of infection. Because of the sedating effects of mirtazapine, persons should determine the degree to which they are affected before engaging in driving or other potentially dangerous activities.

Drug Interactions

Mirtazapine can potentiate the sedation of alcohol and benzodiazepines. Mirtazapine should not be used within 14 days of use of an MAOI.

Laboratory Interferences

No laboratory interferences have yet been described for mirtazapine.

Dosage and Administration

Mirtazapine is available in 15-, 30-, and 45-mg scored tablets. Mirtazapine is also available in 15-, 30-, and 45-mg orally disintegrating tablets for persons who have difficulty swallowing pills. If persons fail to respond to the initial dose of 15 mg of mirtazapine before sleep, the dose may be increased in 15-mg increments every 5 days to a maximum of 45 mg before sleep. Lower dosages may be necessary for elderly persons or persons with renal or hepatic insufficiency.

NEFAZODONE AND TRAZODONE

Nefazodone (Serzone) and Trazodone (Desyrel) are mechanistically and

structurally related drugs approved as treatments for depression. Nefazodone (Serzone) is an analog of trazodone. When nefazodone was introduced in 1995, there were expectations that it would become widely used because it did not cause the sexual side effects and sleep disruption associated with the selective SSRIs. Although it was devoid of these side effects, it was nevertheless found to produce problematic sedation, nausea, dizziness, and visual disturbances. Consequently, nefazodone was never extensively adopted in clinical practice. This fact, as well as reports of rare cases of sometimes fatal hepatotoxicity, led the original manufacturer to discontinue the production of branded nefazodone in 2004. Generic nefazodone remains available in the United States.

Trazodone received FDA approval in 1981 as a treatment for MDD. Its novel triazolopyridine chemical structure distinguished it from the TCAs, and clinical trials suggested improved safety and tolerability compared with TCAs. There were high expectations that it would replace the older drugs as a mainstay of treatment for depression. However, the extreme sedation associated with trazodone, even at subtherapeutic doses, limited the clinical effectiveness of the drug. However, its soporific properties made trazodone a favorite alternative to standard hypnotics as a sleep-inducing agent. Unlike conventional sleeping pills, trazodone is not a controlled substance.

Nefazodone

Pharmacologic Actions. Nefazodone is rapidly and completely absorbed but is then extensively metabolized so that the bioavailability of active compounds is about 20 percent of the oral dose. Its half-life is 2 to 4 hours. Steady-state concentrations of nefazodone and its principal active metabolite, hydroxynefazodone, are achieved within 4 to 5 days. Metabolism of nefazodone in elderly persons, especially women, is about half of that seen in younger persons, so lowered doses are recommended for elderly persons. An important metabolite of nefazodone is meta-chlorophenylpiperazine (mCPP), which has some serotonergic effects and may cause migraine, anxiety, and weight loss.

Although nefazodone is an inhibitor of serotonin uptake and, more weakly, of norepinephrine reuptake, its antagonism of serotonin 5-HT_A receptors is thought to produce its antianxiety and antidepressant effects. Nefazodone is

also a mild antagonist of the α_1-adrenergic receptors, which predisposes some persons to orthostatic hypotension but is not sufficiently potent to produce priapism.

Therapeutic Indications. Nefazodone is effective for the treatment of major depression. The usual effective dosage is 300 to 600 mg a day. In direct comparison with SSRIs, nefazodone is less likely to cause inhibition of orgasm or decreased sexual desire. Nefazodone is also effective for the treatment of panic disorder and panic with comorbid depression or depressive symptoms, GAD, and PMDD and management of chronic pain. It is not useful for the treatment of OCD. Nefazodone increases rapid eye movement (REM) sleep and increases sleep continuity. Nefazodone is also of use in patients with PTSD and chronic fatigue syndrome. It may also be effective in patients who have been treatment-resistant to other antidepressant drugs.

Precautions and Adverse Reactions. The most common reasons for discontinuing nefazodone use are sedation, nausea, dizziness, insomnia, weakness, and agitation (Table 21-19). Many patients report no specific side effects but describe a vague sense of feeling medicated. Nefazodone also causes visual trails, in which patients see an afterimage when looking at moving objects or when moving their heads quickly.

A significant safety concern with the use of nefazodone is a severe elevation of hepatic enzymes, and, in some instances, liver failure. Accordingly, serial hepatic function tests need to be done when patients are treated with nefazodone. Hepatic effects can be seen early in treatment and are more likely to develop when nefazodone is combined with other drugs metabolized in the liver.

Some patients taking nefazodone may experience a decrease in BP that can cause episodes of postural hypotension. Nefazodone should therefore be used with caution by persons with underlying cardiac conditions or history of stroke or heart attack, dehydration, or hypovolemia or by persons being treated with antihypertensive medications. Patients switched from SSRIs to nefazodone may experience an increase in side effects, possibly because nefazodone does not protect against SSRI withdrawal symptoms. One of its metabolites, mCPP, may intensify these discontinuation symptoms. Patients have survived nefazodone overdoses above 10 g, but deaths have been

reported when it has been combined with alcohol. Nausea, vomiting, and somnolence are the most common signs of toxicity.

Table 21-19
Adverse Reactions Reported with Nefazodone (300–600 mg a day)

Reaction	Patients (%)
Headache	36
Dry mouth	25
Somnolence	25
Nausea	22
Dizziness	17
Constipation	14
Insomnia	11
Weakness	11
Lightheadedness	10
Blurred vision	9
Dyspepsia	9
Infection	8
Confusion	7
Scotomata	7

There are few studies or clinical reports of nefazodone during pregnancy. Nefazodone should, therefore, be used during pregnancy only if the potential benefit to the mother outweighs the potential risks to the fetus. It is not known whether nefazodone is excreted in human breast milk. Therefore, it should be used with caution by lactating mothers. The nefazodone dosage should be lowered in persons with severe hepatic disease, but no adjustment

is necessary for persons with renal disease.

Drug Interactions and Laboratory Interferences. Nefazodone should not be given concomitantly with MAOIs. Also, nefazodone has particular drug–drug interactions with the triazolobenzodiazepines triazolam (Halcion) and alprazolam (Xanax) because of the inhibition of CYP3A4 by nefazodone. Potentially elevated levels of each of these drugs can develop after administration of nefazodone, but the levels of nefazodone are generally not affected. The dose of triazolam should be lowered by 75 percent, and the dose of alprazolam should be lowered by 50 percent, when given concomitantly with nefazodone.

Nefazodone may slow the metabolism of digoxin; therefore, digoxin levels should be monitored carefully in persons taking both medications. Nefazodone also slows the metabolism of haloperidol (Haldol) so that the dosage of haloperidol should be reduced in persons taking both medications. The addition of nefazodone may also exacerbate the adverse effects of lithium carbonate (Eskalith).

There are no known laboratory interferences associated with nefazodone.

Dosage and Clinical Guidelines. Nefazodone is available in 50-, 200-, and 250-mg unscored tablets and 100- and 150-mg scored tablets. The recommended starting dosage of nefazodone is 100 mg twice a day, but 50 mg twice a day may be better tolerated, especially by elderly persons. The dosage should be slowly raised in increments of 100 to 200 mg a day at intervals of no less than 1 week per increase to limit the development of adverse effects. The optimal dosage is 300 to 600 mg daily in two divided doses. However, some studies report that nefazodone is effective when taken once a day, especially at bedtime. Geriatric persons should receive dosages about two-thirds of the usual nongeriatric dosages, with a maximum of 400 mg a day. Similar to other antidepressants, the clinical benefit of nefazodone usually appears after 2 to 4 weeks of treatment. Patients with the premenstrual syndrome are treated with a flexible dosage that averages about 250 mg a day.

Trazodone

Pharmacologic Actions. Trazodone is readily absorbed from the GI tract and reaches peak plasma levels in about 1 hour. It has a half-life of 5 to 9 hours. Trazodone is metabolized in the liver, and 75 percent of its metabolites are excreted in the urine.

Trazodone is a weak inhibitor of serotonin reuptake and a potent antagonist of serotonin 5-HT_{2A} and 5-HT_{2C} receptors. The active metabolite of trazodone is mCPP, which is an agonist at 5-HT_{2C} receptors and has a half-life of 14 hours. mCPP has been associated with migraine, anxiety, and weight loss. The adverse effects of trazodone are partially mediated by α_1-adrenergic receptor antagonism.

Therapeutic Indications

DEPRESSIVE DISORDERS. The main indication for the use of trazodone is MDD. There is a dose–response relationship, with dosages of 250 to 600 mg a day being necessary for trazodone to have therapeutic benefit. Trazodone increases total sleep time, decreases the number and the duration of nighttime awakenings, and decreases the amount of REM sleep. Unlike tricyclic drugs, trazodone does not decrease stage 4 sleep. Trazodone is thus useful for depressed persons with anxiety and insomnia.

INSOMNIA. Trazodone is a first-line agent for the treatment of insomnia because of its marked sedative qualities and favorable effects on sleep architecture (see above) combined with its lack of anticholinergic effects. Trazodone is effective for insomnia caused by depression or the use of drugs. When used as a hypnotic, the usual initial dosage is 25 to 100 mg at bedtime.

ERECTILE DISORDER. Trazodone is associated with an increased risk of priapism. Trazodone can potentiate erections resulting from sexual stimulation. It has thus been used to prolong erectile time and turgidity in some men with erectile disorder. The dosage for this indication is 150 to 200 mg a day. Trazodone-triggered priapism (an erection lasting more than 3 hours with pain) is a medical emergency. The use of trazodone for the treatment of male erectile dysfunction has diminished considerably since the introduction of phosphodiesterase (PDE)-5 agents (see Chapter 16).

OTHER INDICATIONS. Trazodone may be useful in low dosages (50 mg a day) for controlling severe agitation in children with developmental disabilities and elderly persons with dementia. At dosages above 250 mg a day, trazodone reduces the tension and apprehension associated with GAD. It has been used to treat depression in patients with schizophrenia. Trazodone may have a beneficial effect on insomnia and nightmares in persons with PTSD.

Precautions and Adverse Reactions. The most common adverse effects associated with trazodone are sedation, orthostatic hypotension, dizziness, headache, and nausea. Some persons experience dry mouth or gastric irritation. The drug is not associated with anticholinergic adverse effects, such as urinary retention, weight gain, and constipation. A few case reports have noted an association between trazodone and arrhythmias in persons with preexisting premature ventricular contractions or mitral valve prolapse. Neutropenia, usually not of clinical significance, may develop, which should be considered if persons have a fever or sore throat.

Trazodone may cause significant orthostatic hypotension 4 to 6 hours after a dose is taken, especially if taken concurrently with antihypertensive agents or if a large dose is taken without food. Administration of trazodone with food slows absorption and reduces the peak plasma concentration, thus reducing the risk of orthostatic hypotension.

Because suicide attempts often involve the ingestion of sleeping pills, it is essential to be familiar with the symptoms and treatment of trazodone overdose. Patients have survived trazodone overdoses of more than 9 g. Symptoms of overdose include lethargy, vomiting, drowsiness, headache, orthostasis, dizziness, dyspnea, tinnitus, myalgias, tachycardia, incontinence, shivering, and coma. Treatment consists of emesis or lavage and supportive care. Forced diuresis may enhance elimination. Treat hypotension and sedation as appropriate.

Trazodone causes priapism, prolonged erection in the absence of sexual stimuli, in one of every 10,000 men. Trazodone-induced priapism usually appears in the first 4 weeks of treatment but may occur as late as 18 months into treatment. It can appear at any dose. In such cases, trazodone use should be discontinued, and another antidepressant should be used. Painful erections or erections lasting more than 1 hour are warning signs that warrant immediate discontinuation of the drug and medical evaluation. The first step

in the emergency management of priapism is an intracavernosal injection of an α_1-adrenergic agonist pressor agent, such as metaraminol (Aramine) or epinephrine. In about one-third of reported cases, surgical intervention was required. In some cases, permanent impairment of erectile function or impotence resulted.

The use of trazodone is contraindicated in pregnant and nursing women. Trazodone should be used with caution in persons with hepatic and renal diseases.

Drug Interactions. Trazodone potentiates the CNS depressant effects of other centrally acting drugs and alcohol. Concurrent use of trazodone and antihypertensives may cause hypotension. No cases of hypertensive crisis have been reported when trazodone has been used to treat MAOI-associated insomnia. Trazodone can increase levels of digoxin and phenytoin. Trazodone should be used with caution in combination with warfarin. Drugs that inhibit CYP3A4 can increase levels of trazodone's primary metabolite, mCPP, leading to an increase in side effects.

Laboratory Interferences. No known laboratory interferences are associated with the administration of trazodone.

Dosage and Clinical Guidelines. Trazodone is available in 50-, 100-, 150-, and 300-mg tablets. Once-a-day dosing is as effective as divided dosing and reduces daytime sedation. The usual starting dose is 50 mg before sleep. The dosage can be increased in increments of 50 mg every 3 days if sedation or orthostatic hypotension does not become a problem. The therapeutic range for trazodone is 200 to 600 mg a day in divided doses. Some reports indicate that dosages of 400 to 600 mg a day are required for maximal therapeutic effects; other reports indicate that 250 to 400 mg a day is sufficient. The dosage may be titrated up to 300 mg a day; then, the person can be evaluated for the need for further dosage increases based on the presence or the absence of signs of clinical improvement.

TRICYCLICS AND TETRACYCLICS

The observation in 1957 that imipramine (Tofranil) had antidepressant effects

led to the development of a new class of antidepressant compounds, the tricyclics (TCAs). In turn, the finding that imipramine blocked reuptake of norepinephrine led to research into the role of catecholamines in depression. After the introduction of imipramine, several other antidepressant compounds were developed that shared a basic tricyclic structure and had relatively similar effects. Later, other heterocyclic compounds were also marketed that were somewhat similar in structure and that had relatively comparable secondary properties. At one time, amitriptyline (Elavil, Endep) and imipramine were the two most commonly prescribed antidepressants in the United States. However, because of their anticholinergic and antihistaminic side effects, they are rarely used for depression. Nortriptyline (Aventyl, Pamelor) and desipramine (Norpramin, Pertofrane) became preferred. Nortriptyline has the least effect on orthostatic hypotension, and desipramine is the least anticholinergic. Although introduced as antidepressants, the therapeutic indications for these agents have grown to include panic disorder, GAD, PTSD, OCD, and pain syndromes. The introduction of newer antidepressant agents with more selective actions on neurotransmitters or with unique mechanisms of action has sharply reduced the prescribing of TCAs and tetracyclics. The improved safety profiles of the newer drugs, especially when taken in overdose, also contributed to the decline in the use of older drugs. Nevertheless, the TCAs and tetracyclics remain unsurpassed in terms of their antidepressant efficacy. Table 21-20 lists TCA and tetracyclic drugs and their available preparations.

Pharmacologic Actions

The absorption of most TCAs is complete after oral administration, and there is significant metabolism from the first-pass effect. Peak plasma concentrations occur within 2 to 8 hours, and the half-lives of the TCAs vary from 10 to 70 hours; nortriptyline, maprotiline (Ludiomil), and particularly protriptyline (Vivactil) can have longer half-lives. The long half-lives allow all the compounds to be given once daily; 5 to 7 days is needed to reach steady-state plasma concentrations. Imipramine pamoate (Tofranil) is a depot form of the drug for intramuscular (IM) administration; indications for the use of this preparation are limited.

The TCAs undergo hepatic metabolism by the CYP450 enzyme system.

Clinically relevant drug interactions may result from competition for enzyme CYP2D6 among TCAs and quinidine, cimetidine (Tagamet), fluoxetine (Prozac), sertraline (Zoloft), paroxetine (Paxil), phenothiazines, carbamazepine (Tegretol), and the type IC antiarrhythmics propafenone (Rythmol) and flecainide (Tambocor). Concomitant administration of TCAs and these inhibitors may slow down the metabolism and raise the plasma concentrations of TCAs. Additionally, genetic variations in the activity of CYP2D6 may account for up to a 40-fold difference in plasma TCA concentrations in different persons. The dosage of the TCA may need to be adjusted to correct changes in the rate of hepatic TCA metabolism.

Table 21-20
Tricyclic and Tetracyclic Drug Preparations

Drug	Tablets (mg)	Capsules (mg)	Parenteral (mg/mL)	Solution
Imipramine (Tofranil)	10, 25, and 50	75, 100, 125, and 150	12.5	—
Desipramine (Norpramin, Pertofrane)	10, 25, 50, 75, 100, and 150	—	—	—
Trimipramine (Surmontil)	—	25, 50, and 100	—	—
Amitriptyline (Elavil)	10, 25, 50, 75, 100, and 150	—	10	—
Nortriptyline (Aventyl, Pamelor)	—	10, 25, 50, and 75	—	10 mg/5 mL
Protriptyline (Vivactil)	5 and 10	—	—	—
Amoxapine (Asendin)	25, 50, 100, and 150	—	—	—
Doxepin (Sinequan)	—	10, 25, 50, 75, 100, and 150	—	10 mg/mL
Maprotiline (Ludiomil)	25, 50, and 75	—	—	—
Clomipramine (Anafranil)	—	25, 50, and 75	—	—

The TCAs block the transporter site for norepinephrine and serotonin, thus increasing synaptic concentrations of these neurotransmitters. Each drug differs in its affinity for each of these transporters, with clomipramine (Anafranil) being the most serotonin selective and desipramine the most norepinephrine selective of the TCAs. Secondary effects of the TCAs include antagonism at the muscarinic acetylcholine, histamine H_1, and α_1- and α_2-adrenergic receptors. The potency of these effects on other receptors largely determines the side effect profile of each drug. Amoxapine, nortriptyline, desipramine, and maprotiline have the least anticholinergic activity; doxepin has the most antihistaminergic activity. Although they are more likely to cause constipation, sedation, dry mouth, or lightheadedness than the SSRIs, the TCAs are less prone to cause sexual dysfunction, significant long-term

weight gain, and sleep disturbances than the SSRIs. The half-lives and plasma clearance for most TCAs are very similar.

Therapeutic Indications

The indications are similar to those for the SSRIs, which have widely replaced the TCAs. However, the TCAs represent a reasonable alternative for persons who cannot tolerate the adverse effects of the SSRIs.

Major Depressive Disorder. The treatment of a major depressive episode and the prophylactic treatment of MDD are the principal indications for using TCAs. Although the TCAs are effective in the treatment of depression in persons with bipolar I disorder, they are more likely to induce mania, hypomania, or cycling than the newer antidepressants, most notably the SSRIs and bupropion. It is thus not advised that TCAs be routinely used to treat depression associated with bipolar I or bipolar II disorder.

Melancholic features, prior major depressive episodes, and a family history of depressive disorders increase the likelihood of therapeutic response. All of the available TCAs are equally effective in the treatment of depressive disorders. In the case of a person, however, one tricyclic or tetracyclic may be useful, and another one may be ineffective. The treatment of a major depressive episode with psychotic features almost always requires the coadministration of an antipsychotic drug and an antidepressant.

Although it is used worldwide as an antidepressant, clomipramine is only approved in the United States for the treatment of OCD.

Panic Disorder with Agoraphobia. Imipramine is the TCA most studied for panic disorder with agoraphobia, but other TCAs are also useful when taken at the usual antidepressant dosages. Because of the potential initial anxiogenic effects of the TCAs, starting dosages should be small, and the dosage should be titrated upward slowly. Small doses of benzodiazepines may be used initially to deal with this side effect.

Generalized Anxiety Disorder. The FDA approves the use of doxepin for the treatment of anxiety disorders. Some research data show that imipramine may also be useful. Although rarely used anymore, a chlordiazepoxide–amitriptyline combination (Limbitrol) is available for mixed anxiety and

depressive disorders.

Obsessive-Compulsive Disorder. Patients with OCD appear to respond specifically to clomipramine, as well as the SSRIs. Some improvement is usually seen in 2 to 4 weeks, but a further reduction in symptoms may continue for the first 4 to 5 months of treatment. None of the other TCAs appears to be nearly as effective as clomipramine for the treatment of this disorder. Clomipramine may also be a drug of choice for depressed persons with marked obsessive features.

Pain. The TCAs are widely used to treat chronic neuropathic pain and in the prophylaxis of migraine headache. Amitriptyline is the TCA most often used in this role. During the treatment of pain, doses are generally lower than those used in depression; for example, 75 mg of amitriptyline may be sufficient. These effects also appear more rapidly.

Other Disorders. Childhood enuresis is often treated with imipramine. Peptic ulcer disease can be treated with doxepin, which has marked antihistaminergic effects. Other indications for the TCAs are narcolepsy, nightmare disorder, and PTSD. The drugs are sometimes used for the treatment of children and adolescents with ADHD, sleepwalking disorder, separation anxiety disorder, and sleep terror disorder. Clomipramine has also been used to treat premature ejaculation, movement disorders, and compulsive behavior in children with autistic disorders; however, because the TCAs have caused sudden death in several children and adolescents, they should not be used in children.

Precautions and Adverse Reactions

The TCAs are associated with a wide range of problematic side effects and can be lethal when taken in overdose.

Psychiatric Effects. The TCAs can induce a switch to mania or hypomania in susceptible individuals. The TCAs may also exacerbate psychotic disorders in susceptible persons. At high plasma concentrations (levels above 300 ng/mL), the anticholinergic effects of the TCAs can cause confusion or delirium. Patients with dementia are particularly vulnerable to

this development.

Anticholinergic Effects. Anticholinergic effects often limit the tolerable dosage to relatively low ranges. Some persons may develop a tolerance for the anticholinergic effects with continued treatment. Anticholinergic effects include dry mouth, constipation, blurred vision, delirium, and urinary retention. Sugarless gum, candy, or fluoride lozenges can alleviate dry mouth. Bethanechol (Urecholine), 25 to 50 mg three or four times a day, may reduce urinary hesitancy and may be helpful in erectile dysfunction when the drug is taken 30 minutes before sexual intercourse. Anticholinergic drugs can also aggravate narrow-angle glaucoma, and the precipitation of glaucoma requires emergency treatment with a miotic agent. The TCAs should be avoided in persons with narrow-angle glaucoma, and an SSRI should be substituted. Severe anticholinergic effects can lead to CNS anticholinergic syndrome. This syndrome includes symptoms of confusion and delirium, especially if the TCAs are administered with DRAs or anticholinergic drugs. IM or IV physostigmine (Antilirium, Eserine) is used to diagnose and treat anticholinergic delirium.

Cardiac Effects. When administered in their usual therapeutic dosages, the TCAs may cause tachycardia, flattened T waves, prolonged QT intervals, and depressed ST segments in the electrocardiographic (ECG) recording. Imipramine has a quinidine-like effect at therapeutic plasma concentrations and may reduce the number of premature ventricular contractions. Because the drugs prolong conduction time, their use in persons with preexisting conduction defects is contraindicated. In persons with a history of any type of heart disease, the TCAs should be used only after SSRIs or other newer antidepressants have been found ineffective, and if used, they should be introduced at low dosages, with gradual increases in dosage and monitoring of cardiac functions. All of the TCAs can cause tachycardia, which may persist for months and is one of the most common reasons for drug discontinuation, especially in younger persons. At high plasma concentrations, as seen in overdoses, the drugs become arrhythmogenic.

Other Autonomic Effects. Orthostatic hypotension is the most common cardiovascular autonomic adverse effect, and the most common reason TCAs

are discontinued. It can result in falls and injuries in affected persons. Nortriptyline may be the drug least likely to cause this problem. Orthostatic hypotension is treated with avoidance of caffeine, intake of at least 2 L of fluid per day, and addition of salt to the diet unless the person is being treated for hypertension. In persons taking antihypertensive agents, reduction of the dosage may reduce the risk of orthostatic hypotension. Other possible autonomic effects are profuse sweating, palpitations, and increased BP. Although some persons respond to fludrocortisone (Florinef), 0.02 to 0.05 mg twice a day, the drug has potential toxicities. It is preferable to substitute an SSRI than to use a mineralocorticoid such as fludrocortisone. The TCAs' use should be discontinued several days before elective surgery because of the occurrence of hypertensive episodes during surgery in persons receiving TCAs.

Sedation. Sedation is a common effect of the TCAs and may be welcomed if sleeplessness has been a problem. The sedative effect of the TCAs is a result of anticholinergic and antihistaminergic activities. Amitriptyline, trimipramine, and doxepin are the most sedating agents; imipramine, amoxapine, nortriptyline, and maprotiline are less sedating; and desipramine and protriptyline are the least sedating agents.

Neurologic Effects. A fine, rapid tremor may occur. Myoclonic twitches and tremors of the tongue and the upper extremities are common. Rare effects include speech blockage, paresthesia, peroneal palsies, and ataxia.

Amoxapine is unique in causing parkinsonian symptoms, akathisia, and even dyskinesia because of the dopaminergic blocking activity of one of its metabolites. Amoxapine may also cause neuroleptic malignant syndrome in rare cases. Maprotiline may cause seizures when the dosage is increased too quickly or is kept at high levels for too long. Clomipramine and amoxapine may lower the seizure threshold more than other drugs in the class. As a class, however, the TCAs have a relatively low risk for inducing seizures except in persons who are at risk for seizures (e.g., persons with epilepsy and those with brain lesions). Although such persons can still use the TCAs, the initial dosages should be lower than usual, and subsequent dosage increases should be gradual.

Allergic and Hematologic Effects. Exanthematous rashes are seen in 4 to 5 percent of all persons treated with maprotiline. Jaundice is rare. Agranulocytosis, leukocytosis, leukopenia, and eosinophilia are rare complications of TCA treatment. However, a person who has a sore throat or a fever during the first few months of TCA treatment should have a CBC done immediately.

Hepatic Effects. Mild and self-limited increases in serum transaminase concentrations may occur and should be monitored. The TCAs can also produce a fulminant acute hepatitis in 0.1 to 1 percent of persons. This side effect can be life-threatening, and the antidepressant should be discontinued.

Other Adverse Effects. Modest weight gain is typical. Amoxapine exerts a DRA effect and may cause hyperprolactinemia, impotence, galactorrhea, anorgasmia, and ejaculatory disturbances. Other TCAs have also been associated with gynecomastia and amenorrhea. The syndrome of inappropriate secretion of antidiuretic hormone has also been reported with TCAs. Other effects include nausea, vomiting, and hepatitis.

TERATOGENICITY AND PREGNANCY-RELATED RISKS. A definitive link between the tricyclic compounds and tetracyclic compounds and teratogenic effects has not been established, but isolated reports of morphogenesis have been reported. TCAs cross the placenta, and neonatal drug withdrawal can occur. This syndrome includes tachypnea, cyanosis, irritability, and poor sucking reflex. If possible, tricyclic and tetracyclic medications should be discontinued 1 week before delivery. Recently, norepinephrine and serotonin transporters have been identified in the placenta. They appear to play an essential role in the clearance of these amines in the fetus. The understanding of the effects of reuptake inhibitors on these transporters during pregnancy is limited. However, one study compared intelligence and language development in 80 children exposed to TCAs during pregnancy with 84 children exposed to other nonteratogenic agents and found no deleterious effects of the TCAs. The TCAs are excreted in breast milk at concentrations similar to plasma. The actual quantity delivered, however, is small, so drug levels in the infant are usually undetectable or very low. Because the risk of relapse is a serious concern in patients with recurrent depression, and these

risks may be increased during pregnancy or the postpartum period, the risks and benefits of continuing or withdrawing treatment need to be discussed with the patient and weighed carefully.

Precautions. The TCAs may cause a withdrawal syndrome in newborns consisting of tachypnea, cyanosis, irritability, and poor sucking reflex. The drugs do pass into breast milk but at concentrations that are usually undetectable in the infant's plasma. We should use these drugs cautiously in patients with hepatic or renal diseases. The TCAs should not be administered during a course of ECT, primarily because of the risk of serious adverse cardiac effects.

Drug Interactions

Monoamine Oxidase Inhibitors. The TCAs should not be taken within 14 days of administration of an MAOI.

Antihypertensives. The TCAs block the therapeutic effects of antihypertensive medication. The TCAs may block the antihypertensive effects of the β-adrenergic receptor antagonists (e.g., propranolol [Inderal] and clonidine [Catapres]). The coadministration of a TCA and α-methyldopa (Aldomet) may cause behavioral agitation.

Antiarrhythmic Drugs. The antiarrhythmic properties of TCAs can be additive to those of quinidine, an effect that is further exacerbated by the inhibition of TCA metabolism by quinidine.

Dopamine Receptor Antagonists. Concurrent administration of TCAs and DRAs increases the plasma concentrations of both drugs. Desipramine plasma concentrations may increase twofold during concurrent administration with perphenazine (Trilafon). The DRAs also add to the anticholinergic and sedative effects of the TCAs. Concomitant use of SDAs also increases those effects.

Central Nervous System Depressants. Opioids, alcohol, anxiolytics, hypnotics, and over-the-counter cold medications have additive effects by causing CNS depression when coadministered with TCAs. Persons should be

advised to avoid driving or using dangerous equipment if sedated by TCAs.

Sympathomimetics. Tricyclic drug use with sympathomimetic drugs may cause serious cardiovascular effects.

Oral Contraceptives. Birth control pills may decrease TCA plasma concentrations through the induction of hepatic enzymes.

Other Drug Interactions. Nicotine may reduce TCA concentrations. Plasma concentrations may also be lowered by ascorbic acid, ammonium chloride, barbiturates, cigarette smoking, carbamazepine, chloral hydrate, lithium (Eskalith), and primidone (Mysoline). TCA plasma concentrations may be increased by concurrent use of acetazolamide (Diamox), sodium bicarbonate, acetylsalicylic acid, cimetidine, thiazide diuretics, fluoxetine, paroxetine, and fluvoxamine (Luvox). Plasma concentrations of the TCAs may rise three- to fourfold when administered concurrently with fluoxetine, fluvoxamine, and paroxetine.

Laboratory Interferences

The tricyclic compounds are present at low concentrations and are not likely to interfere with other laboratory assays. They may interfere with the determination of conventional neuroleptic blood concentrations because of their structural similarity and the low concentrations of some neuroleptics.

Dosage and Clinical Guidelines

Persons who intend to take TCAs should undergo routine physical and laboratory examinations, including a CBC, a WBC count with differential, and serum electrolytes with liver function tests. An ECG should be obtained for all persons, especially women older than 40 years of age and men older than 30 years of age. The TCAs are contraindicated in persons with a QT_C greater than 450 milliseconds. The initial dose should be small and should be raised gradually. Because of the availability of highly effective alternatives to TCAs, a newer agent should be used if there is any medical condition that may interact adversely with the TCAs.

Elderly persons and children are more sensitive to TCA adverse effects

than are young adults. In children, the ECG should be regularly monitored during the use of a TCA.

The available preparations of TCAs are presented in Table 21-20. The dosages and therapeutic blood levels for the TCAs vary among the drugs (Table 21-21). Except for protriptyline, all of the TCAs should be started at 25 mg a day and increased as tolerated. Divided doses at first reduce the severity of the adverse effects, although most of the dosage should be given at night to help induce sleep if a sedating drug such as amitriptyline is used. Eventually, the entire daily dose can be given at bedtime. A common clinical mistake is to stop increasing the dosage when the person is tolerating the drug but taking less than the maximum therapeutic dose and does not show clinical improvement. The clinician should routinely assess the person's pulse and orthostatic changes in BP while the dosage is being increased.

Nortriptyline use should be started at 25 mg a day. Most patients need only 75 mg a day to achieve a blood level of 100 mg/nL. However, the dosage may be raised to 150 mg a day if needed. Amoxapine use should be started at 150 mg a day and raised to 400 mg a day. Protriptyline use should be started at 15 mg a day and raised to 60 mg a day. Maprotiline has been associated with an increased incidence of seizures. This risk is most significant if the dosage is raised too quickly or is maintained at too high a level. Maprotiline use should be started at 25 mg a day and increased over 4 weeks to 225 mg a day. It should be kept at that level for only 6 weeks and then be reduced to 175 to 200 mg a day.

Persons with chronic pain may be particularly sensitive to adverse effects when TCA use is started. Therefore, treatment should begin with low dosages that are raised in small increments. However, persons with chronic pain may experience relief on long-term low-dosage therapy, such as amitriptyline or nortriptyline at 10 to 75 mg a day.

Table 21-21
General Information for the Tricyclic and Tetracyclic Antidepressants

Generic Name	Trade Name	Usual Adult Dosage Range (mg/day)	Therapeutic Plasma Concentrations (µg/mL)

Imipramine	Tofranil	150–300	150–300[a]
Desipramine	Norpramin, Pertofrane	150–300	150–300[a]
Trimipramine	Surmontil	150–300	150–300
Amitriptyline	Elavil, Endep	150–300	100–250[b]
Nortriptyline	Pamelor, Aventyl	50–150	50–150[a] (maximum)
Protriptyline	Vivactil	15–60	75–250
Amoxapine	Asendin	150–400	200–500[c]
Doxepin	Adapin, Sinequan	150–300	100–250[a]
Maprotiline	Ludiomil	150–230	150–300[a]
Clomipramine	Anafranil	130–250	50 to 250[c]

[a]Exact range may vary among laboratories.

[b]Includes parent compound and desmethyl metabolite.

[c]Estimated from limited studies.

The TCAs should be avoided in children except as a last resort. Dosing guidelines in children for imipramine include initiation at 1.5 mg/kg a day. The dosage can be titrated to no more than 5 mg/kg a day. In enuresis, the dosage is usually 50 to 100 mg a day, taken at bedtime. Clomipramine use can be initiated at 50 mg a day and increased to no more than 3 mg/kg per day or 200 mg a day.

When TCA treatment is discontinued, the dosage should first be decreased to three-fourths the maximal dosage for a month. At that time, if no symptoms are present, drug use can be tapered by 25 mg (5 mg for protriptyline) every 4 to 7 days. Slow tapering avoids a cholinergic rebound syndrome consisting of nausea, upset stomach, sweating, headache, neck pain, and vomiting. This syndrome can be treated by reinstituting a small dosage of the drug and tapering more slowly than before. Several case reports note the appearance of rebound mania or hypomania after the abrupt

discontinuation of TCA use.

Plasma Concentrations and Therapeutic Drug Monitoring. Clinical determinations of plasma concentrations should be conducted after 5 to 7 days on the same dosage of medication and 8 to 12 hours after the last dose. Because of variations in absorption and metabolism, there may be a 30- to 50-fold difference in the plasma concentrations in persons given the same dosage of a TCA. Nortriptyline is unique in its association with a therapeutic window—that is, plasma concentrations below 50 ng/mL or above 150 ng/mL may reduce its efficacy.

Plasma concentrations may be useful in confirming compliance, assessing reasons for drug failures, and documenting effective plasma concentrations for future treatment. Clinicians should always treat the person and not the plasma concentration. Some persons have adequate clinical responses with seemingly subtherapeutic plasma concentrations, and other persons only respond at supratherapeutic plasma concentrations without experiencing adverse effects. The latter situation, however, should alert the clinician to monitor the person's condition with, for example, serial ECG recordings.

Overdose Attempts. Overdose attempts with TCAs are severe and can often be fatal. Prescriptions for these drugs should be nonrefillable and for no longer than 1 week at a time for patients at risk for suicide. Amoxapine may be more likely than the other TCAs to result in death when taken in overdose. The newer antidepressants are safer in overdose.

Symptoms of overdose include agitation, delirium, convulsions, hyperactive deep tendon reflexes, bowel and bladder paralysis, dysregulation of BP and temperature, and mydriasis. The patient then progresses to coma and perhaps respiratory depression. Cardiac arrhythmias may not respond to treatment. Because of the long half-lives of TCAs, the patients are at risk of cardiac arrhythmias for 3 to 4 days after the overdose, so they should be monitored in intensive care medical settings.

MONOAMINE OXIDASE INHIBITORS

Introduced in the late 1950s, MAOIs were the first class of approved antidepressant drugs. The first of these drugs, isoniazid, was intended to be

used as a treatment for tuberculosis, but its antidepressant properties were discovered by chance when some treated patients experienced elevation of mood during treatment. Despite their effectiveness, prescription of MAOIs as first-line agents has always been limited by concern about the development of potentially lethal hypertension and the consequent need for a restrictive diet. The use of MAOIs declined further after the introduction of the SSRIs and other new agents. They are now mainly relegated to use in treatment-resistant cases. Thus, the second-line status of MAOIs has less to do with considerations of efficacy than with safety concerns. The currently available MAOIs include phenelzine (Nardil), isocarboxazid (Marplan), tranylcypromine (Parnate), rasagiline (Azilect), moclobemide (Manerix), and selegiline (Eldepryl).

Two subsequent advances in the field of antidepressant MAOIs involve the introduction of a selective reversible inhibitor of MAO_A (RIMA), moclobemide (Manerix), in the early 1990s into most countries except the United States, and in 2005, the introduction of a transdermal delivery form of selegiline (Emsam) in the United States that is used for the treatment of parkinsonism. Other RIMA agents, including brofaromine (Consonar) and befloxatone, have not been submitted for registration despite favorable outcomes in clinical trials.

Pharmacologic Actions

Phenelzine, tranylcypromine, and isocarboxazid are readily absorbed after oral administration and reach peak plasma concentrations within 2 hours. Whereas their plasma half-lives are in the range of 2 to 3 hours, their tissue half-lives are considerably longer. Because they irreversibly inactivate MAOs, the therapeutic effect of a single dose of irreversible MAOIs may persist for as long as 2 weeks. The RIMA moclobemide is rapidly absorbed and has a half-life of 0.5 to 3.5 hours. Because it is a reversible inhibitor, moclobemide has a much briefer clinical effect after a single dose than do irreversible MAOIs.

The MAO enzymes are found on the outer membranes of mitochondria, where they degrade cytoplasmic and extraneuronal monoamine neurotransmitters such as norepinephrine, serotonin, dopamine, epinephrine, and tyramine. MAOIs act in the CNS, the sympathetic nervous system, the

liver, and the GI tract. There are two types of MAOs, MAO_A and MAO_B. MAO_A primarily metabolizes norepinephrine, serotonin, and epinephrine; both MAO_A and MAO_B metabolize dopamine and tyramine.

The structures of phenelzine and tranylcypromine are similar to those of amphetamine and have similar pharmacologic effects in that they increase the release of dopamine and norepinephrine with attendant stimulant effects on the brain.

Therapeutic Indications

MAOIs are used for the treatment of depression. Some research indicates that phenelzine is more effective than TCAs in depressed patients with mood reactivity, extreme sensitivity to interpersonal loss or rejection, prominent anergia, hyperphagia, and hypersomnia—a constellation of symptoms conceptualized as atypical depression. Evidence also suggests that MAOIs are more effective than TCAs as a treatment for bipolar depression.

Patients with panic disorder and social phobia respond well to MAOIs. MAOIs have also been used to treat bulimia nervosa, PTSD, anginal pain, atypical facial pain, migraine, ADHD, idiopathic orthostatic hypotension, and depression associated with traumatic brain injury.

Precautions and Adverse Reactions

The most frequent adverse effects of MAOIs are orthostatic hypotension, insomnia, weight gain, edema, and sexual dysfunction. Orthostatic hypotension can lead to dizziness and falls. Thus, cautious upward tapering of the dosage should be used to determine the maximum tolerable dosage. Treatment for orthostatic hypotension includes avoidance of caffeine; intake of 2 L of fluid per day; addition of dietary salt or adjustment of antihypertensive drugs (if applicable); support stockings; and in severe cases, treatment with fludrocortisone (Florinef), a mineralocorticoid, 0.1 to 0.2 mg a day. Orthostatic hypotension associated with tranylcypromine use can usually be relieved by dividing the daily dosage.

Insomnia can be treated by dividing the dose, not giving the medication after dinner, and using a benzodiazepine hypnotic if necessary. Weight gain, edema, and sexual dysfunction often do not respond to any treatment and may warrant switching to another agent. When switching from one MAOI to

another, the clinician should taper and stop the use of the first drug for 10 to 14 days before beginning the use of the second drug.

Paresthesias, myoclonus, and muscle pains are occasionally seen in persons treated with MAOIs. Paresthesias may be secondary to MAOI-induced pyridoxine deficiency, which may respond to supplementation with pyridoxine, 50 to 150 mg orally each day. Occasionally, persons complain of feeling drunk or confused, perhaps indicating that the dosage should be reduced and then increased gradually. Reports that the hydrazine MAOIs are associated with hepatotoxic effects are relatively uncommon. MAOIs are less cardiotoxic and less epileptogenic than are the tricyclic and tetracyclic drugs.

The most common adverse effects of the RIMA moclobemide are dizziness, nausea, and insomnia or sleep disturbance. RIMAs cause fewer GI adverse effects than do SSRIs. Moclobemide does not have adverse anticholinergic or cardiovascular effects, and it has not been reported to interfere with sexual function.

MAOIs should be used with caution by persons with renal disease, cardiovascular disease, or hyperthyroidism. MAOIs may alter the dosage of a hypoglycemic agent required by persons with diabetes. MAOIs have been significantly associated with the induction of mania in persons in the depressed phase of bipolar I disorder and triggering a psychotic decompensation in persons with schizophrenia. MAOIs are contraindicated during pregnancy, although data on their teratogenic risk are minimal. Nursing women should not take MAOIs because the drugs can pass into breast milk.

Tyramine-Induced Hypertensive Crisis. The most worrisome side effect of MAOIs is the tyramine-induced hypertensive crisis. The amino acid tyramine is usually transformed via GI metabolism. However, MAOIs inactivate GI metabolism of dietary tyramine, thus allowing intact tyramine to enter the circulation. A hypertensive crisis may subsequently occur as a result of a powerful pressor effect of the amino acid. Tyramine-containing foods should be avoided for 2 weeks after the last dose of an irreversible MAOI to allow the resynthesis of adequate concentrations of MAO enzymes.

Accordingly, foods rich in tyramine (Table 21-22) or other sympathomimetic amines, such as ephedrine, pseudoephedrine (Sudafed), or dextromethorphan (Trocal), should be avoided by persons who are taking

irreversible MAOIs. Patients should be advised to continue the dietary restrictions for 2 weeks after they stop MAOI treatment to allow the body to resynthesize the enzyme. Bee stings may cause a hypertensive crisis. In addition to severe hypertension, other symptoms may include headache, stiff neck, diaphoresis, nausea, and vomiting. A patient with these symptoms should seek immediate medical treatment.

Table 21-22
Tyramine-Rich Foods to Be Avoided in Planning Monoamine Oxidase Inhibitor Diets

High Tyramine Content[a] (≥2 mg of tyramine a serving)
- Cheese: English Stilton, blue cheese, white (3 yr old), extra old, old cheddar, Danish blue, mozzarella, cheese snack spreads
- Fish, cured meats, sausage; pâtés and organs, salami, mortadella, air-dried sausage
- Alcoholic beverages[b]: Liqueurs and concentrated after-dinner drinks
- Marmite (concentrated yeast extract)
- Sauerkraut (Krakus)

Moderate Tyramine Content[a] (0.5–1.99 mg of tyramine a serving)
- Cheese: Swiss Gruyere, muenster, feta, parmesan, gorgonzola, blue cheese dressing, Black Diamond
- Fish, cured meats, sausage, pâtés and organs: Chicken liver (5 days old); bologna; aged sausage, smoked meat; salmon mousse
- Alcoholic beverages: Beer and ale (12 oz per bottle)—Amstel, Export Draft, Blue Light, Guinness Extra Stout, Old Vienna, Canadian, Miller Light, Export, Heineken, Blue Wines (per 4-oz glass)—Rioja (red wine)

Low Tyramine Content[a] (0.01 to >0.49 mg of tyramine a serving)
- Cheese: Brie, Camembert, Cambozola with or without rind
- Fish, cured meat, sausage, organs, and pâtés; pickled herring; smoked fish; kielbasa sausage; chicken liver; liverwurst (<2 days old)
- Alcoholic beverages: Red wines, sherry, scotch[c]

Others: Banana or avocado (ripe or not), banana peel

[a]Any food left out to age or spoil can spontaneously develop tyramine through fermentation.

[b]Alcohol can produce profound orthostasis interacting with monoamine oxidase inhibitors (MAOIs) but cannot produce direct hypotensive reactions.

[c]White wines, gin, and vodka have no tyramine content.

Table by Jonathan M. Himmelhoch, M.D.

An MAOI-induced hypertensive crisis should be treated with α-adrenergic antagonists—for example, phentolamine (Regitine) or chlorpromazine (Thorazine). These drugs lower BP within 5 minutes. IV furosemide (Lasix) can be used to reduce fluid load, and a β-adrenergic receptor antagonist can control tachycardia. A sublingual 10-mg dose of nifedipine (Procardia) can be given and repeated after 20 minutes. Persons with thyrotoxicosis or pheochromocytoma should not use MAOIs.

The risk of tyramine-induced hypertensive crises is relatively low for persons who are taking RIMAs, such as moclobemide and befloxatone. These drugs have relatively little inhibitory activity for MAO_B, and because they are reversible, regular activity of existing MAO_A returns within 16 to 48 hours of the last dose of a RIMA. Therefore, the dietary restrictions are less stringent for RIMAs, applying only to foods containing high concentrations of tyramine, which need to be avoided for 3 days after the last dose of a RIMA. A reasonable dietary recommendation for persons taking RIMAs is to avoid eating tyramine-containing foods 1 hour before and 2 hours after taking a RIMA.

Spontaneous, nontyramine-induced hypertensive crisis is a rare occurrence, usually shortly after the first exposure of an MAOI. Persons experiencing such a crisis should avoid MAOIs altogether.

Withdrawal. Abrupt cessation of regular doses of MAOIs may cause a self-limited discontinuation syndrome consisting of arousal, mood disturbances, and somatic symptoms. Dosages should be gradually tapered over several weeks to avoid these symptoms.

Overdose. It often takes 1 to 6 hours after an overdose for the toxic symptoms to occur. MAOI overdose is characterized by agitation that can progress to coma with hyperthermia, hypertension, tachypnea, tachycardia,

dilated pupils, and hyperactive deep tendon reflexes. Involuntary movements may be present, particularly in the face and the jaw. Acidification of the urine markedly hastens the excretion of MAOIs, and dialysis can be of some use. Phentolamine or chlorpromazine may be useful if hypertension is a problem. Moclobemide alone in overdosage causes relatively mild and reversible symptoms.

Drug Interactions

The significant drug–drug interactions involving MAOIs are listed in Table 21-23. Most antidepressants, as well as precursor agents, should be avoided. Persons should be instructed to tell any other physicians or dentists who are treating them that they are taking an MAOI. MAOIs may potentiate the action of CNS depressants, including alcohol and barbiturates. MAOIs should not be coadministered with serotonergic drugs, such as SSRIs and clomipramine (Anafranil), because this combination can trigger serotonin syndrome. The use of lithium or tryptophan with an irreversible MAOI may also induce serotonin syndrome. Initial symptoms of serotonin syndrome can include tremor, hypertonicity, myoclonus, and autonomic signs, which can then progress to hallucinosis, hyperthermia, and even death. Fatal reactions had occurred when MAOIs were combined with meperidine (Demerol) or fentanyl (Sublimaze).

Table 21-23
Drugs to Be Avoided during Monoamine Oxidase Inhibitor Treatment (Partial Listing)

Never Use

- Antiasthmatics
- Antihypertensives (methyldopa, guanethidine, reserpine)
- Buspirone
- Levodopa
- Opioids (especially meperidine, dextromethorphan, propoxyphene, tramadol; morphine or codeine may be less dangerous)
- Cold, allergy, or sinus medications containing dextromethorphan

or sympathomimetics
SSRIs, clomipramine, venlafaxine, sibutramine
Sympathomimetics (amphetamines, cocaine, methylphenidate, dopamine, epinephrine, norepinephrine, isoproterenol, ephedrine, pseudoephedrine, phenylpropanolamine)
L-Tryptophan
Use Carefully
Anticholinergics
Antihistamines
Disulfiram
Bromocriptine
Hydralazine
Sedative-hypnotics
Terpin hydrate with codeine
Tricyclics and tetracyclics (avoid clomipramine)

SSRI, selective serotonin reuptake inhibitor.

When switching from an irreversible MAOI to any other type of antidepressant drug, persons should wait at least 14 days after the last dose of the MAOI before beginning the use of the next drug to allow replenishment of the body's MAOs. When switching from an antidepressant to an irreversible MAOI, persons should wait 10 to 14 days (or 5 weeks for fluoxetine [Prozac]) before starting the use of the MAOI to avoid drug–drug interactions. In contrast, MAO activity recovers completely 24 to 48 hours after the last dose of a RIMA.

The effects of the MAOIs on hepatic enzymes are poorly studied. Tranylcypromine inhibits CYP2C19. Moclobemide inhibits CYP2D6, CYP2C19, and CYP1A2 and is a substrate for 2C19.

Cimetidine (Tagamet) and fluoxetine significantly reduce the elimination of moclobemide. Modest doses of fluoxetine and moclobemide administered concurrently may be well tolerated, with no significant pharmacodynamic or pharmacokinetic interactions.

Laboratory Interferences

MAOIs may lower blood glucose concentrations. MAOIs artificially raise

urinary metanephrine concentrations and may cause a false-positive test result for pheochromocytoma or neuroblastoma. MAOIs have been reported to be associated with a minimal false elevation in thyroid function test results.

Dosage and Clinical Guidelines

There is no definitive rationale for choosing one irreversible MAOI over another. Table 21-24 lists MAOI preparations and typical dosages. Phenelzine use should begin with a test dose of 15 mg on the first day. The dosage can be increased to 15 mg three times daily during the first week and increased by 15 mg a day each week after that until the dosage of 90 mg a day, in divided doses, is reached by the end of the fourth week. Tranylcypromine and isocarboxazid use should begin with a test dosage of 10 mg and may be increased to 10 mg three times daily by the end of the first week. Many clinicians and researchers have recommended upper limits of 50 mg a day for isocarboxazid and 40 mg a day for tranylcypromine. Administration of tranylcypromine in multiple small daily doses may reduce its hypotensive effects.

Table 21-24
Typical Dosage Forms and Recommended Dosages for Currently Available Monoamine Oxidase Inhibitors

Drug	Usual Dose (mg/day)	Maximum Dose (mg/day)	Dosage (Oral) Formulation
Isocarboxazid (Marplan)	20–40	60	10-mg tablets
Phenelzine (Nardil)	30–60	90	15-mg tablets
Tranylcypromine (Parnate)	20–60	60	10-mg tablets
Rasagiline	0.5–1.0	1.0	0.5- or 1.0-mg tablets
Selegiline	10	30	5-mg tablets

(Eldepryl)			
Moclobemide (Manerix)	300–600	600	100- or 150-mg tablets

Even though coadministration of MAOIs with TCAs, SSRIs, or lithium is generally contraindicated, these combinations have been used successfully and safely to treat patients with refractory depression. However, they should be used with extreme caution.

Hepatic transaminase serum concentrations should be monitored periodically because of the potential for hepatotoxicity, especially with phenelzine and isocarboxazid. Elderly persons may be more sensitive to MAOI adverse effects than are younger adults. MAO activity increases with age, so MAOI dosages for elderly persons are the same as those required for younger adults. We know little about using MAOIs in children.

Studies have suggested that transdermal selegiline has antidepressant properties. Although selegiline is a type B inhibitor at low doses, it becomes less selective as the dose is increased.

THYROID HORMONES

Thyroid hormones—levothyroxine (Synthroid, Levothroid, Levoxine) and liothyronine (Cytomel)—are used in psychiatry either alone or as an augmentation to treat persons with depression or rapid-cycling bipolar I disorder. They can convert an antidepressant-nonresponsive person into an antidepressant-responsive person. Thyroid hormones are also used as replacement therapy for persons treated with lithium (Eskalith) who have developed a hypothyroid state. Successful use of thyroid hormone as an intervention for treatment-resistant patients was first reported in the early 1970s. Study results since then have been mixed; however, most show that patients taking triiodothyronine (T_3) are twice as likely to respond to antidepressant treatment versus placebo. These studies have found that augmentation with T_3 is significant with TCAs and SSRIs. Nevertheless, many endocrinologists object to the use of thyroid hormones as antidepressant augmentation agents, citing such risks as osteoporosis and cardiac arrhythmias.

Pharmacologic Actions

Thyroid hormones are administered orally, and their absorption from the GI tract is variable. Absorption is increased if the drug is administered on an empty stomach. Thyroxine (T_4) crosses the blood–brain barrier and diffuses into neurons, where it is converted into T_3, which is the physiologically active form. The half-life of T_4 is 6 to 7 days, and that of T_3 is 1 to 2 days.

The mechanism of action for thyroid hormone effects on antidepressant efficacy is unknown. Thyroid hormone binds to intracellular receptors that regulate the transcription of a wide range of genes, including several receptors for neurotransmitters.

Therapeutic Indications

The primary indication for thyroid hormones in psychiatry is as an adjuvant to antidepressants. There is no clear correlation between the laboratory measures of thyroid function and the response to thyroid hormone supplementation of antidepressants. If a patient has not responded to a 6-week course of antidepressants at appropriate dosages, adjuvant therapy with either lithium or a thyroid hormone is an alternative. Most clinicians use adjuvant lithium before trying a thyroid hormone. Several controlled trials have indicated that liothyronine use converts about 50 percent of antidepressant nonresponders to responders.

The dosage of liothyronine is 25 or 50 µg a day added to the patient's antidepressant regimen. Liothyronine has been used primarily as an adjuvant for tricyclic drugs; however, evidence suggests that liothyronine augments the effects of all of the antidepressant drugs.

Thyroid hormones have not been shown to cause particular problems in pediatric or geriatric patients; however, the hormones should be used with caution in elderly persons who may have occult heart disease.

Precautions and Adverse Reactions

At the dosages usually used for augmentation—25 to 50 µg a day—adverse effects occur infrequently. The most common adverse effects associated with thyroid hormones are transient headache, weight loss, palpitations, nervousness, diarrhea, abdominal cramps, sweating, tachycardia, increased

BP, tremors, and insomnia. Osteoporosis may also occur with long-term treatment, but this has not been found in studies involving liothyronine augmentation. Overdoses of thyroid hormones can lead to cardiac failure and death.

Patients with cardiac disease, angina, or hypertension should not take thyroid hormones. The hormones are contraindicated in thyrotoxicosis and uncorrected adrenal insufficiency and persons with acute myocardial infarctions. Thyroid hormones can be administered safely to pregnant women, provided that laboratory thyroid indexes are monitored. Thyroid hormones are minimally excreted in breast milk and have not been shown to cause problems in nursing babies.

Drug Interactions

Thyroid hormones can potentiate the effects of warfarin (Coumadin) and other anticoagulants by increasing the catabolism of clotting factors. They may increase the insulin requirement for diabetic persons and the digitalis requirement for persons with cardiac disease. We should not coadminister with sympathomimetics, ketamine (Ketalar), or maprotiline (Ludiomil) because of the risk of cardiac decompensation. Administration of SSRIs, tricyclic and tetracyclic drugs, lithium, or carbamazepine (Tegretol) can mildly lower serum T_4 and raise serum thyrotropin concentrations in euthyroid persons or persons taking thyroid replacements. This interaction warrants close serum monitoring and may require an increase in the dosage or initiation of thyroid hormone supplementation.

Laboratory Interferences

Levothyroxine has not been reported to interfere with any laboratory test other than thyroid function indexes. Liothyronine, however, suppresses the release of endogenous T_4, thereby lowering the result of any thyroid function test that depends on the measure of T_4.

Thyroid Function Tests

Several thyroid function tests are available, including tests for T_4 by competitive protein binding (T_4 [D]) and by radioimmunoassay (T_4 RIA)

involving a specific antigen–antibody reaction. More than 90 percent of T_4 is bound to serum protein and is responsible for thyroid-stimulating hormone (TSH) secretion and cellular metabolism. Other thyroid measures include the free T_4 index (FT_4I), T_3 uptake, and total serum T_3 measured by radioimmunoassay (T_3 RIA). Those tests are used to rule out hypothyroidism, which can be associated with symptoms of depression. In some studies, up to 10 percent of patients complaining of depression and associated fatigue had an incipient hypothyroid disease. Lithium can cause hypothyroidism and, more rarely, hyperthyroidism. Neonatal hypothyroidism results in intellectual disability and is preventable if the diagnosis is made at birth.

Thyrotropin-Releasing Hormone Stimulation Test. The thyrotropin-releasing hormone (TRH) stimulation test is indicated for patients who have marginally abnormal thyroid test results with suspected subclinical hypothyroidism, which may account for clinical depression. It is also used in patients with possible lithium-induced hypothyroidism. The procedure entails an intravenous injection of 500 mg of protirelin (TRH), which produces a sharp increase in serum TSH levels are measured at 15, 30, 60, and 90 minutes. An increase in serum TSH of 5 to 25 mIU/mL above the baseline is normal. An increase of less than 7 mIU/mL is considered a blunted response, which may correlate with a diagnosis of depression. Eight percent of all patients with depression have some thyroid illness.

Dosage and Clinical Guidelines

Liothyronine is available in 5-, 25-, and 50-µg tablets. Levothyroxine is available in 12.5-, 25-, 50-, 75-, 88-, 100-, 112-, 125-, 150-, 175-, 200-, and 300-µg tablets; it is also available in a 200 and 500 µg parenteral form. The dosage of liothyronine is 25 or 50 µg a day added to the person's antidepressant regimen. Liothyronine has been used as an adjuvant for all of the available antidepressant drugs. An adequate trial of liothyronine supplementation should last 2 to 3 weeks. If liothyronine supplementation is successful, it should be continued for 2 months and then tapered off at a rate of 12.5 µg a day every 3 to 7 days.

NOVEL AGENTS

Several agents with novel mechanisms are currently approved for use. They are usually given in specialized centers, and clinicians should only administer after special training to manage their significant safety profile.

NMDA Receptor Antagonists

Ketamine, an anesthetic agent, is used in specialized centers for depression. It has a unique action, as after a single low dose, much lower than the usual anesthetic dose, it can produce rapid relief from depression. This effect often occurs within 4 hours of IV administration. The effects persist for several weeks, but then without additional intervention, the depression often relapses. The drug has several significant side effects, including its general anesthetic effect as well as its psychotomimetic effect. Most experts consider it safe at lower doses; however, the clinical team should be ready to provide medical treatment should the drug have a profound effect on a patient's breathing or cause significant bradycardia.

Ketamine's enantiomer, esketamine (Ketanest), was approved by the FDA for the treatment of depression in adults in 2019. It has the advantage over ketamine, in that in addition to an injectable form, it is available as a nasal spray. Esketamine's mechanism of action is similar to ketamine's, although not identical; for example, both are noncompetitive NMDA receptor antagonist and inhibit dopamine transporters. However, esketamine does not act on the sigma receptors, which may account for part of ketamine's antidepressant effect. This lack of effect on sigma receptors is thought to reduce the psychotomimetic properties of the drug. It must be provided in a clinical setting that has the staff and facilities to observe the patient for at least 2 hours following administration. The main side effects are sedation, difficulties with vision and speaking, and cognitive effects, including confusion, dissociation, and potentially delirium. It may also cause anxiety and increased BP in some patients.

$GABA_A$ Allosteric Modulators

Brexanolone, also called allopregnanolone, was approved in the United States in 2019 under the priority review process as a breakthrough therapy for the treatment of postpartum depression. It is a neurosteroid which positively modulates the $GABA_A$ receptor. It is also a negative allosteric modulator of

the nicotinic acetylcholine receptor and may have action on serotonin HT_3 as well. The mechanism of its antidepressant effect is not clear, as other positive allosteric modulators of $GABA_A$, such as benzodiazepines, do not have a significant antidepressant effect. However, like ketamine, it provides a rapid response in patients who respond to the drug, usually within 2 to 3 days. We know little about the long term efficacy of the drug.

The drug is marketed under the brand name Zulresso and is a Schedule IV controlled substance. It is only available through a national registry and has several other drawbacks limiting its widespread acceptance. One is its long administration time, as the drug must be given by continuous IV infusion over 60 hours, during which the dose is slowly increased. This extended hospitalization is to prevent excess sedation or syncope.

Perhaps the most significant drawback of the medication is its cost. Currently, the drug costs about $34,000 for a single dose, as well as the price of remaining in a medical facility for 60 hours, and is not currently covered by most insurance companies.

21.3 Mood Stabilizers

LITHIUM

The effectiveness of lithium for mania and the prophylactic treatment of manic–depressive disorder was established in the early 1950s as a result of research done by John F.J. Cade, an Australian psychiatrist. Concerns about toxicity limited initial acceptance of lithium use in the United States, but its use increased gradually in the late 1960s. It was not until 1970 that the FDA approved its labeling for the treatment of mania. The only other approved FDA indication came in 1974 when it was accepted as maintenance therapy in patients with a history of mania. For several decades, lithium was the only drug approved for both acute and maintenance treatment. It is also used as an adjunctive medication in the treatment of MDD.

Lithium (Li), a monovalent ion, is a member of the group IA alkali metals on the periodic table, a group that also includes sodium, potassium, rubidium, cesium, and francium. Lithium exists in nature as both ^{6}Li (7.42 percent) and

^{7}Li (92.58 percent). The latter isotope allows the imaging of lithium by magnetic resonance spectroscopy. Some 300 mg of lithium is contained in 1,597 mg of lithium carbonate (Li_2CO_3). Most lithium used in the United States is obtained from dry lake mining in Chile and Argentina.

Pharmacologic Actions

Lithium is rapidly and completely absorbed after oral administration, with peak serum concentrations occurring in 1 to 1.5 hours with standard preparations and in 4 to 4.5 hours with slow-release and controlled-release preparations. Lithium does not bind to plasma proteins, is not metabolized, and is excreted through the kidneys. The plasma half-life is initially 1.3 days and is 2.4 days after administration for more than 1 year. The blood–brain barrier permits only the slow passage of lithium, which is why a single overdose does not necessarily cause toxicity and why long-term lithium intoxication is slow to resolve. The elimination half-life of lithium is 18 to 24 hours in young adults but is shorter in children and more prolonged in elderly persons. Renal clearance of lithium is decreased with renal insufficiency. Equilibrium is reached after 5 to 7 days of regular intake. Obesity is associated with higher rates of lithium clearance. The excretion of lithium is complex during pregnancy; excretion increases during pregnancy but decreases after delivery. Lithium is excreted in breast milk and insignificant amounts in the feces and sweat. Thyroid and renal concentrations of lithium are higher than serum levels.

An explanation for the mood-stabilizing effects of lithium remains elusive. Theories include alterations of ion transport and effects on neurotransmitters and neuropeptides, signal transduction pathways, and second messenger systems.

Therapeutic Indications

Bipolar I Disorder

MANIC EPISODES. Lithium controls acute mania and prevents relapse in about 80 percent of persons with bipolar I disorder and in a somewhat smaller percentage of persons with mixed (mania and depression) episodes, rapid-cycling bipolar disorder, or mood changes in encephalopathy. Lithium has a

relatively slow onset of action when used and exerts its antimanic effects over 1 to 3 weeks. Thus, a benzodiazepine, DRA, SDA, or valproic acid is usually administered for the first few weeks. Patients with mixed or dysphoric mania, rapid cycling, comorbid substance abuse, or organicity respond less well to lithium than those with classic mania.

BIPOLAR DEPRESSION. Lithium is effective in the treatment of depression associated with bipolar I disorder, as well as in the role of add-on therapy for patients with severe MDD. Augmentation of lithium therapy with valproic acid (Depakene) or carbamazepine (Tegretol) is usually well tolerated, with little risk of precipitation of mania.

When a depressive episode occurs in a person taking maintenance lithium, the differential diagnosis should include lithium-induced hypothyroidism, substance abuse, and lack of compliance with lithium therapy. One approach is to increase the lithium concentration (up to 1 to 1.2 mEq/L). Alternately we may augment with valproate or carbamazepine. It may also help to add supplemental thyroid hormone (e.g., 25 µg a day of liothyronine [Cytomel]), even in the presence of normal findings on thyroid function tests. Antidepressants or ECT are sometimes added judiciously. After the acute depressive episode resolves, other therapies should be tapered in favor of lithium monotherapy, if clinically tolerated.

MAINTENANCE. Maintenance treatment with lithium markedly decreases the frequency, severity, and duration of manic and depressive episodes in persons with bipolar I disorder. Lithium provides relatively more effective prophylaxis for mania than for depression, and supplemental antidepressant strategies may be necessary either intermittently or continuously. Lithium maintenance is almost always indicated after the first episode of bipolar I disorder, depression or mania, and should be considered after the first episode for adolescents or for persons who have a family history of bipolar I disorder. Others who benefit from lithium maintenance are those who have poor support systems, had no precipitating factors for the first episode, have a high suicide risk, had a sudden onset of the first episode, or had a first episode of mania. Clinical studies have shown that lithium reduces the incidence of suicide in bipolar I disorder patients six- or sevenfold. Lithium is also an effective treatment for persons with severe cyclothymic disorder.

It is wise to initiate maintenance therapy after the first manic episode, based on several observations. First, each episode of mania increases the risk of subsequent episodes. Second, among people responsive to lithium, relapses are 28 times more likely after lithium use is discontinued. Third, case reports describe persons who initially responded to lithium, discontinued taking it, and then had a relapse but no longer responded to lithium in subsequent episodes. Continued maintenance treatment with lithium is often associated with increased efficacy and reduced mortality. Therefore, an episode of depression or mania that occurs after a relatively short time on lithium maintenance does not necessarily represent treatment failure. However, lithium treatment alone may begin to lose its effectiveness after several years of successful use. If this occurs, then supplemental treatment with carbamazepine or valproate may be useful.

Maintenance lithium dosages can often be adjusted to achieve plasma concentration somewhat lower than that needed for the treatment of acute mania. If lithium use is to be discontinued, then the dosage should be slowly tapered. Abrupt discontinuation of lithium therapy is associated with an increased risk of recurrence of manic and depressive episodes.

Major Depressive Disorder. Lithium is effective in the long-term treatment of major depression, but it is not more effective than antidepressant drugs. The most common role for lithium in MDD is as an adjuvant to antidepressant use in persons who have failed to respond to the antidepressants alone. About 50 to 60 percent of antidepressant nonresponders do respond when lithium, 300 mg three times daily, is added to the antidepressant regimen. In some cases, a response may be seen within days, but most often, several weeks are required to see the efficacy of the regimen. Lithium alone may effectively treat depressed persons who have bipolar I disorder but have not yet had their first manic episode. Lithium has been reported to be effective in persons with MDD whose disorder has marked cyclicity.

Schizoaffective Disorder and Schizophrenia. Persons with prominent mood symptoms—either bipolar type or depressive type—with schizoaffective disorder are more likely to respond to lithium than those with predominant psychotic symptoms. Although SDAs and DRAs are the

treatments of choice for persons with schizoaffective disorder, lithium is a useful augmentation agent. This approach is particularly true for persons whose symptoms are resistant to treatment with SDAs and DRAs. Lithium augmentation of an SDA or DRA medication may be an effective treatment for persons with schizoaffective disorder even in the absence of a prominent mood disorder component. Some persons with schizophrenia who cannot take antipsychotic drugs may benefit from lithium treatment alone.

Other Indications. Over the years, reports have appeared about the use of lithium to treat a wide range of other psychiatric and nonpsychiatric conditions (Tables 21-25 and 21-26). The effectiveness and safety of lithium for most of these disorders have not been confirmed. Lithium has an anti-aggressive activity that is separate from its effects on mood. Aggressive outbursts in persons with schizophrenia, violent prison inmates, and children with conduct disorder and aggression, or self-mutilation in persons with intellectual disability, can sometimes be controlled with lithium.

Table 21-25
Psychiatric Uses of Lithium

Well established (FDA approved)
- Bipolar disorder
  - Manic episode
  - Maintenance therapy

Reasonably well established
- Bipolar I disorder, depressive episode
- Bipolar II disorder
- Rapid-cycling bipolar I disorder
- Cyclothymic disorder
- Major depressive disorder
  - Acute depression (as an augmenting agent)
  - Maintenance therapy
- Schizoaffective disorder

Evidence of benefit in particular groups
- Schizophrenia

Aggression (episodic), explosive behavior, and self-mutilation
Conduct disorder in children and adolescents
Intellectual disability
Cognitive disorders
Aggressive prisoners

Anecdotal, controversial, unresolved, or doubtful

Alcohol and other substance-related disorders
Cocaine abuse
Substance-induced mood disorder with manic features
Obsessive-compulsive disorder
Phobias
Posttraumatic stress disorder
ADHD
Eating disorders
  Anorexia nervosa
  Bulimia nervosa
Impulse-control disorders
Kleine–Levin syndrome
Mental disorders caused by a general medical condition (e.g., mood disorder caused by a general medical condition with manic features)
Periodic catatonia
Periodic hypersomnia
Personality disorders (e.g., antisocial, borderline, emotionally unstable, schizotypal)
Premenstrual dysphoric disorder
Sexual disorders
  Transvestism
  Exhibitionism
  Pathologic hypersexuality

FDA, Food and Drug Administration; ADHD, attention-deficit/hyperactivity disorder.

Table 21-26
Nonpsychiatric Uses of Lithium[a]

- Neurologic
  - Epilepsy
  - Headache (chronic cluster, hypnic, migraine, particularly cyclic)
  - Ménière disease (not supported by controlled studies)
  - Movement disorders
  - Huntington disease
  - L-Dopa–induced hyperkinesias
  - On–off phenomenon in Parkinson disease (controlled study found decreased akinesia but development of dyskinesia in a few cases)
  - Spasmodic torticollis
  - Tardive dyskinesia (not supported by controlled studies, and pseudoparkinsonism has been reported)
  - Tourette disorder
  - Pain (facial pain syndrome, painful shoulder syndrome, fibromyalgia)
  - Periodic paralysis (hypokalemic and hypermagnesic but not hyperkalemic)
- Hematologic
  - Aplastic anemia
  - Cancer—chemotherapy-induced, radiotherapy-induced
  - Neutropenia (one study found increased risk of sudden death in patients with preexisting cardiovascular disorder)
  - Drug-induced neutropenia (e.g., from carbamazepine, antipsychotics, immunosuppressives, and zidovudine)
  - Felty syndrome
  - Leukemia
- Endocrine
  - Thyroid cancer as an adjunct to radioactive iodine
  - Thyrotoxicosis
  - Syndrome of inappropriate antidiuretic hormone secretion
- Cardiovascular
  - Antiarrhythmic agent (animal data only)
- Dermatologic
  - Genital herpes (controlled studies support topical and oral use)

Eczematoid dermatitis
Seborrheic dermatitis (controlled study supports)
Gastrointestinal
Cyclic vomiting
Gastric ulcers
Pancreatic cholera
Ulcerative colitis
Respiratory
Asthma (controlled study did not support)
Cystic fibrosis
Other
Bovine spastic paresis

[a]All the uses listed here do not have Food and Drug Administration(FDA)–approved labeling. There are conflicting reports about many of these uses—some have negative findings in controlled studies, and a few involve reports of possible adverse effects.

L-Dopa, levodopa.

Precautions and Adverse Effects

More than 80 percent of patients taking lithium experience side effects. It is crucial to minimize the risk of adverse events through monitoring of lithium blood levels and to use appropriate pharmacologic interventions to counteract unwanted effects when they occur. The most common adverse effects are summarized in Table 21-27. Patient education can play an essential role in reducing the incidence and severity of side effects. Patients taking lithium should be advised that changes in the body's water and salt content can affect the amount of lithium excreted, resulting in either increases or decreases in lithium concentrations. Excessive sodium intake (e.g., a dramatic dietary change) lowers lithium concentrations.

Table 21-27
Adverse Effects of Lithium

Neurologic
Benign, nontoxic: dysphoria, lack of spontaneity, slowed reaction time, memory difficulties
Tremor: postural, occasional extrapyramidal

	Toxic: coarse tremor, dysarthria, ataxia, neuromuscular irritability, seizures, coma, death
	Miscellaneous: peripheral neuropathy, benign intracranial hypertension, myasthenia gravis–like syndrome, altered creativity, lowered seizure threshold
Endocrine	
	Thyroid: goiter, hypothyroidism, exophthalmos, hyperthyroidism (rare)
	Parathyroid: hyperparathyroidism, adenoma
Cardiovascular	
	Benign T-wave changes, sinus node dysfunction
Renal	
	Concentrating defect, morphologic changes, polyuria (nephrogenic diabetes insipidus), reduced GFR, nephrotic syndrome, renal tubular acidosis
Dermatologic	
	Acne, hair loss, psoriasis, rash
Gastrointestinal	
	Appetite loss, nausea, vomiting, diarrhea
Miscellaneous	
	Altered carbohydrate metabolism, weight gain, fluid retention

GFR, glomerular filtration rate.

Conversely, too little sodium (e.g., fad diets) can lead to potentially toxic concentrations of lithium. Decreases in body fluid (e.g., excessive perspiration) can lead to dehydration and lithium intoxication. Patients should report whenever another clinician prescribes medications, because many commonly used agents can affect lithium concentrations.

Cardiac Effects. Lithium can cause diffuse slowing, widening of the frequency spectrum, and potentiation and disorganization of background rhythm on electrocardiography (ECG). Bradycardia and cardiac arrhythmias may occur, especially in people with cardiovascular disease. Lithium infrequently reveals Brugada syndrome, an inherited, life-threatening heart problem that some people may have without knowing it. It can cause a severe

abnormal heartbeat and other symptoms (such as severe dizziness, fainting, shortness of breath) that need medical attention right away. Before starting lithium treatment, clinicians should ask about known heart conditions, unexplained fainting, and family history of problems or sudden unexplained death before age 45.

Gastrointestinal Effects. GI symptoms—which include nausea, decreased appetite, vomiting, and diarrhea—can be diminished by dividing the dosage, administering the lithium with food, or switching to another lithium preparation. The lithium preparation least likely to cause diarrhea is lithium citrate. Some lithium preparations contain lactose, which can cause diarrhea in lactose-intolerant persons. Persons taking slow-release formulations of lithium who experience diarrhea caused by unabsorbed medication in the lower part of the GI tract may experience less diarrhea than with standard-release preparations. Diarrhea may also respond to antidiarrheal preparations such as loperamide (Imodium, Kaopectate), bismuth subsalicylate (Pepto-Bismol), or diphenoxylate with atropine (Lomotil).

Weight Gain. Weight gain results from a poorly understood effect of lithium on carbohydrate metabolism. Weight gain can also result from lithium-induced hypothyroidism, lithium-induced edema, or excessive consumption of soft drinks and juices to quench lithium-induced thirst.

Neurologic Effects

TREMOR. A lithium-induced postural tremor may occur that is usually 8 to 12 Hz and is most notable in outstretched hands, especially in the fingers, and during tasks involving fine manipulations. The tremor can be reduced by dividing the daily dosage, using a sustained-release formulation, reducing caffeine intake, reassessing the concomitant use of other medicines, and treating comorbid anxiety. β-Adrenergic receptor antagonists, such as propranolol, 30 to 120 mg a day in divided doses, and primidone (Mysoline), 50 to 250 mg a day, are usually effective in reducing the tremor. In persons with hypokalemia, potassium supplementation may improve the tremor. When a person taking lithium has a severe tremor, the possibility of lithium toxicity should be suspected and evaluated.

COGNITIVE EFFECTS. Lithium use has been associated with dysphoria, lack of spontaneity, slowed reaction times, and impaired memory. We should note these symptoms carefully because they are a frequent cause of noncompliance. The differential diagnosis for such symptoms should include depressive disorders, hypothyroidism, hypercalcemia, other illnesses, and other drugs. Some, but not all, persons have reported that fatigue and mild cognitive impairment decrease with time.

OTHER NEUROLOGIC EFFECTS. Uncommon neurologic adverse effects include symptoms of mild parkinsonism, ataxia, and dysarthria, although the last two symptoms may also be attributable to lithium intoxication. Lithium is rarely associated with the development of peripheral neuropathy, benign intracranial hypertension (pseudotumor cerebri), findings resembling myasthenia gravis, and increased risk of seizures.

Renal Effect. The most common adverse renal effect of lithium is polyuria with secondary polydipsia. The symptom is particularly a problem in 25 to 35 percent of persons taking lithium who may have a urine output of more than 3 L a day (reference range: 1 to 2 L a day). The polyuria primarily results from lithium antagonism to the effects of antidiuretic hormone, which thus causes diuresis. When polyuria is a significant problem, the person's renal function should be evaluated and followed up with 24-hour urine collections for creatinine clearance determinations. Treatment consists of fluid replacement, the use of the lowest effective dosage of lithium, and single daily dosing of lithium. Treatment can also involve the use of a thiazide or potassium-sparing diuretic. For example, amiloride (Midamor), spironolactone (Aldactone), triamterene (Dyrenium), or amiloride–hydrochlorothiazide (Moduretic) may help. If treatment with a diuretic is initiated, the lithium dosage should be halved, and the diuretic should not be started for 5 days, because the diuretic is likely to increase lithium retention.

The most severe renal adverse effects, which are rare and associated with continuous lithium administration for 10 years or more, involve the appearance of nonspecific interstitial fibrosis, associated with gradual decreases in glomerular filtration rate and increases in serum creatinine concentrations, and rarely with renal failure. Lithium is occasionally

associated with nephrotic syndrome and features of distal renal tubular acidosis. Another pathologic finding in patients with lithium nephropathy is the presence of microcysts. Magnetic resonance imaging (MRI) can be used to demonstrate renal microcysts secondary to chronic lithium nephropathy and therefore avoid renal biopsy. It is prudent for persons taking lithium to check their serum creatinine concentration, urine chemistries, and 24-hour urine volume at 6-month intervals. If creatinine levels do rise, then more frequent monitoring and MRI might be considered.

Thyroid Effects. Lithium causes a generally benign and often transient diminution in the concentrations of circulating thyroid hormones. Reports have attributed goiter (5 percent of persons), benign reversible exophthalmos, hyperthyroidism, and hypothyroidism (7 to 10 percent of persons) to lithium treatment. Lithium-induced hypothyroidism is more common in women (14 percent) than in men (4.5 percent). Women are at the highest risk during the first 2 years of treatment. Persons taking lithium to treat bipolar disorder are twice as likely to develop hypothyroidism if they develop rapid cycling. About 50 percent of persons receiving long-term lithium treatment have laboratory abnormalities, such as an abnormal TRH response, and about 30 percent have elevated concentrations of TSH. If symptoms of hypothyroidism are present, replacement with levothyroxine (Synthroid) is indicated. Even in the absence of hypothyroid symptoms, some clinicians treat persons with significantly elevated TSH concentrations with levothyroxine. In lithium-treated persons, TSH concentrations should be measured every 6 to 12 months. Lithium-induced hypothyroidism should be considered when evaluating depressive episodes that emerge during lithium therapy.

Cardiac Effects. The cardiac effects of lithium resemble those of hypokalemia on ECG. The displacement of intracellular potassium by the lithium ion causes this. The most common changes on the ECG are T-wave flattening or inversion. The changes are benign and disappear after lithium is excreted from the body.

Lithium depresses the pacemaking activity of the sinus node, sometimes resulting in sinus dysrhythmias, heart block, and episodes of syncope. Lithium treatment, therefore, is contraindicated in persons with sick sinus syndrome. In rare cases, ventricular arrhythmias and congestive heart failure

have been associated with lithium therapy. Lithium cardiotoxicity is prevalent in persons on a low-salt diet, those taking certain diuretics or ACEIs, and those with fluid–electrolyte imbalances or any renal insufficiency.

Dermatologic Effects. Dermatologic effects may be dose-dependent. They include acneiform, follicular, and maculopapular eruptions; pretibial ulcerations; and worsening of psoriasis. Occasionally, aggravated psoriasis or acneiform eruptions may force the discontinuation of lithium treatment. Alopecia has also been reported. Persons with many of those conditions respond favorably to changing to another lithium preparation and the usual dermatologic measures. Lithium concentrations should be monitored if tetracycline is used for the treatment of acne because it can increase the retention of lithium.

Lithium Toxicity and Overdoses. The early signs and symptoms of lithium toxicity include neurologic symptoms, such as coarse tremor, dysarthria, and ataxia; GI symptoms; cardiovascular changes; and renal dysfunction. The later signs and symptoms include impaired consciousness, muscular fasciculations, myoclonus, seizures, and coma. Signs and symptoms of lithium toxicity are outlined in Table 21-28. Risk factors include exceeding the recommended dosage, renal impairment, low-sodium diet, drug interaction, and dehydration. Elderly persons are more vulnerable to the effects of increased serum lithium concentrations. The greater the degree and duration of elevated lithium concentrations, the worse are the symptoms of lithium toxicity.

Table 21-28
Signs and Symptoms of Lithium Toxicity

1. Mild to moderate intoxication (lithium level, 1.5–2.0 mEq/L)	
GI	Vomiting Abdominal pain Dryness of mouth
Neurologic	Ataxia Dizziness

	Slurred speech
	Nystagmus
	Lethargy or excitement
	Muscle weakness
2. Moderate to severe intoxication (lithium level: 2.0–2.5 mEq/L)	
GI	Anorexia
	Persistent nausea and vomiting
Neurologic	Blurred vision
	Muscle fasciculations
	Clonic limb movements
	Hyperactive deep tendon reflexes
	Choreoathetoid movements
	Convulsions
	Delirium
	Syncope
	Electroencephalographic changes
	Stupor
	Coma
	Circulatory failure (lowered BP, cardiac arrhythmias, and conduction abnormalities)
3. Severe lithium intoxication (lithium level >2.5 mEq/L)	
	Generalized convulsions
	Oliguria and renal failure
	Death

Lithium toxicity is a medical emergency, potentially causing permanent neuronal damage and death. In cases of toxicity (Table 21-29), lithium should be stopped and dehydration treated. Unabsorbed lithium can be removed from the GI tract by ingestion of sodium polystyrene sulfonate (Kayexalate) or polyethylene glycol solution (GoLYTELY), but not activated charcoal. Ingestion of a single large dose may create clumps of medication in the stomach, which can be removed by gastric lavage with a wide-bore tube. The

value of forced diuresis is still debated. In severe cases, hemodialysis rapidly removes excessive amounts of serum lithium. Postdialysis serum lithium concentrations may increase as lithium is redistributed from tissues to the blood, so repeat dialysis may be needed. Neurologic improvement may lag behind the clearance of serum lithium by several days because lithium crosses the blood–brain barrier slowly.

Table 21-29
Management of Lithium Toxicity

1. Contact personal physician or go to a hospital emergency department
2. Lithium should be discontinued
3. Vital signs and a neurologic examination with complete formal mental status examination
4. Lithium level, serum electrolytes, renal function tests, and ECG
5. Emesis, gastric lavage, and absorption with Kayexalate or GoLYTELY
6. For any patient with a serum lithium level greater than 4.0 mEq/L, hemodialysis

ECG, electrocardiography.

Adolescents. The serum lithium concentrations for adolescents are similar to those for adults. Weight gain and acne associated with lithium use can be particularly troublesome to adolescents.

Elderly Persons. Lithium is a safe and effective drug for elderly persons. However, the treatment of elderly persons taking lithium may be complicated by the presence of other medical illnesses, decreased renal function, special diets that affect lithium clearance, and generally increased sensitivity to lithium. Elderly persons should initially be given low dosages, their dosages should be switched less frequently than those of younger persons, and a longer time must be allowed for renal excretion to equilibrate with absorption before lithium can be assumed to have reached its steady-state concentrations.

Pregnant Women. Lithium should not be administered to pregnant women in the first trimester because of the risk of congenital disabilities. The most common malformations involve the cardiovascular system, most commonly Ebstein anomaly of the tricuspid valves. The risk of Ebstein malformation in lithium-exposed fetuses is 1 in 1,000, which is 20 times the risk in the general population. The possibility of fetal cardiac anomalies can be evaluated with fetal echocardiography. The teratogenic risk of lithium (4 to 12 percent) is higher than that for the general population (2 to 3 percent) but appears to be lower than that associated with the use of valproate or carbamazepine. A woman who continues to take lithium during pregnancy should use the lowest effective dosage. The maternal lithium concentration must be monitored closely during pregnancy, and especially after pregnancy, because of the significant decrease in renal lithium excretion as the renal function returns to normal in the first few days after delivery. Adequate hydration can reduce the risk of lithium toxicity during labor. Lithium prophylaxis is recommended for all women with bipolar disorder as they enter the postpartum period. Lithium is excreted into breast milk and should be taken by a nursing mother only after careful evaluation of potential risks and benefits. Signs of lithium toxicity in infants include lethargy, cyanosis, abnormal reflexes, and sometimes hepatomegaly.

Miscellaneous Effects. Lithium should be used with caution in diabetic persons, who should monitor their blood glucose concentrations carefully to avoid diabetic ketoacidosis. Benign, reversible leukocytosis is commonly associated with lithium treatment. Dehydrated, debilitated, and medically ill persons are most susceptible to adverse effects and toxicity.

Drug Interactions

Lithium drug interactions are summarized in Table 21-30.

Lithium is commonly used in conjunction with DRAs. This combination is typically sufficient and safe. However, coadministration of higher dosages of a DRA and lithium may result in a synergistic increase in the symptoms of lithium-induced neurologic side effects and neuroleptic extrapyramidal symptoms. In rare instances, encephalopathy has been reported with this combination.

The coadministration of lithium and carbamazepine, lamotrigine, valproate, and clonazepam may increase lithium concentrations and aggravate lithium-induced neurologic adverse effects. Treatment with the combination should be initiated at slightly lower dosages than usual, and the dosages should be increased gradually. Changes from one to another treatment for mania should be made carefully, with as little temporal overlap between the drugs as possible.

Most diuretics (e.g., thiazide and potassium-sparing) can increase lithium concentrations; when treatment with such a diuretic is stopped, the clinician may need to increase the person's daily lithium dosage. Osmotic and loop diuretics, carbonic anhydrase inhibitors, and xanthines (including caffeine) may reduce lithium concentrations to below therapeutic concentrations. Whereas ACEIs may cause an increase in lithium concentrations, the AT_1 angiotensin II receptor inhibitors losartan (Cozaar) and irbesartan (Avapro) do not alter lithium concentrations. A wide range of NSAIDs can decrease lithium clearance, thereby increasing lithium concentrations. These drugs include indomethacin (Indocin), phenylbutazone (Azolid), diclofenac (Voltaren), ketoprofen (Orudis), oxyphenbutazone (Oxalid), ibuprofen (Motrin, Advil), piroxicam (Feldene), and naproxen (Naprosyn). Aspirin and sulindac (Clinoril) do not affect lithium concentrations.

The coadministration of lithium and quetiapine (Seroquel) may cause somnolence but is otherwise well tolerated. The coadministration of lithium and ziprasidone (Geodon) may modestly increase the incidence of tremors. The coadministration of lithium and calcium channel inhibitors should be avoided because of potentially fatal neurotoxicity.

A person taking lithium who is about to undergo ECT should discontinue taking lithium 2 days before beginning ECT to reduce the risk of delirium.

Laboratory Interferences

Lithium does not interfere with any laboratory tests, but lithium-induced alterations include an increased WBC count, decreased serum thyroxine, and increased serum calcium. Blood collected in a lithium–heparin anticoagulant tube will produce falsely elevated lithium concentrations.

Dosage and Clinical Guidelines

Initial Medical Workup. All patients should have a routine laboratory workup and physical examination before being started on lithium. The laboratory tests should include serum creatinine concentration (or a 24-hour urine creatinine if the clinician has any reason to be concerned about renal function), electrolytes, thyroid function (TSH, T_3 [triiodothyronine], and T_4 [thyroxine]), a CBC, ECG, and a pregnancy test in women of childbearing age.

Dosage Recommendations. Lithium formulations include immediate-release 150-, 300-, and 600-mg lithium carbonate capsules (Eskalith and generic), 300 mg lithium carbonate tablets (Lithotabs), 450-mg controlled-release lithium carbonate capsules (Eskalith CR and Lithonate), and 8 mEq/5 mL of lithium citrate syrup.

The starting dosage for most adults is 300 mg of the regular-release formulation three times daily. The starting dosage for elderly persons or persons with renal impairment should be 300 mg once or twice daily. After stabilization, dosages between 900 and 1,200 mg a day usually produce a therapeutic plasma concentration of 0.6 to 1 mEq/L, and a daily dose of 1,200 to 1,800 mg usually produces a therapeutic concentration of 0.8 to 1.2 mEq/L. Maintenance dosing can be given either in two or three divided doses of the regular-release formulation or in a single dosage of the sustained-release formulation equivalent to the combined daily dosage of the regular-release formulation. The use of divided doses reduces gastric upset and avoids single high-peak lithium concentrations. Discontinuation of lithium should be gradual to minimize the risk of early recurrence of mania and to permit recognition of early signs of recurrence.

Table 21-30
Drug Interactions with Lithium

Drug Class	Reaction
Antipsychotics	Case reports of encephalopathy, worsening of extrapyramidal adverse effects, and neuroleptic malignant syndrome; inconsistent reports of altered red blood cell and plasma

	concentrations of lithium, antipsychotic drug, or both
Antidepressants	Occasional reports of a serotonin-like syndrome with potent serotonin reuptake inhibitors
Anticonvulsants	No significant pharmacokinetic interactions with carbamazepine or valproate; reports of neurotoxicity with carbamazepine; combinations helpful for treatment resistance
NSAIDs	May reduce renal lithium clearance and increase serum concentration; toxicity reported (exception is aspirin)
Diuretics	
Thiazides	Well-documented reduced renal lithium clearance and increased serum concentration; toxicity reported
Potassium sparing	Limited data; may increase lithium concentration
Loop	Lithium clearance unchanged (some case reports of increased lithium concentration)
Osmotic (mannitol, urea)	Increase renal lithium clearance and decrease lithium concentration
Xanthine (aminophylline, caffeine, theophylline)	Increase renal lithium clearance and decrease lithium concentration
Carbonic anhydrase inhibitors (acetazolamide)	Increase renal lithium clearance
ACEIs	Reports of reduced lithium clearance, increased

	concentrations, and toxicity
Calcium channel inhibitors	Case reports of neurotoxicity; no consistent pharmacokinetic interactions
Miscellaneous	
Succinylcholine, pancuronium	Reports of prolonged neuromuscular blockade
Metronidazole	Increased lithium concentration
Methyldopa	Few reports of neurotoxicity
Sodium bicarbonate	Increased renal lithium clearance
Iodides	Additive antithyroid effects
Propranolol	Used for lithium tremor; possible slight increase in lithium concentration

NSAID, nonsteroidal anti-inflammatory drug; ACEI, angiotensin-converting enzyme inhibitor.

Laboratory Monitoring. The periodic measurement of serum lithium concentration is an essential aspect of patient care, but it should always be combined with sound clinical judgment. A laboratory report listing the therapeutic range as 0.5 to 1.2 mEq/L may lull a clinician into disregarding early signs of lithium intoxication in patients whose levels are around 1.2 mEq/L. Clinical toxicity, especially in elderly persons, has been well documented at or slightly above the upper limit of the therapeutic range.

Regular monitoring of serum lithium concentrations is essential. Lithium levels should be obtained every 2 to 6 months except when there are signs of toxicity, during dosage adjustments, and in persons suspected to be noncompliant with the prescribed dosages. Under these circumstances, levels may be done weekly. Baseline ECG studies are essential and should be repeated annually.

When obtaining blood for lithium levels, patients should be at steady-state lithium dosing (usually after 5 days of constant dosing), preferably using a twice-daily or thrice-daily dosing regimen, and the blood sample must be drawn 12 hours (±30 minutes) after a given dose. Lithium concentrations 12

hours postdose in persons treated with sustained-release preparations are generally about 30 percent higher than the corresponding concentrations obtained from those taking the regular-release preparations. Because available data are based on a sample population following a multiple-dosage regimen, regular-release formulations given at least twice daily should be used for the initial determination of the appropriate dosages. Factors that may cause fluctuations in lithium measurements include dietary sodium intake, mood state, activity level, body position, and use of an improper blood sample tube.

Laboratory values that do not seem to correspond to clinical status may result from the collection of blood in a tube with a lithium–heparin anticoagulant (which can give results falsely elevated by as much as 1 mEq/L) or aging of the lithium ion-selective electrode (which can cause inaccuracies of up to 0.5 mEq/L). After the daily dose has been set, it is reasonable to change to the sustained-release formulation given once daily.

Effective serum concentrations for mania are 1.0 to 1.2 mEq/L, a level associated with 1,800 mg a day. The recommended range for maintenance treatment is 0.4 to 0.8 mEq/L, which is usually achieved with a daily dose of 900 to 1,200 mg. A small number of persons will not achieve therapeutic benefit with a lithium concentration of 1.2 mEq/L, yet will have no signs of toxicity. For such persons, titration of the lithium dosage to achieve a concentration above 1.2 mEq/L may be warranted. Some patients can be maintained at concentrations below 0.4 mEq/L. There may be considerable variation from patient to patient, so it is best to follow the maxim, “treat the patient, not the laboratory results.” The only way to establish an optimal dose for a patient may be through trial and error.

Package inserts (US) for lithium products list effective serum concentrations for mania between 1.0 and 1.2 mEq/L (usually achieved with 1,800 mg of lithium carbonate daily) and for long-term maintenance between 0.6 and 1.2 mEq/L (usually achieved with 900 to 1,200 mg of lithium carbonate daily). The dose–blood level relationship may vary considerably from patient to patient. The likelihood of achieving a response at levels above 1.2 mEq/L is usually significantly outweighed by the increased risk of toxicity, although rarely a patient may both require and tolerate a higher-than-usual blood concentration.

What constitutes the lower end of the therapeutic range remains a matter of

debate. A prospective 3-year study found patients who maintained a concentration between 0.4 and 0.6 mEq/L (mean 0.54) were 2.6 times more likely to relapse than those who maintained between 0.8 and 1.0 mEq/L (mean 0.83). However, higher blood concentrations produced more adverse effects and were less well tolerated.

If there is no response after 2 weeks at a concentration that is beginning to cause adverse effects, then the person should taper off lithium over 1 to 2 weeks, and other mood-stabilizing drugs should be tried.

Patient Education. Lithium has a narrow therapeutic index, and many factors can upset the balance between lithium concentrations that are well tolerated and therapeutic, and those that produce side effects or toxicity. It is thus imperative that persons taking lithium be educated about signs and symptoms of toxicity, factors that affect lithium levels, how and when to obtain laboratory testing, and the importance of regular communication with the prescribing physician. Lithium concentrations can be disrupted by common factors such as excessive sweating from ambient heat or exercise or the use of widely prescribed agents such as ACEIs or NSAIDs. Patients may stop taking their lithium because they are feeling well or because they are experiencing side effects. They should be advised against discontinuing or modifying their lithium regimen. Table 21-31 lists some essential instructions for patients.

VALPROATE

Valproate (Depakene, Depakote), or valproic acid, is approved for the treatment of manic episodes associated with bipolar I disorder and is one of the most widely prescribed mood stabilizers in psychiatry. It has a rapid onset of action and is well-tolerated, and numerous studies suggest that it reduces the frequency and intensity of recurrent manic episodes over extended periods.

Chemistry

Valproate is a simple-chain branch carboxylic acid. It is called valproic acid because it is rapidly converted to the acid form in the stomach. Multiple formulations of valproic acid are marketed. These include valproic acid

(Depakene), divalproex sodium (Depakote), an enteric-coated delayed-release 1:1 mixture of valproic acid and sodium valproate available in tablet and sprinkle formulation (can be opened and spread on food); and sodium valproate injection (Depacon). Extended-release preparation is also available. Each of these is therapeutically equivalent because, at physiologic pH, valproic acid dissociates into valproate ion.

Table 21-31
Instructions to Patients Taking Lithium

Lithium can be remarkably effective in treating your disorder. If not used appropriately and not monitored closely, it can be ineffective and potentially harmful. It is important to keep the following instructions in mind.

Dosing

Take lithium exactly as directed by your doctor—never take more or less than the prescribed dose.

Do not stop taking without speaking to your doctor.

If you miss a dose, take it as soon as possible. If it is within 4 hr of the next dose, skip the missed dose (about 6 hr in the case of extended-release or slow-release preparations). Never double up doses.

Blood Tests

Comply with the schedule of recommended regular blood tests.

Despite their inconvenience and discomfort, your lithium blood levels, thyroid function, and kidney status need to be monitored as long as you take lithium.

When going to have lithium levels checked, you should have taken your last lithium dose 12 hr earlier.

Use of Other Medications

Do not start any prescription or over-the-counter medications without telling your doctor.

Even drugs such as ibuprofen (Advil, Motrin) and naproxen (Aleve) can significantly increase lithium levels.

Diet and Fluid Intake

Avoid sudden changes in your diet or fluid intake. If you do go on a diet, your doctor may need to increase the frequency of blood tests.

Caffeine and alcohol act as diuretics and can lower your lithium concentrations.

During treatment with lithium, it is recommended that you drink about 2 or 3 quarts of fluid daily and use normal amounts of salt.

Inform your doctor if you start or stop a low-salt diet.

Recognizing Potential Problems

If you engage in vigorous exercise or have an illness that causes sweating, vomiting, or diarrhea, consult your doctor because these might affect lithium levels.

Nausea, constipation, shakiness, increased thirst, frequency of urination, weight gain, or swelling of the extremities should be reported to your doctor.

Blurred vision, confusion, loss of appetite, diarrhea, vomiting, muscle weakness, lethargy, shakiness, slurred speech, dizziness, loss of balance, inability to urinate, or seizures could indicate severe toxicity and should prompt immediate medical attention.

Pharmacologic Actions

Regardless of how it is formulated, valproate is rapidly and completely absorbed 1 to 2 hours after oral administration, with peak concentrations occurring 4 to 5 hours after oral administration. The plasma half-life of valproate is 10 to 16 hours. Valproate is highly protein-bound. Protein binding becomes saturated at higher dosages, and concentrations of therapeutically effective free valproate increase at serum concentrations above 50 to 100 µg/mL. The unbound portion of valproate is considered to be pharmacologically active and can cross the blood–brain barrier. The extended-release preparation produces lower peak concentrations and higher minimum concentrations and can be given once a day. Valproate is metabolized primarily by hepatic glucuronidation and mitochondrial β

oxidation.

The biochemical basis of valproate's therapeutic effects remains poorly understood. Postulated mechanisms include enhancement of GABA activity, modulation of voltage-sensitive sodium channels, and action on extrahypothalamic neuropeptides.

Therapeutic Indications

Valproate is currently approved as monotherapy or adjunctive therapy of complex partial seizures, monotherapy and adjunctive therapy of simple and complex absence seizures, and adjunctive therapy for patients with multiple seizures that include absence seizures. Divalproex has additional indications for prophylaxis of migraine.

Bipolar I Disorder

ACUTE MANIA. About two-thirds of persons with acute mania respond to valproate. The majority of patients with mania usually respond within 1 to 4 days after achieving valproate serum concentrations above 50 µg/mL. The antimanic response is generally associated with levels greater than 50 µg/mL, in a range of 50 to 125 µg/mL. This serum concentration may be gradually achieved within 1 week of initiation of dosing, but rapid oral loading strategies achieve therapeutic serum concentrations in 1 day and can control manic symptoms within 5 days. The short-term antimanic effects of valproate can be augmented with the addition of lithium, carbamazepine (Tegretol), SDAs, or DRAs. Numerous studies have suggested that the irritable manic subtype responds significantly better to sodium valproate than lithium or placebo. Because of its more favorable profile of cognitive, dermatologic, thyroid, and renal adverse effects, valproate is preferred to lithium for the treatment of acute mania in children and elderly persons.

ACUTE BIPOLAR DEPRESSION. Valproate possesses some activity as a short-term treatment of depressive episodes in bipolar I disorder, but this effect is far less pronounced than for the treatment of manic episodes. Among depressive symptoms, valproate is more useful for the treatment of agitation than dysphoria. In clinical practice, valproate is most often used as add-on therapy to an antidepressant to prevent the development of mania or rapid

cycling.

PROPHYLAXIS. Studies suggest that valproate is useful in the prophylactic treatment of bipolar I disorder, resulting in fewer, less severe, and shorter manic episodes. In direct comparison, valproate is at least as effective as lithium and is better tolerated than lithium. It may be particularly useful in persons with rapid-cycling and ultrarapid-cycling bipolar disorders, dysphoric or mixed mania, and mania caused by a general medical condition as well as in persons who have comorbid substance use disorders or panic attacks and in persons who have not had complete favorable responses to lithium treatment.

Schizophrenia and Schizoaffective Disorder. Valproate may accelerate response to antipsychotic therapy in patients with schizophrenia or schizoaffective disorder. Valproate alone is generally less effective in schizoaffective disorder than in bipolar I disorder. Valproate alone is ineffective for the treatment of psychotic symptoms and is typically used in combination with other drugs in patients with these symptoms.

Other Mental Disorders. Valproate has been studied for possible efficacy in a broad range of psychiatric disorders. These include alcohol withdrawal and relapse prevention, panic disorder, PTSD, impulse control disorder, borderline personality disorder, and behavioral agitation and dementia. Evidence supporting use in these cases is weak, and any observed therapeutic effects may be related to the treatment of a comorbid bipolar disorder.

Precautions and Adverse Reactions

Although valproate treatment is generally well tolerated and safe, it carries quite a few black box warnings and other warnings (Table 21-32). The two most serious adverse effects of valproate treatment affect the pancreas and liver. Risk factors for potentially fatal hepatotoxicity include young age (younger than 3 years); concurrent use of phenobarbital; and the presence of neurologic disorders, especially inborn errors of metabolism. The rate of fatal hepatotoxicity in persons who have been treated with valproate alone is 0.85 per 100,000 persons; no persons older than the age of 10 years have been reported to have died from hepatotoxicity. Therefore, the risk of this adverse

reaction in adult psychiatric patients is low.

Table 21-32
Black Box Warnings and Other Warnings for Valproate

More Serious Side Effect	Management Considerations
Hepatotoxicity	Rare, idiosyncratic event Estimated risk, 1:118,000 (adults) Greatest risk profile (polypharmacy, younger than 2 yr of age, intellectual disability): 1:800
Pancreatitis	Rare, similar pattern to hepatotoxicity Incidence in clinical trial data is 2 in 2,416 (0.0008%) Postmarketing surveillance shows no increased incidence Relapse with rechallenge Asymptomatic amylase not predictive
Hyperammonemia	Rare; more common in combination with carbamazepine (Tegretol) Associated with coarse tremor and may respond to L-carnitine administration
Associated with urea cycle disorders	Discontinue valproate and protein intake Assess underlying urea cycle disorder Divalproex is contraindicated in patients with urea cycle disorders
Teratogenicity	Neural tube defect: 1–4% with valproate Preconceptual education and folate–vitamin B complex supplementation for all young women of childbearing potential
Somnolence in elderly persons	Slower titration than conventional doses Regular monitoring of fluid and nutritional intake

Thrombocytopenia	Decrease dose if clinically symptomatic (i.e., bruising, bleeding gums) Thrombocytopenia more likely with valproate levels ≥110 µg/mL (women) and ≥135 µg/mL (men)

Nevertheless, if symptoms of lethargy, malaise, anorexia, nausea and vomiting, edema, and abdominal pain occur in a person treated with valproate, the clinician must consider the possibility of severe hepatotoxicity. A modest increase in liver function test results does not correlate with the development of severe hepatotoxicity. Rare cases of pancreatitis have been reported; they occur most often in the first 6 months of treatment, and the condition occasionally results in death. The pancreatic function can be assessed and followed by serum amylase concentrations. Other potentially severe consequences of treatment include hyperammonemia-induced encephalopathy and thrombocytopenia. Thrombocytopenia and platelet dysfunction occur most commonly at high dosages and result in the prolongation of bleeding times.

There are multiple concerns regarding the use of valproate during pregnancy. Women who require valproate therapy should, therefore, inform their physicians if they intend to become pregnant. First-trimester use of valproate has been associated with a 3 to 5 percent risk of neural tube defects, as well as an increased risk of other malformations affecting the heart and other organ systems. Multiple reports have also indicated that in utero exposure to valproate may negatively affect cognitive development in children of mothers who take valproate during pregnancy. They have lower IQ scores at age 6 years compared with those exposed to other antiepileptic drugs. Fetal valproate exposure has dose-dependent associations with reduced cognitive abilities across a range of domains at 6 years of age. Valproate exposure may also increase the risk of autistic spectrum disorder.

Valproate is also associated with teratogenicity, most notably neural tube defects (e.g., spina bifida). The risk is about 1 to 4 percent of all women who take valproate during the first trimester of pregnancy. The risk of valproate-induced neural tube defects can be reduced with daily folic acid supplements (1 to 4 mg a day). All women with childbearing potential who take the drug

should be given folic acid supplements. Infants breastfed by mothers taking valproate develop serum valproate concentrations 1 to 10 percent of maternal serum concentrations, but no data suggest that this poses a risk to the infant. Valproate is not contraindicated in nursing mothers. We should avoid this drug in patients with hepatic diseases. Valproate may be especially problematic for adolescents and young women. Cases of polycystic ovarian disease have been reported in women using valproate. Even when the full syndromal criteria for this syndrome are not met, many of these women develop menstrual irregularities, hair loss, and hirsutism. These effects are thought to result from a metabolic syndrome that is driven by insulin resistance and hyperinsulinemia.

The common adverse effects associated with valproate (Table 21-33) are those affecting the GI system, such as nausea, vomiting, dyspepsia, and diarrhea. The GI effects are generally most common in the first month of treatment, significantly if the dosage is increased rapidly. Unbuffered valproic acid (Depakene) is more likely to cause GI symptoms than the enteric-coated "sprinkle" or the delayed-release divalproex sodium formulations. Other common adverse effects involve the nervous system, such as sedation, ataxia, dysarthria, and tremor. Valproate-induced tremor may respond well to treatment with β-adrenergic receptor antagonists or gabapentin. Treatment of the other neurologic adverse effects usually requires lowering the valproate dosage.

Weight gain is a common adverse effect, especially in long-term treatment, and can best be treated by strict limitation of caloric intake. Hair loss may occur in 5 to 10 percent of all persons treated, and rare cases of complete loss of body hair have been reported. Some clinicians have recommended treatment of valproate-associated hair loss with vitamin supplements that contain zinc and selenium. About 5 to 40 percent of persons experience a persistent but clinically insignificant elevation in liver transaminases up to three times the upper limit of normal, which is usually asymptomatic and resolves after discontinuation of the drug. High dosages of valproate (above 1,000 mg a day) may rarely produce mild to moderate hyponatremia, most likely because of some degree of the syndrome of secretion of inappropriate antidiuretic hormone, which is reversible upon lowering of the dosage. Overdoses of valproate can lead to coma and death.

Table 21-33
Adverse Effects of Valproate

Common
GI irritation
Nausea
Sedation
Tremor
Weight gain
Hair loss
Uncommon
Vomiting
Diarrhea
Ataxia
Dysarthria
Persistent elevation of hepatic transaminases
Rare
Fatal hepatotoxicity (primarily in pediatric patients)
Reversible thrombocytopenia
Platelet dysfunction
Coagulation disturbances
Edema
Hemorrhagic pancreatitis
Agranulocytosis
Encephalopathy and coma
Respiratory muscle weakness and respiratory failure

GI, gastrointestinal.

Drug Interactions

Valproate is commonly prescribed as part of a regimen involving other psychotropic agents. The only consistent drug interaction with lithium, if both drugs are maintained in their respective therapeutic ranges, is the exacerbation of drug-induced tremors, which can usually be treated with β-receptor antagonists. The combination of valproate and DRAs may result in increased sedation, as can be seen when valproate is added to any CNS

depressant (e.g., alcohol), and increased severity of extrapyramidal symptoms, which usually responds to treatment with antiparkinsonian drugs. Valproate can usually be safely combined with carbamazepine or SDAs. Perhaps the most worrisome interaction of valproate and a psychotropic drug involves lamotrigine. Since the approval of lamotrigine for the treatment of bipolar disorder, it is more likely that patients will be treated with both agents. Valproate more than doubles lamotrigine concentrations, increasing the risk of a severe rash (Stevens–Johnson syndrome and toxic epidermal necrolysis).

The plasma concentrations of carbamazepine, diazepam (Valium), amitriptyline (Elavil), nortriptyline (Pamelor), and phenobarbital (Luminal) may also be increased when these drugs are coadministered with valproate. Also, the plasma concentrations of phenytoin (Dilantin) and desipramine (Norpramin) may be decreased when they are combined with valproate. The plasma concentrations of valproate may be decreased when the drug is coadministered with carbamazepine and may be increased when coadministered with guanfacine (Tenex), amitriptyline, or fluoxetine (Prozac). Valproate can be displaced from plasma proteins by carbamazepine, diazepam, and aspirin. Persons who are treated with anticoagulants (e.g., aspirin and warfarin [Coumadin]) should also be monitored when valproate use is initiated to assess the development of any undesired augmentation of the anticoagulation effects. Interactions of valproate with other drugs are listed in Table 21-34.

Table 21-34
Interactions of Valproate with Other Drugs

Drug	Interactions Reported with Valproate
Lithium	Increased tremor
Antipsychotics	Increased sedation; increased extrapyramidal effects; delirium and stupor (single report)
Clozapine	Increased sedation; confusional syndrome (single report)
Carbamazepine	Acute psychosis (single report); ataxia, nausea,

	lethargy (single report); may decrease valproate serum concentrations
Antidepressants	Amitriptyline and fluoxetine may increase valproate serum concentrations
Diazepam	Serum concentration increased by valproate
Clonazepam	Absence status (rare; reported only in patients with preexisting epilepsy)
Phenytoin	Serum concentration decreased by valproate
Phenobarbital	Serum concentration increased by valproate; increased sedation
Other CNS depressants	Increased sedation
Anticoagulants	Possible potentiation of effect

CNS, central nervous system.

Laboratory Interferences

Valproate may cause a laboratory increase of serum-free fatty acids. Valproate metabolites may produce a false-positive test result for urinary ketones as well as falsely abnormal thyroid function test results.

Table 21-35
Recommended Laboratory Tests during Valproate Therapy

Before Treatment
Standard chemistry screen with special attention to liver function tests
CBC, including WBC and platelet count
During Treatment
Liver function tests at 1 mo; then every 6–24 mo if no abnormalities are found.
Complete blood count with platelet count at 1 mo; then every 6–24 mo if findings are normal.

If Liver Function Test Results Become Abnormal

Mild transaminase elevation (less than three times normal): monitoring every 1–2 wk; if stable and patient is responding to valproate, results are monitored monthly to every 3 mo.

Pronounced transaminase elevation (more than three times normal): dosage reduction or discontinuation of valproate; increase dose or rechallenge if transaminases normalize and if the patient is a valproate responder.

CBC, complete blood count; WBC, white blood cell.

Dosage and Clinical Guidelines

When starting valproate therapy, a baseline hepatic panel, CBC and platelet counts, and pregnancy testing should be ordered. Additional testing should include amylase and coagulation studies if baseline pancreatic disease or coagulopathy is suspected. In addition to baseline laboratory tests, hepatic transaminase concentrations should be obtained 1 month after initiation of therapy and every 6 to 24 months after that. However, because even frequent monitoring may not predict severe organ toxicity, it is more prudent to reinforce the need for prompt evaluation of any illnesses when reviewing the instructions with patients. Asymptomatic elevation of transaminase concentrations up to three times the upper limit of normal are typical and do not require any change in dosage. Table 21-35 lists the recommended laboratory tests for valproate treatment.

Valproate is available in several formulations (Table 21-36). For the treatment of acute mania, an oral loading strategy of initiation with 20 to 30 mg/kg a day can be used to accelerate the control of symptoms. This strategy is usually well tolerated but can cause excessive sedation and tremor in elderly persons. Agitated behavior can be rapidly stabilized with IV infusion of valproate. If acute mania is absent, it is best to initiate drug treatment gradually to minimize the common adverse effects of nausea, vomiting, and sedation. The dose on the first day should be 250 mg administered with a meal. The dosage can be raised to 250 mg orally three times daily for over 3 to 6 days. The plasma concentrations can be assessed in the morning before the first daily dose is administered. Therapeutic plasma concentrations for the control of seizures range between 50 and 100 µg/mL. It is reasonable to use

the same range for the treatment of mental disorders; most of the controlled studies have used 50 to 125 µg/mL. Most persons attain therapeutic plasma concentrations on a dosage between 1,200 and 1,500 mg a day in divided doses. After a person's symptoms are well controlled, the full daily dose can be taken all at once before sleep.

Table 21-36
Valproate Preparations Available in the United States

Generic Name	Trade Name, Form (Doses)	Time to Peak
Valproate sodium injection	Depacon injection (100-mg valproic acid/mL)	1 hr
Valproic acid	Depakene, syrup (250 mg/5 mL)	1–2 hr
	Depakene, capsules (250 mg)	1–2 hr
Divalproex sodium	Depakote, delayed-released tablets (125, 250, 500 mg)	3–8 hr
Divalproex sodium-coated particles in	Depakote, sprinkle capsules (125 mg)	Compared with divalproex tablets, divalproex sprinkle has earlier onset and slower absorption, with slightly lower peak plasma concentration

capsules		
Divalproex sodium extended-release	Depakote ER (250, 500 mg)	4–17 hr

LAMOTRIGINE

Lamotrigine (Lamictal) was developed as a result of screening folate antagonists as anticonvulsants. Lamotrigine proved effective in several animal models of epilepsy, was developed as an antiepileptic drug, and was marketed for the adjunctive treatment of partial seizures in the United States in 1995. Initial, postmarketing, open, clinical experience suggested efficacy in a variety of neurologic and psychiatric conditions, coupled with good tolerability (aside from the risk of rash). Later, double-blind, placebo-controlled studies revealed that lamotrigine was useful for some, but not all, of the neurologic and psychiatric conditions reported in open studies. Therefore, lamotrigine appeared effective as a maintenance treatment for bipolar disorder and was approved for the maintenance treatment of bipolar I disorder in 2003. Lamotrigine also appeared to have potential utility in acute bipolar depression. However, the magnitude of the effect was too modest to yield consistently superior performance compared with placebo, and hence lamotrigine did not receive approval for the treatment of acute bipolar depression.

Similarly, limited data suggested that lamotrigine had potential utility in rapid-cycling bipolar disorder. Lamotrigine did not appear to be as effective as the primary intervention in acute mania. Thus, lamotrigine has emerged as an agent that appears to “stabilize mood from below” in the sense that it may maximally impact the depressive component of bipolar disorders.

Pharmacologic Actions

Lamotrigine is wholly absorbed, has a bioavailability of 98 percent, and has a steady-state plasma half-life of 25 hours. However, the rate of metabolism of lamotrigine varies over a sixfold range, depending on which other drugs are administered concomitantly. Dosing is escalated slowly to twice-a-day

maintenance dosing. Food does not affect its absorption, and it is 55 percent protein-bound in the plasma; 94 percent of lamotrigine and its inactive metabolites are excreted in the urine. Among the better-delineated biochemical actions of lamotrigine is the blockade of voltage-sensitive sodium channels, which in turn modulates the release of glutamate and aspartate and has a slight effect on calcium channels. Lamotrigine modestly increases plasma serotonin concentrations, possibly through inhibition of serotonin reuptake, and is a weak inhibitor of serotonin 5-HT_3 receptors.

Therapeutic Indications

Bipolar Disorder. Lamotrigine is indicated in the treatment of bipolar disorder and may prolong the time between episodes of depression and mania. It is more effective in lengthening the intervals between depressive episodes than manic episodes. It is also useful as a treatment for rapid-cycling bipolar disorder.

Other Indications. There have been reports of therapeutic benefit in the treatment of borderline personality disorder and the treatment for various pain syndromes.

Precautions and Adverse Reactions

Lamotrigine is remarkably well tolerated. The absence of sedation, weight gain, and other metabolic effects are noteworthy. The most common adverse effects—dizziness, ataxia, somnolence, headache, diplopia, blurred vision, and nausea—are typically mild. Anecdotal reports of cognitive impairment and joint or back pain are standard.

The appearance of a rash, which is common and occasionally very severe, is a source of concern. About 8 percent of patients started on lamotrigine develop a benign maculopapular rash during the first 4 months of treatment, and the drug should be discontinued if a rash develops. Even though these rashes are benign, there is concern that, in some cases, they may represent early manifestations of Stevens–Johnson syndrome or toxic epidermal necrolysis. Nevertheless, even if lamotrigine is discontinued immediately upon the development of a rash or other signs of hypersensitivity reaction, such as fever and lymphadenopathy, this may not prevent subsequent

development of a life-threatening rash or permanent disfiguration.

Estimates of the rate of severe rash vary, depending on the source of the data. In some studies, the incidence of severe rashes was 0.08 percent in adult patients receiving lamotrigine as initial monotherapy and 0.13 percent in adult patients receiving lamotrigine as adjunctive therapy. German registry data, based on clinical practice, suggest that the risk of rash may be as low as 1 in 5,000 patients. The appearance of any rash necessitates immediate discontinuation of drug administration.

It is known that the likelihood of a rash increases if the recommended starting dose and speed of dose increase exceed what is recommended. Concomitant administration of valproic acid also increases risk and should be avoided if possible. If valproate is used, a more conservative dosing regimen is followed. Children and adolescents younger than age 16 years appear to be more susceptible to rash with lamotrigine. If patients miss more than 4 consecutive days of lamotrigine treatment, they need to restart therapy at the initial starting dose and titrate upward as if they had not already been on the medication.

Laboratory Testing

There is no proven correlation between lamotrigine blood concentrations and either antiseizure effects or efficacy in bipolar disorders. Laboratory tests are not useful in predicting the occurrence of adverse events.

Drug Interactions

Lamotrigine has significant, well-characterized drug interactions involving other anticonvulsants. The most potentially serious lamotrigine drug interaction involves concurrent use of valproic acid, which doubles serum lamotrigine concentrations. Lamotrigine decreases the plasma concentration of valproic acid by 25 percent. Sertraline (Zoloft) also increases plasma lamotrigine concentrations, but to a lesser extent than does valproic acid. Lamotrigine concentrations are decreased by 40 to 50 percent with concomitant administration of carbamazepine, phenytoin, or phenobarbital. Combinations of lamotrigine and other anticonvulsants have complex effects on the time of peak plasma concentration and the plasma half-life of lamotrigine.

Laboratory Interferences

Lamotrigine does not interfere with any laboratory tests.

Dosage and Administration

In the clinical trials leading to the approval of lamotrigine as a treatment for bipolar disorder, no consistent increase in efficacy was associated with doses above 200 mg/day. Most patients should take between 100 and 200 mg a day. In epilepsy, the drug is administered twice daily, but in bipolar disorder, the total dose can be taken once a day, either in the morning or night, depending on whether the patient finds the drug activating or sedating.

Lamotrigine is available as unscored 25-, 100-, 150-, and 200-mg tablets. The primary determinant of lamotrigine dosing is the minimization of the risk of rash. Lamotrigine should not be taken by anyone younger than 16 years of age. Because valproic acid markedly slows the elimination of lamotrigine, concomitant administration of these two drugs necessitates a much slower titration (Table 21-37). People with renal insufficiency should aim for a lower maintenance dosage. The appearance of any rash necessitates immediate discontinuation of lamotrigine administration. Lamotrigine should usually be discontinued gradually over 2 weeks unless a rash emerges, in which case it should be discontinued over 1 to 2 days.

Lamotrigine orally disintegrating tablets (Lamictal ODT) are available for patients who have difficulty swallowing. It is the only antiepileptic treatment that is available in an orally disintegrating formulation. It is available in 25, 50, 100, and 200 mg strengths and matches the dose of lamotrigine tablets. Chewable dispersible tablets of 2, 5, and 25 mg are also available.

CARBAMAZEPINE AND OXCARBAZEPINE

Carbamazepine (Tegretol) possesses some structural similarity to the TCA imipramine (Tofranil). It was approved for use in the United States for the treatment of trigeminal neuralgia in 1968 and temporal lobe epilepsy (complex partial seizures) in 1974. Interestingly, carbamazepine was first synthesized as a potential antidepressant, but because of its atypical profile in several animal models, it was initially developed for use in pain and seizure disorders. It is now recognized in most guidelines as a second-line mood

stabilizer useful in the treatment and prevention of both phases of bipolar affective disorder. A long-acting sustained release formulation (Equetro) was approved by the U.S. FDA for the treatment of acute mania in 2002.

Table 21-37
Lamotrigine Dosing (mg/day)

Treatment	Weeks 1–2	Weeks 3–4	Weeks 4–5
Lamotrigine monotherapy	25	50	100–200 (200 maximum)
Lamotrigine + carbamazepine	50	100	200–400 (400 maximum)
Lamotrigine + valproate	25 every other day	25	50–100 (100 maximum)

An analog of carbamazepine, oxcarbazepine (Trileptal), was marketed as an antiseizure medication in the United States in 2000. Previously it was used as a treatment for pediatric epilepsy in Europe since 1990. Because of its similarity to carbamazepine, many clinicians began to use it as a treatment for patients with bipolar disorder. Despite some reports that oxcarbazepine has mood-stabilizing properties, this has not been confirmed in large, placebo-controlled trials.

Carbamazepine

Pharmacologic Actions. The absorption of carbamazepine is slow and unpredictable. Food enhances absorption. Peak plasma concentrations are reached 2 to 8 hours after a single dose, and steady-state levels are reached after 2 to 4 days on a steady dosage. It is 70 to 80 percent protein-bound. The half-life of carbamazepine ranges from 18 to 54 hours, with an average of 26 hours. However, with chronic administration, the half-life of carbamazepine decreases to an average of 12 hours. This results from the induction of hepatic CYP450 enzymes by carbamazepine, specifically the autoinduction of carbamazepine metabolism. The induction of hepatic enzymes reaches its

maximum level after about 3 to 5 weeks of therapy.

The pharmacokinetics of carbamazepine are different for two long-acting preparations of carbamazepine, each of which uses slightly different technology. One formulation, Tegretol XR, requires food to ensure standard GI transit time. The other preparation, Carbatrol, relies on a combination of intermediate, extended-release, and very slow release beads, making it suitable for bedtime administration.

Carbamazepine is metabolized in the liver, and the 10,11-epoxide metabolite is active as an anticonvulsant. Its activity in the treatment of bipolar disorders is unknown. Long-term use of carbamazepine is associated with an increased ratio of the epoxide to the parent molecule.

The anticonvulsant effects of carbamazepine are thought to be mediated mainly by binding to voltage-dependent sodium channels in the inactive state and prolonging their inactivation. This action secondarily reduces voltage-dependent calcium channel activation and, thus, synaptic transmission. Additional effects include reduction of currents through *N*-methyl-D-aspartate (NMDA) glutamate-receptor channels, competitive antagonism of adenosine a_1-receptors, and potentiation of CNS catecholamine neurotransmission. Whether any or all of these mechanisms also result in mood stabilization is not known.

Therapeutic Indications

Bipolar Disorder

ACUTE MANIA. The acute antimanic effects of carbamazepine are typically evident within the first several days of treatment. About 50 to 70 percent of all persons respond within 2 to 3 weeks of initiation. Studies suggest that carbamazepine may be especially useful in persons who are not responsive to lithium (Eskalith), such as persons with dysphoric mania, rapid cycling, or an adverse family history of mood disorders. The antimanic effects of carbamazepine can be, and often are, augmented by concomitant administration of lithium, valproic acid (Depakene), thyroid hormones, DRAs, or SDAs. Some persons may respond to carbamazepine but not lithium or valproic acid and vice versa.

PROPHYLAXIS. Carbamazepine is effective in preventing relapses, particularly among patients with bipolar II disorder and schizoaffective disorder, and dysphoric mania.

ACUTE DEPRESSION. A subgroup of treatment-refractory patients with acute depression responds well to carbamazepine. Patients with more severe episodic and less chronic depression seem to be better responders to carbamazepine. Nevertheless, carbamazepine remains an alternative drug for depressed persons who have not responded to conventional treatments, including ECT.

OTHER DISORDERS. Carbamazepine helps to control symptoms associated with acute alcohol withdrawal, although benzodiazepines are more effective in this population. Carbamazepine has been suggested as a treatment for the recurrent paroxysmal component of PTSD. Uncontrolled studies suggest that carbamazepine is effective in controlling impulsive, aggressive behavior in nonpsychotic persons of all ages, including children and elderly persons. Carbamazepine is also effective in controlling nonacute agitation and aggressive behavior in patients with schizophrenia and schizoaffective disorder. Persons with prominent positive symptoms (e.g., hallucinations) may be likely to respond, as are persons who display impulsive aggressive outbursts.

Precautions and Adverse Reactions. Carbamazepine is relatively well tolerated. Mild GI (nausea, vomiting, gastric distress, constipation, diarrhea, and anorexia) and CNS (ataxia, drowsiness) side effects are the most common. The severity of these adverse effects is reduced if the dosage of carbamazepine is increased slowly and kept at the minimal effective plasma concentration. In contrast to lithium and valproate (other drugs used to manage bipolar disorder), carbamazepine does not appear to cause weight gain. Because of the phenomena of autoinduction, with consequent reductions in carbamazepine concentrations, side effect tolerability may improve over time. Most of the adverse effects of carbamazepine are correlated with plasma concentrations above 9 μg/mL. The rarest but most serious adverse effects of carbamazepine are blood dyscrasias, hepatitis, and severe skin reactions (Table 21-38).

BLOOD DYSCRASIAS. The drug's hematologic effects are not dose-related. Severe blood dyscrasias (aplastic anemia, agranulocytosis) occur in about 1 in 125,000 persons treated with carbamazepine. There does not appear to be a correlation between the degree of benign WBC suppression (leukopenia), which is seen in 1 to 2 percent of persons, and the emergence of life-threatening blood dyscrasias. Persons should be warned that the emergence of such symptoms as fever, sore throat, rash, petechiae, bruising, and easy bleeding can potentially herald a serious dyscrasia, and they should seek medical evaluation immediately. Routine hematologic monitoring in carbamazepine-treated persons is recommended at 3, 6, 9, and 12 months. If there is no significant evidence of bone marrow suppression by that time, many experts will reduce the interval of monitoring. However, even assiduous monitoring may fail to detect severe blood dyscrasias before they cause symptoms.

Table 21-38
Adverse Events Associated with Carbamazepine

Dosage-Related Adverse Effects	Idiosyncratic Adverse Effects
Double or blurred vision	Agranulocytosis
Vertigo	Stevens–Johnson syndrome
Gastrointestinal disturbances	Aplastic anemia
Task performance impairment	Hepatic failure
Hematologic effects	Rash Pancreatitis

HEPATITIS. Within the first few weeks of therapy, carbamazepine can cause both hepatitis associated with increases in liver enzymes, particularly transaminases, and cholestasis associated with elevated bilirubin and alkaline phosphatase. Mild transaminase elevations warrant observation only, but persistent elevations more than three times the upper limit of normal indicate the need to discontinue the drug. Hepatitis can recur if the drug is reintroduced to the person and can result in death.

DERMATOLOGIC EFFECTS. About 10 to 15 percent of those treated with carbamazepine develop a benign maculopapular rash within the first 3 weeks of treatment. Stopping the medication usually leads to resolution of the rash. Some patients may experience life-threatening dermatologic syndromes, including exfoliative dermatitis, erythema multiforme, Stevens–Johnson syndrome, and toxic epidermal necrolysis. The possible emergence of these serious dermatologic problems causes most clinicians to discontinue carbamazepine use in people who develop any rash. The risk of drug rash is about equal between valproic acid and carbamazepine in the first 2 months of use but is subsequently much higher for carbamazepine. If carbamazepine seems to be the only effective drug for a person who has a benign rash with carbamazepine treatment, a retrial of the drug can be undertaken. Many patients can be rechallenged without reemergence of the rash. Pretreatment with prednisone (Deltasone; 40 mg a day) may suppress the rash, although other symptoms of an allergic reaction (e.g., fever and pneumonitis) may develop even with steroid pretreatment.

RENAL EFFECTS. Carbamazepine is occasionally used to treat diabetes insipidus not associated with lithium use. This activity results from direct or indirect effects at the vasopressin receptor. It may also lead to the development of hyponatremia and water intoxication in some patients, mainly elderly persons, or when used in high doses.

OTHER ADVERSE EFFECTS. Carbamazepine decreases cardiac conduction (although less than the tricyclic drugs do) and can thus exacerbate preexisting cardiac disease. Carbamazepine should be used with caution in persons with glaucoma, prostatic hypertrophy, diabetes, or a history of alcohol abuse. Carbamazepine occasionally activates vasopressin receptor function, which results in a condition resembling the syndrome of secretion of inappropriate antidiuretic hormone, characterized by hyponatremia and, rarely, water intoxication. This effect is the opposite of the renal effects of lithium (i.e., nephrogenic diabetes insipidus). Augmentation of lithium with carbamazepine does not reverse the lithium effect, however. The emergence of confusion, severe weakness, or headache in a person taking carbamazepine should prompt the measurement of serum electrolytes.

Carbamazepine use rarely elicits an immune hypersensitivity response

consisting of fever, rash, eosinophilia, and possibly fatal myocarditis.

Cleft palate, fingernail hypoplasia, microcephaly, and spina bifida in infants may be associated with the maternal use of carbamazepine during pregnancy. Pregnant women should not use carbamazepine unless necessary. All women with childbearing potential should take 1 to 4 mg of folic acid daily, even if they are not trying to conceive. Carbamazepine is secreted in breast milk.

Drug Interactions. Carbamazepine decreases serum concentrations of numerous drugs as a result of the prominent induction of hepatic CYP3A4 (Table 21-39). Monitoring for a decrease in clinical effects is frequently indicated. Carbamazepine can decrease the blood concentrations of oral contraceptives, resulting in breakthrough bleeding and uncertain prophylaxis against pregnancy. Carbamazepine should not be administered with MAOIs, which should be discontinued at least 2 weeks before initiating treatment with carbamazepine. Grapefruit juice inhibits the hepatic metabolism of carbamazepine. When carbamazepine and valproate are used in combination, the dosage of carbamazepine should be decreased because valproate displaces carbamazepine binding on proteins, and the dosage of valproate may need to be increased.

Table 21-39
Carbamazepine: Drug Interactions

Effect of Carbamazepine on Plasma Concentrations of Concomitant Agents	Agents that May Affect Carbamazepine Plasma Concentrations
Carbamazepine may decrease drug plasma concentration of:	*Agents that may increase carbamazepine plasma concentration:*
Acetaminophen	Allopurinol
Alprazolam	Cimetidine
Amitriptyline	Clarithromycin
Bupropion	Danazol
Clomipramine	Diltiazem
Clonazepam	Erythromycin
Clozapine	

- Cyclosporine
- Desipramine
- Dicumarol
- Doxepin
- Doxycycline
- Ethosuximide
- Felbamate
- Fentanyl
- Fluphenazine
- Haloperidol
- Hormonal contraceptives
- Imipramine
- Lamotrigine
- Methadone
- Methsuximide
- Methylprednisolone
- Nimodipine
- Pancuronium
- Phensuximide
- Phenytoin
- Primidone
- Theophylline
- Valproate
- Warfarin

Carbamazepine may increase drug plasma concentrations of

- Clomipramine
- Phenytoin
- Primidone
- Fluoxetine
- Fluvoxamine
- Gemfibrozil
- Itraconazole
- Ketoconazole
- Isoniazid[a]
- Itraconazole
- Lamotrigine
- Loratadine
- Macrolides
- Nefazodone
- Nicotinamide
- Propoxyphene
- Terfenadine
- Troleandomycin
- Valproate[a]
- Verapamil
- Viloxazine

Drugs that may decrease carbamazepine plasma concentrations

- Carbamazepine (autoinduction)
- Cisplatin
- Doxorubicin HCl
- Felbamate
- Phenobarbital
- Phenytoin
- Primidone
- Rifampin[b]
- Theophylline
- Valproate

[a]Increased concentrations of the active 10,11-epoxide.

[b]Decreased concentrations of carbamazepine and increased concentrations of the 10,11-epoxide.

Table by Carlos A. Zarate, Jr., M.D. and Mauricio Tohen, M.D.

Laboratory Interferences. Circulating levels of thyroxine and triiodothyronine are associated with a decrease in TSH and may be associated with treatment. Carbamazepine is also associated with an increase in total serum cholesterol, primarily by increasing high-density lipoproteins. The thyroid and cholesterol effects are not clinically significant. Carbamazepine may interfere with the dexamethasone (Decadron) suppression test and may also cause false-positive pregnancy test results.

Dosing and Administration. The target dose for antimanic activity is 1,200 mg a day, although this varies considerably. Immediate-release carbamazepine needs to be taken three or four times a day, which leads to lapses in compliance. Extended-release formulations are thus preferred because they can be taken once or twice a day. One form of extended-release carbamazepine, Carbatrol, comes as 100-, 200-, and 300-mg capsules. Another form, Equetro, is identical to Carbatrol and is marketed as a treatment for bipolar disorder. These capsules contain tiny beads with three different types of coatings, so they dissolve at different times. Capsules should not be crushed or chewed. However, the contents can be sprinkled over food without affecting the extended-release qualities. This formulation can be taken either with or without meals. The entire daily dose can be given at bedtime. The rate of absorption is faster when it is given with a high-fat meal. Another extended-release form of carbamazepine, Tegretol XR, uses a different drug-delivery system than Carbatrol. It is available in 100-, 200-, and 300-mg tablets.

Preexisting hematologic, hepatic, and cardiac diseases can be relative contraindications for carbamazepine treatment. Persons with hepatic disease require only one-third to one-half the usual dosage; the clinician should be cautious about raising the dosage in such persons and should do so only slowly and gradually. The laboratory examination should include a CBC with platelet count, liver function tests, serum electrolytes, and an electrocardiogram in persons older than 40 years of age or with preexisting cardiac disease. An electroencephalogram is not necessary before the initiation of treatment, but it may be helpful in some cases for the documentation of objective changes correlated with clinical improvement. Table 21-40 presents a brief user's guide to carbamazepine in bipolar disorder.

Routine Laboratory Monitoring. Serum levels for antimanic efficacy have not been established. The anticonvulsant blood concentration range for carbamazepine is 4 to 12 µg/mL, and this range should be reached before determining that carbamazepine is not effective in the treatment of a mood disorder. A clinically insignificant suppression of the WBC count commonly occurs during carbamazepine treatment. This benign decrease can be reversed by adding lithium, which enhances colony-stimulating factor. Potential serious hematologic effects of carbamazepine, such as pancytopenia, agranulocytosis, and aplastic anemia, occur in about 1 in 125,000 patients. Complete laboratory blood assessments may be performed every 2 weeks for the first 2 months of treatment and quarterly after that, but the FDA has revised the package insert for carbamazepine to suggest that blood monitoring be performed at the discretion of the physician. Patients should be informed that fever, sore throat, rash, petechiae, bruising, or unusual bleeding may indicate a hematologic problem and should prompt immediate notification of a physician. This approach is probably more useful than is frequent blood monitoring during long-term treatment. It has also been suggested that liver and renal function tests be conducted quarterly, although the benefit of conducting tests this frequently has been questioned. It seems reasonable, however, to assess hematologic status, along with liver and renal functions, whenever a routine examination of the person is being conducted. A monitoring protocol is listed in Table 21-41.

Table 21-40
Carbamazepine in Bipolar Illness: A Brief User's Guide

1. Start with low (200 mg) bedtime dose in depression or euthymia; higher doses (600–800 mg/day in divided doses) in manic inpatients.
2. All bedtime dosing is reasonable with carbamazepine extended-release preparation.
3. Titrate slowly to the individual's response or side effects threshold.
4. Hepatic enzyme CYP450 (3A4) induction and autoinduction occur in 2–3 wk; slightly higher doses may be needed or tolerated at that time.

5. Warn regarding benign rash, which occurs in 5–10% of those taking the drug; progression to rare, severe rash is unpredictable, so the drug should be discontinued if any rash develops.
6. Benign white blood cell count decreases occur regularly (usually inconsequential).
7. Rarely, agranulocytosis and aplastic anemia may develop (several per million new exposures); warn regarding appearance of fever, sore throat, petechiae, and bleeding gums and to check with physician to obtain an immediate complete blood cell count.
8. Use adequate birth control methods, including higher dosage forms of estrogen (as carbamazepine lowers estrogen levels).
9. Avoid carbamazepine in pregnancy (spina bifida occurs in 0.5%; other severe adverse outcomes occur in about 8%).
10. Some people will respond well to carbamazepine and not other mood stabilizers (lithium) or anticonvulsants (valproic acid).
11. Combination treatment often required to maintain remission and prevent loss of effect via tolerance.
12. Major drug interactions associated with increases in carbamazepine and potential toxicity from 3A4 enzyme inhibition include calcium channel blockers (isradipine and verapamil); erythromycin and related macrolide antibiotics; and valproate.

Carbamazepine treatment should be discontinued, and a consult with a hematologist should be obtained, if the following laboratory values are found: total WBC count below 3,000/mm^3, erythrocytes below 4.0 × 10^6/mm^3, neutrophils below 1,500/mm^3, hematocrit less than 32 percent, hemoglobin less than 11 g/100 mL, platelet count below 100,000/mm^3, reticulocyte count below 0.3 percent, and a serum iron concentration below 150 mg/100 mL.

Table 21-41
Laboratory Monitoring of Carbamazepine for Adult Psychiatric Disorders

	Baseline	Weekly to Stability	Monthly for 6 Months	6–12 Months
CBC	+	+	+	+
Bilirubin	+		+	+
Alanine aminotransferase	+		+	+
Aspartate aminotransferase	+		+	+
Alkaline phosphatase	+		+	+
Carbamazepine level	+	+		+

CBC, complete blood count.

Oxcarbazepine

Although structurally related to carbamazepine, the usefulness of oxcarbazepine as a treatment for mania has not been established in controlled trials.

Pharmacokinetics. Absorption is rapid and unaffected by food. Peak concentrations occur after about 45 minutes. The elimination half-life of the parent compound is 2 hours, which remains stable over long-term treatment. The monohydroxide has a half-life of 9 hours. Most of the drug's anticonvulsant activity is presumed to result from this monohydroxy derivative.

Side Effects. The most common side effects are sedation and nausea. Less frequent side effects are cognitive impairment, ataxia, diplopia, nystagmus, dizziness, and tremor. In contrast to carbamazepine, oxcarbazepine does not have an increased risk of severe blood dyscrasias, so hematologic monitoring is not necessary. The frequency of benign rash is lower than observed with carbamazepine, and severe rashes are extremely rare. However, about 25 to 30 percent of patients who develop an allergic rash while taking carbamazepine also develop a rash with oxcarbazepine. Oxcarbazepine is

more likely to cause hyponatremia than carbamazepine. Approximately 3 to 5 percent of patients taking oxcarbazepine develop this side effect. It is advisable to obtain serum sodium concentrations early in the course of treatment because hyponatremia may be clinically silent. In severe cases, confusion and seizure may occur.

Dosing and Administration. Oxcarbazepine dosing for bipolar disorder has not been established. It is available in 150-, 300-, and 600-mg tablets. The dose range may vary from 150 to 2,400 mg/day, given in divided doses twice a day. In clinical trials for mania, the doses typically used were from 900 to 1,200 mg/day with a starting dose of 150 or 300 mg at night.

Drug Interactions. Drugs such as phenobarbital and alcohol, which induce CYP34A, increase clearance and reduce oxcarbazepine concentrations. Oxcarbazepine induces CYP3A4/5 and inhibits CYP2C19, which may affect the metabolism of drugs that use that pathway. Women taking oral contraceptives should be told to consult with their gynecologists, because oxcarbazepine may reduce concentrations of their contraceptive and thus decrease its efficacy.

OTHER ANTICONVULSANTS

The anticonvulsants described in this section were developed for the treatment of epilepsy but were also found to have beneficial effects in psychiatric disorders. Also, these agents are used as skeletal muscle relaxants and in neurogenic pain. These drugs have a variety of mechanisms, including increasing GABAergic function or decreasing glutamatergic function. This section includes seven anticonvulsants: gabapentin (Neurontin), levetiracetam (Keppra), pregabalin (Lyrica), tiagabine (Gabitril), topiramate (Topamax), and zonisamide (Zonegran), as well as one of the first used anticonvulsants, phenytoin (Dilantin). Carbamazepine (Tegretol), valproate (Depakene, Depakote), lamotrigine (Lamictal), and oxcarbazepine (Trileptal) are discussed in separate sections.

In 2008, the FDA issued a warning that these drugs may increase the risk of suicidal ideation or act in some persons compared with placebo; however, the relative risk for suicidality was higher in patients with epilepsy compared with those with psychiatric disorders. However, some published data contradict this warning. These studies suggest that anticonvulsants may have a protective effect on suicidal thoughts in bipolar disorder. Considering the inherently increased risk of suicide in persons with bipolar disorder, clinicians should be aware of these warnings.

Gabapentin

Gabapentin was first introduced as an antiepileptic drug and was found to have sedative effects that were useful in some psychiatric disorders, especially insomnia. It was also found to be beneficial in reducing neuropathic pain, including postherpetic neuralgia. It is used in anxiety disorders (social phobia and panic disorder), but not as the primary intervention in mania or treatment-resistant mood disorders.

Pharmacologic Actions. Gabapentin circulates in the blood primarily unbound and is not appreciably metabolized in humans. It is eliminated unchanged by renal excretion and can be removed by hemodialysis. Food only moderately affects the rate and extent of absorption. Clearance is decreased in elderly persons, requiring dosage adjustments. Gabapentin

appears to increase cerebral GABA and may inhibit glutamate synthesis as well. It increases human whole blood serotonin concentrations and modulates calcium channels to reduce monoamine release. It has antiseizure as well as antispastic activity and antinociceptive effects in pain.

Therapeutic Indications. In neurology, gabapentin is used for the treatment of both general and partial seizures. It is useful in reducing the pain of postherpetic neuralgia and other pain syndromes associated with diabetic neuropathy, neuropathic cancer pain, fibromyalgia, meralgia paresthetica, amputation, and headache. It is useful in some cases of chronic pruritus.

In psychiatry, gabapentin is used as a hypnotic agent because of its sedating effects. It has anxiolytic properties and benefits patients with social anxiety and panic disorder. It may decrease the craving for alcohol in some patients and improve mood as well; hence, it may have some use in depressed patients. Some bipolar patients have benefited when gabapentin is used adjunctively with mood stabilizers.

Precautions and Adverse Reactions. Adverse effects are mild, with the most common being daytime somnolence, ataxia, and fatigue, which are usually dose-related. Overdose (over 45 g) has been associated with diplopia, slurred screech, lethargy, and diarrhea, but all patients recovered. The drug was classified as pregnancy category C in the former FDA classification system and is excreted in breast milk, so it is best to avoid it in pregnant women and nursing mothers.

Drug Interactions. Gabapentin bioavailability may decrease as much as 20 percent when administered with antacids. In general, there are no drug interactions. Chronic use does not interfere with lithium administration.

Laboratory Interferences. Gabapentin does not interfere with any laboratory tests, although spontaneous reports of false-positive drug toxicology screenings for amphetamines, barbiturates, benzodiazepines, and marijuana have been reported.

Dosages and Clinical Guidelines. Gabapentin is well tolerated, and the dosage can be increased to the maintenance range within a few days. A

general approach is to start with 300 mg on day 1, increase to 600 mg on day 2, 900 mg on day 3, and subsequently increase up to 1,800 mg/day in divided doses as needed to relieve symptoms. Final total daily doses tend to be between 1,200 and 2,400 mg/day, but occasionally results may be achieved with dosages as low as 200 to 300 mg/day, especially in elderly persons. Sedation is usually the limiting factor in determining the dosage. Some patients have taken dosages as high as 4,800 mg/day.

Gabapentin is available as 100-, 300-, and 400-mg capsules and as 600- and 800-mg tablets. A 250-mg/5-mL oral solution is also available. Although abrupt discontinuation of gabapentin does not cause withdrawal effects, the use of all anticonvulsant drugs should be gradually tapered.

Topiramate

Topiramate (Topamax) was developed as an anticonvulsant and was found useful in a variety of psychiatric and neurologic conditions, including migraine prevention, treatment of obesity, bulimia, binge eating, and alcohol dependence.

Pharmacologic Actions. Topiramate has GABAergic effects and increases cerebral GABA in humans. It has 80 percent oral bioavailability and is not significantly altered by food. It is 15 percent protein-bound, and about 70 percent of the drug is eliminated by renal excretion. With renal insufficiency, topiramate clearance decreases by about 50 percent, so the dosage needs to be decreased. It has a half-life of around 24 hours.

Therapeutic Indications. Topiramate is used mainly as an antiepileptic medication and has been found superior to placebo as monotherapy in patients with seizure disorders. It is also used in the prevention of migraine, smoking cessation, pain syndromes (e.g., low back pain), PTSD, and essential tremor. The drug has been associated with weight loss, and that fact has been used to counteract the weight gain caused by many psychotropic drugs. It has also been used in general obesity and the treatment of bulimia and binge-eating disorder. Self-mutilating behavior may be decreased in borderline personality disorder. It is of little or no benefit in the treatment of psychotic disorders. In one study, the combination of topiramate with bupropion (Wellbutrin) showed some efficacy in bipolar depression, but

double-blind, placebo-controlled trials failed to demonstrate topiramate monotherapy efficacy in acute mania in adults.

Precautions and Adverse Reactions. The most common adverse effects of topiramate include paresthesias, weight loss, somnolence, anorexia, dizziness, and memory problems. Sometimes disturbances in the sense of taste occur. In many cases, the adverse effects are mild to moderate and can be attenuated by decreasing the dose. No deaths have been reported during an overdose. The drug affects acid–base balance (low serum bicarbonate), which can be associated with cardiac arrhythmias and the formation of renal calculi in about 1.5 percent of cases. Patients taking the drug should be encouraged to drink plenty of fluids. It is not known if the drug passes through the placenta or is present in breast milk, and pregnant women or nursing mothers should avoid it.

Drug Interactions. Topiramate has few drug interactions with other anticonvulsant drugs. Topiramate may increase phenytoin concentrations up to 25 percent and valproic acid 11 percent; it does not affect the concentration of carbamazepine, phenobarbital (Luminal), or primidone. Topiramate concentrations are decreased by 40 to 48 percent with concomitant administration of carbamazepine or phenytoin. We should not combine topiramate with other carbonic anhydrase inhibitors, as it increases the risk of nephrolithiasis or heat-related problems (oligohidrosis and hyperthermia). These include acetazolamide (Diamox) or dichlorphenamide (Daranide).

Laboratory Interferences. Topiramate does not interfere with any laboratory tests.

Dosages and Clinical Guidelines. Topiramate is available as unscored 25-, 100-, and 200-mg tablets. Topiramate dosage is titrated gradually over 8 weeks to a maximum of 200 mg twice a day to reduce the risk of adverse cognitive and sedative effects. Off-label topiramate is typically used adjunctively, starting with 25 mg at bedtime and increasing weekly by 25 mg as necessary and tolerated. Final doses in efforts to promote weight loss are often between 75 and 150 mg/day at bedtime. Doses higher than 400 mg are not associated with increased efficacy. All of the doses can be given at

bedtime to take advantage of the sedative effects. Persons with renal insufficiency should reduce doses by half.

Tiagabine

Tiagabine was introduced as a treatment for epilepsy in 1997 and was found to have efficacy in some psychiatric conditions, including acute mania. However, safety concerns (see later), along with a lack of controlled data, have limited the use of tiagabine in disorders other than epilepsy.

Pharmacologic Actions. Tiagabine is well absorbed with a bioavailability of about 90 percent and is extensively (96 percent) bound to plasma proteins. Tiagabine is a cytochrome P450 CYP3A substrate and is extensively transformed into inactive 5-oxo-tiagabine and glucuronide metabolites, with only 2 percent being excreted unchanged in the urine. The remainder is excreted as metabolites in the feces (65 percent) and the urine (25 percent). Tiagabine blocks the uptake of the inhibitory amino acid neurotransmitter GABA into neurons and glia, enhancing the inhibitory action of GABA at both $GABA_A$ and $GABA_B$ receptors, putatively yielding anticonvulsant and antinociceptive effects, respectively. It has mild blocking effects on histamine 1 (H_1), serotonin type 1B ($5\text{-}HT_{1B}$), benzodiazepine, and chloride channel receptors.

Therapeutic Indications. Tiagabine is rarely used for psychiatric disorders, and then it is used only for GAD and insomnia. Its main indication is in generalized epilepsy.

Precautions and Adverse Reactions. Tiagabine may cause withdrawal seizures, cognitive or neuropsychiatric problems (impaired concentration, speech or language problems, somnolence, and fatigue), status epilepticus, and sudden unexpected death in epilepsy (SUDEP). Acute oral overdoses of tiagabine have been associated with seizures, status epilepticus, coma, ataxia, confusion, somnolence, drowsiness, impaired speech, agitation, lethargy, myoclonus, stupor, tremors, disorientation, vomiting, hostility, temporary paralysis, and respiratory depression. Deaths have been reported in polydrug overdoses involving tiagabine. Cases of severe rash may occur, including

Stevens–Johnson syndrome.

Tiagabine was classified as pregnancy category C in the former FDA classification system because fetal loss and teratogenicity have been demonstrated in animals. It is not known if the drug is excreted in breast milk. Pregnant women and nursing mothers should not be given the drug.

Laboratory Tests. Tiagabine does not interfere with any laboratory tests.

Dosage and Administration. Tiagabine should not be rapidly loaded or rapidly initiated because of the risk of severe adverse effects. In adults and adolescents 12 years of age or older with epilepsy who are also taking enzyme inducers, tiagabine should be initiated at 4 mg/day and increased weekly by 4 mg/day during the first month. The dose should then be increased weekly by 4 to 8 mg/day for weeks 5 and 6, yielding 24 to 32 mg/day administered in two to four divided doses by week 6. In adults (but not adolescents), tiagabine doses may be further increased weekly by 4 to 8 mg/day to as high as 56 mg/day. Plasma concentrations in patients with epilepsy commonly range between 20 and 100 ng/mL but do not appear to be systematically related to antiseizure effects and thus are not routinely monitored.

Levetiracetam

Initially developed as a nootropic (memory enhancing) drug, levetiracetam proved to be a potent anticonvulsant and marketed as a treatment for partial seizures. It has been used to treat acute mania and anxiety and to augment antidepressant drug therapy.

Pharmacologic Actions. The CNS effects are not well understood, but it appears to enhance GABA inhibition indirectly. It is wholly and rapidly absorbed, and peak concentrations are reached in 1 hour. Food delays the rate of absorption and decreases the amount of absorption. Levetiracetam is not significantly plasma protein-bound and is not metabolized through the hepatic CYP system. Its metabolism involves the hydrolysis of the acetamide group. Serum concentrations are not correlated with therapeutic effects.

Therapeutic Indications. The primary indication is for the treatment of

convulsive disorders, including partial-onset seizures, myoclonic seizures, and idiopathic generalized epilepsy. In psychiatry, levetiracetam has been used off label to treat acute mania, as an add-on treatment for major depression, and as an anxiolytic agent.

Precautions and Adverse Reactions. The most common side effects of levetiracetam include drowsiness, dizziness, ataxia, diplopia, memory impairment, apathy, and paresthesias. Some patients develop behavioral disturbances during treatment, and hallucinations may occur. Suicidal patients may become agitated. It should not be used in pregnant or lactating women.

Drug Interactions. There are few if any interactions with other drugs, including other anticonvulsants. There is no interaction with lithium.

Laboratory Interferences. No laboratory interferences have been reported.

Dosages and Clinical Guidelines. The drug is available as 250-, 500-, 750-, and 1,000-mg tablets; 500-mg extended-release tablets; a 100-mg/mL oral solution; and a 100-mg/mL intravenous solution. In epilepsy, the typical adult daily dose is 1,000 mg.

Because of its renal clearance, dosages should be reduced in patients with impaired renal function.

Zonisamide

Zonisamide, another anticonvulsant, was also found to be useful in bipolar disorder, obesity, and binge-eating disorder.

Pharmacologic Actions. Zonisamide blocks sodium channels and may weakly potentiate dopamine and serotonin activity. It also inhibits carbonic anhydrase. Some evidence suggests that it may block calcium channels. The hepatic CYP3A system metabolizes zonisamide, so enzyme-inducing agents such as carbamazepine, alcohol, and phenobarbital increase the clearance and reduce the availability of the drug. Zonisamide does not affect the metabolism of other drugs. It has a long half-life of 60 hours, so it is

efficiently dosed once daily, preferably at nighttime.

Therapeutic Indications. Its primary use is in the treatment of generalized seizure disorders and refractory partial seizures. In psychiatry, controlled studies found it to be of use in obesity and binge-eating disorder. Uncontrolled trials have found it useful in bipolar disorder, particularly mania; however, further studies are warranted for this indication.

Precautions and Adverse Reactions. Zonisamide is a sulfonamide and thus may cause a fatal rash and blood dyscrasias, although these events are rare. About 4 percent of patients develop kidney stones. The most common side effects are drowsiness, cognitive impairment, insomnia, ataxia, nystagmus, paresthesia, speech abnormalities, constipation, diarrhea, nausea, and dry mouth. Weight loss is also a common side effect, which has been exploited as a therapy for patients who have gained weight during treatment with psychotropics or, as mentioned above, have ongoing difficulty controlling their eating. Zonisamide should not be used in pregnant women or breastfeeding mothers.

Drug Interactions. Zonisamide does not inhibit CYP isoenzymes and does not instigate drug interactions. It is important not to combine carbonic anhydrase inhibitors with zonisamide because of an increased risk of nephrolithiasis related to increased blood levels of urea.

Laboratory Interferences. Zonisamide can elevate hepatic alkaline phosphatase and increase blood urea nitrogen and creatinine.

Dosages and Clinical Guidelines. Zonisamide is available in 100- and 200-mg capsules. In epilepsy, the dosage range is 100 to 400 mg/day, with side effects becoming more pronounced at doses above 300 mg. Because of its long half-life, zonisamide can be given once a day.

Pregabalin

Pregabalin is pharmacologically similar to gabapentin. It is believed to work by inhibiting the release of excess excitatory neurotransmitters. It increases neuronal GABA levels, its binding affinity is six times greater than that of

gabapentin, and it has a longer half-life.

Pharmacologic Actions. Pregabalin exhibits linear pharmacokinetics. It is rapidly absorbed in proportion to its dose. The time to maximal plasma concentration is about 1 hour, and to steady state is within 24 to 48 hours. Pregabalin demonstrates high bioavailability, and it has a mean elimination half-life of about 6.5 hours. Food does not affect absorption. Pregabalin does not bind to plasma proteins and is excreted virtually unchanged (<2 percent metabolism) by the kidneys. It is not subject to hepatic metabolism and does not induce or inhibit liver enzymes. Dose reduction may be necessary for patients with creatinine clearance (CLcr) less than 60 mL/min. Daily doses should be further reduced by approximately 50 percent for each additional 50 percent decrease in CLcr. Pregabalin is highly cleared by hemodialysis so that additional doses may be needed for patients on chronic hemodialysis treatment after each hemodialysis treatment.

Therapeutic Indications. Pregabalin is approved for the management of diabetic peripheral neuropathy and postherpetic neuralgia and adjunctive treatment of partial-onset seizures. It is of benefit to some patients with GAD. In studies, no consistent dose–response relationship was found, although 300 mg of pregabalin per day was more effective than 150 or 450 mg. Some patients with panic disorder or social anxiety disorder may benefit from pregabalin, but little evidence supports its routine use in treating persons with these disorders. It was most recently approved for the treatment of fibromyalgia.

Precautions and Adverse Reactions. The most common adverse events associated with pregabalin use are dizziness, somnolence, blurred vision, peripheral edema, amnesia or loss of memory, and tremors. Pregabalin potentiates the sedating effects of alcohol, antihistamines, benzodiazepines, and other CNS depressants. It remains to be seen if pregabalin is associated with benzodiazepine-type withdrawal symptoms. There are scant data about its use in pregnant women or nursing mothers, and it is best avoided in these patients.

Drug Interactions. Given the absence of hepatic metabolism, pregabalin

lacks metabolic drug interactions.

Laboratory Interferences. There are no effects on laboratory tests.

Dosage and Clinical Guidelines. The recommended dose for postherpetic neuralgia is 50 or 100 mg orally three times a day. The recommended dose for diabetic peripheral neuropathy is 100 to 200 mg orally three times a day. Patients with fibromyalgia may require up to 450 to 600 mg/day given in divided doses. Pregabalin is available as 25-, 50-, 75-, 100-, 150-, 200-, 225-, and 300-mg capsules.

Phenytoin

Phenytoin sodium (Dilantin) is an antiepileptic drug and is related to the barbiturates in chemical structure. It is indicated for the control of generalized tonic–clonic (grand mal) and complex partial (psychomotor, temporal lobe) seizures and prevention and treatment of seizures occurring during or after neurosurgery. Studies have shown comparable efficacy of phenytoin to other anticonvulsants in bipolar disorder, but clinicians should take into account the danger of gingival hyperplasia, leukopenia, or anemia and the danger of toxicity caused by nonlinear pharmacokinetics.

Pharmacologic Action. Similar to other anticonvulsants, phenytoin causes blockade of voltage-activated sodium channels and hence is efficacious as an antimanic agent. The plasma half-life after oral administration averages 22 hours, with a range of 7 to 42 hours. Steady-state therapeutic levels are achieved at least 7 to 10 days (5 to 7 half-lives) after initiation of therapy, with recommended doses of 300 mg/day. Serum level should be obtained at least 5 to 7 half-lives after treatment initiation. Phenytoin is excreted in the bile, which is then reabsorbed from the intestinal tract and excreted in the urine. Urinary excretion of phenytoin occurs partly with glomerular filtration and by tubular secretion. Small incremental doses of phenytoin may increase the half-life and produce very substantial increases in serum levels. Patients should adhere strictly to the prescribed dosage, and serial monitoring of phenytoin levels is recommended.

Therapeutic Indications. Apart from its indication in generalized tonic–

clonic (grand mal) and complex partial (psychomotor, temporal lobe) seizures, phenytoin is also used for the treatment of acute mania in bipolar disorder.

Precautions and Adverse Reactions. The most common adverse reactions reported with phenytoin therapy are usually dose-related and include nystagmus, ataxia, slurred speech, decreased coordination, and mental confusion. Other side effects include dizziness, insomnia, transient nervousness, motor twitching, and headaches. There have been rare reports of phenytoin induced dyskinesias, similar to those induced by phenothiazine and other neuroleptic drugs. More severe side effects include thrombocytopenia, leukopenia, agranulocytosis, and pancytopenia, with or without bone marrow suppression.

Several reports have suggested the development of lymphadenopathy (local or generalized), including benign lymph node hyperplasia, pseudolymphoma, lymphoma, and Hodgkin's disease. Prenatal exposure to phenytoin may increase the risks for congenital malformations, and a potentially life-threatening bleeding disorder related to decreased levels of vitamin K–dependent clotting factors may occur in newborns exposed to phenytoin in utero. Hyperglycemia has been reported with phenytoin use; also, the agent may increase the serum glucose level in patients with diabetes.

Drug Interactions. Acute alcohol intake, amiodarone, chlordiazepoxide, cimetidine, diazepam, disulfiram, estrogens, fluoxetine, H_2-antagonists, isoniazid, methylphenidate, phenothiazines, salicylates, and trazodone may increase phenytoin serum levels. Drugs that may lower phenytoin levels include carbamazepine, chronic alcohol abuse, and reserpine.

Laboratory Interferences. Phenytoin may decrease serum concentrations of thyroxine. It may cause increased serum levels of glucose, alkaline phosphatase, and γ-glutamyl transpeptidase.

Dosage and Clinical Guidelines. Patients may be started on one 100-mg extended oral capsule three times daily, and the dosage then adjusted to suit individual requirements. Patients may then be switched to once-a-day dosing, which is more convenient. In this case, extended-release capsules may be

used. Serial monitoring of phenytoin levels is recommended, and the normal range is usually 10 to 20 µg/mL.

CALCIUM CHANNEL BLOCKERS

The intracellular calcium ion regulates the activity of multiple neurotransmitters such as serotonin and dopamine, and that action may account for its role as a treatment in mood disorders. Calcium channel inhibitors are used in psychiatry as antimanic agents for persons who are refractory to or cannot tolerate treatment with first-line mood-stabilizing agents such as lithium (Eskalith), carbamazepine (Tegretol), and sodium valproate (Depakote). Calcium channel inhibitors include nifedipine (Procardia, Adalat), nimodipine (Nimotop), isradipine (DynaCirc), amlodipine (Norvasc, Lotrel), nicardipine (Cardene), nisoldipine (Sular), nitrendipine, and verapamil (Calan). They are used for control of mania and ultradian bipolar disorder (mood cycling in less than 24 hours).

The results of a large genetic study have rekindled interest in the potential clinical uses of calcium channel blockers (CCBs). Two genome-wide findings implicated genes encoding L-type voltage-gated calcium channel subunits as susceptibility genes for bipolar disorder, schizophrenia, MDD, ADHD, and autism.

Pharmacologic Actions

The calcium channel inhibitors are nearly completely absorbed after oral use, with significant first-pass hepatic metabolism. Considerable intraindividual and interindividual variations are seen in the plasma concentrations of the drugs after a single dose. Peak plasma levels of most of these agents are achieved within 30 minutes. Amlodipine does not reach peak plasma levels for about 6 hours. The half-life of verapamil after the first dose is 2 to 8 hours; the half-life increases to 5 to 12 hours after the first few days of therapy. The half-lives of the other CCBs range from 1 to 2 hours for nimodipine and isradipine to 30 to 50 hours for amlodipine (Table 21-42).

Table 21-42
Half-Lives, Dosages, and Effectiveness of Selected Calcium Channel Inhibitors in Psychiatric Disorders

	Verapamil (Calan, Isoptin)	Nimodipine (Nimotop)	Isradipine (DynaCirc)	Amlodipine (Norvasc)
Half-Life	Short (5–12 hr)	Short (1–2 hr)	Short (1–2 hr)	Long (30–50 hr)
Starting Dosage	30 mg TID	30 mg TID	2.5 mg BID	5 mg HS
Peak Daily Dosage	480 mg	240–450 mg	20 mg	10–15 mg
Antimanic	++	++	++	[a]
Antidepressant	±	+	+	[a]
Antiultradian[b]	±	++	(++)	[a]

BID, twice a day; HS, bedtime; TID, three times a day.
[a]No systematic studies, only case reports.
[b]Rapid-cycling bipolar disorder.
Adapted from Robert M. Post, M.D.

The primary mechanism of action of CCBs in bipolar illness is not known. The calcium channel inhibitors discussed in this section inhibit the influx of calcium into neurons through L-type (long-acting) voltage-dependent calcium channels.

Therapeutic Indications

Bipolar Disorder. Nimodipine and verapamil have been demonstrated to be effective as maintenance therapy in persons with bipolar illness. Patients who respond to lithium appear to also respond to treatment with verapamil. Nimodipine may be useful for ultradian cycling and recurrent brief depression. The clinician should begin treatment with a short-acting drug such as nimodipine or isradipine, beginning with a low dosage and increasing the dosage every 4 to 5 days until clinical response is seen or adverse effects appear. When symptoms are controlled, a longer-acting drug, such as amlodipine, can be substituted as maintenance therapy. Failure to respond to verapamil does not exclude a favorable response to one of the other drugs. Verapamil has been shown to prevent antidepressant-induced mania. The CCBs can be combined with other agents, such as carbamazepine, in patients who are partial responders to monotherapy.

Depression. None of the CCBs is effective as a treatment for depression and may prevent response to antidepressants.

Other Psychiatric Indications. Nifedipine is used to treat hypertensive crises associated with the use of MAOIs. Isradipine may reduce the subjective response to methamphetamine. Calcium channel inhibitors may be beneficial in Tourette disorder, Huntington disease, panic disorder,

intermittent explosive disorder, and tardive dyskinesia.

Other Medical Uses. These drugs have been used to treat medical conditions such as angina, hypertension, migraine headaches, Raynaud phenomenon, esophageal spasm, premature labor, and headache. Verapamil has antiarrhythmic activity and has been used to treat superventricular arrhythmias.

Precautions and Adverse Reactions

The most common adverse effects associated with calcium channel inhibitors are those attributable to vasodilation: dizziness, headache, tachycardia, nausea, dysesthesias, and peripheral edema. Verapamil and diltiazem (Cardizem), in particular, can cause hypotension, bradycardia, and atrioventricular (AV) heart block, which necessitate close monitoring and sometimes discontinuation of the drugs. In all patients with cardiovascular disease, the drugs should be used with caution. Other common adverse effects include constipation, fatigue, rash, coughing, and wheezing. Adverse effects noted with diltiazem include hyperactivity, akathisia, and parkinsonism; with verapamil, delirium, hyperprolactinemia, and galactorrhea; with nimodipine, subjective sense of chest tightness and skin flushing; and with nifedipine, depression. The drugs have not been evaluated for safety in pregnant women and are best avoided. Because the drugs are secreted in breast milk, nursing mothers should also avoid the drugs.

Drug Interactions

All CCBs have the potential for drug–drug interactions. The types and risks of these interactions vary by the compound. Verapamil raises serum levels of carbamazepine, digoxin, and other CYP3A4 substrates. Verapamil and diltiazem but not nifedipine have been reported to precipitate carbamazepine-induced neurotoxicity. Calcium channel inhibitors should not be used by persons taking β-adrenergic receptor antagonists, hypotensives (e.g., diuretics, vasodilators, and ACEIs), or antiarrhythmic drugs (e.g., quinidine and digoxin) without consultation with an internist or cardiologist. Cimetidine (Tagamet) has been reported to increase plasma concentrations of nifedipine and diltiazem. Some patients who are treated with lithium and

calcium channel inhibitors concurrently may be at increased risk for the signs and symptoms of neurotoxicity, and deaths have occurred.

Laboratory Interferences

No known laboratory interferences are associated with the use of calcium channel inhibitors.

Dosage and Clinical Guidelines

Verapamil is available in 40-, 80-, and 120-mg tablets; 120-, 180-, and 240-mg sustained-release tablets; and 100-, 120-, 180-, 200-, 240-, 300-, and 360-mg sustained-release capsules. The starting dosage is 40 mg orally three times a day and can be increased in increments every 4 to 5 days up to 80 to 120 mg three times a day. The patient's BP, pulse, and electrocardiogram (in patients older than 40 years old or with a history of cardiac illness) should be routinely monitored.

Nifedipine is available in 10- and 20-mg capsules and 30-, 60-, and 90-mg extended-release tablets. The administration should be started at 10 mg orally three or four times a day and can be increased up to a maximum dosage of 120 mg a day.

Nimodipine is available in 30-mg capsules. It has been used at 60 mg every 4 hours for ultra–rapid-cycling bipolar disorder and sometimes briefly at up to 360 mg/day.

Isradipine is available in 2.5- and 5-mg capsules, with a maximum of 20 mg/day. An extended-release formulation of isradipine has been discontinued.

Amlodipine is available in 2.5-, 5-, and 10-mg tablets. The administration should start at 5 mg once at night and can be increased to a maximum dosage of 10 to 15 mg a day.

Diltiazem is available in 30-, 60-, 90-, and 120-mg tablets; 60-, 90-, 120-, 180-, 240-, 300-, and 360-mg extended-release capsules; and 60-, 90-, 120-, 180-, 240-, 300-, and 360-mg extended-release tablets. The administration should start with 30 mg orally four times a day and can be increased up to a maximum of 360 mg a day.

Elderly persons are more sensitive to calcium channel inhibitors than are younger adults. No specific information is available regarding the use of the

agents for children.

21.4 Anxiolytics

BENZODIAZEPINES AND DRUGS ACTING ON GABA RECEPTORS

The first benzodiazepine to be introduced was chlordiazepoxide (Librium), in 1959. In 1963, diazepam (Valium) became available. Over the next three decades, superior safety and tolerability helped the benzodiazepines replace the older antianxiety and hypnotic medications, such as the barbiturates and meprobamate (Miltown). Dozens of benzodiazepines and drugs acting on benzodiazepine receptors have been synthesized and marketed worldwide. Many of these agents are not available in the United States. Also, some benzodiazepines have been discontinued because of a lack of use. Table 21-43 lists agents currently available in the United States.

The benzodiazepines derive their name from their molecular structure. They share a common effect on receptors that have been termed benzodiazepine receptors, which in turn modulate GABA activity. Nonbenzodiazepine agonists, such as zolpidem (Ambien), zaleplon (Sonata), and eszopiclone (Lunesta), are similar to these drugs as they bind at a location close to the benzodiazepine receptor. However, we discuss these with the medications for insomnia. Flumazenil (Romazicon), a benzodiazepine receptor antagonist used to reverse benzodiazepine-induced sedation and in emergency care of benzodiazepine overdosage, is also covered here.

Because benzodiazepines have a rapid anxiolytic sedative effect, they are most commonly used for acute treatment of insomnia, anxiety, agitation, or anxiety associated with any psychiatric disorder. Also, the benzodiazepines are used as anesthetics, anticonvulsants, and muscle relaxants and as the preferred treatment for catatonia. Because of the risk of psychological and physical dependence associated with long-term use of benzodiazepines, ongoing assessment should be made as to the continued clinical need for these drugs in treating patients. In most patients, given the nature of their

disorders, it is often best if benzodiazepine agents are used in conjunction with psychotherapy and when alternative agents have been tried and proven ineffective or poorly tolerated. In many forms of chronic anxiety disorders, antidepressant drugs such as SSRIs and SNRIs are now used as primary treatments, with benzodiazepines used as adjuncts. Benzodiazepine abuse is rare, usually found in patients who abuse multiple prescription and recreational drugs.

Table 21-43
Preparations and Doses of Medications Acting on the Benzodiazepine Receptor Available in the United States

Medication	Brand Name	Dose Equivalent	Usual Adult Dose (mg)	How Supplied
Diazepam	Valium	5	2.5–40.0	2-, 5-, and 10-mg tablets 15-mg slow-release tablets
Clonazepam	Klonopin	0.25	0.5–4.0	0.5-, 1.0-, and 2.0-mg tablets
Alprazolam	Xanax	0.5	0.5–6.0	0.25-, 0.5-, 1.0-, and 2.0-mg tablets 1.5-mg sustained-release tablet
Lorazepam	Ativan	1	0.5–6.0	0.5-, 1.0-, and 2.0-mg tablets 4 mg/mL parenteral
Oxazepam	Serax	15	15–120	7.5-, 10.0-, 15.0-, and 30.0-mg capsules 15-mg tablets
Chlordiazepoxide	Librium	25	10–100	5-, 10-, and 25-mg capsules and tablets
Clorazepate	Tranxene	7.5	15–60	3.75-, 7.50-, and 15.00-mg tablets 11.25- and 22.50-mg slow-release tablets
Midazolam	Versed	0.25	1–50	5 mg/mL parenteral 1-, 2-, 5-, and 10-mL vials
Flurazepam	Dalmane	15	15–30	15- and 30-mg capsules
Temazepam	Restoril	15	7.5–30.0	7.5-, 15.0-, and 30.0-mg capsules
Triazolam	Halcion	0.125	0.125–0.250	0.125- and 0.250-mg tablets
Estazolam	ProSom	1	1–2	1- and 2-mg tablets
Quazepam	Doral	5	7.5–15.0	7.5- and 15.0-mg tablets
Zolpidem	Ambien Ambien CR	10 5	5–10 6.25–12.5	5- and 10-mg tablets 6.25- and 12.5-mg tablets
Zaleplon	Sonata	10	5–20	5- and 10-mg capsules
Eszopiclone	Lunesta	1	1–3	1-, 2- and 3-mg tablets
Flumazenil	Romazicon	0.05	0.2–0.5/min	0.1 mg/mL 5- and 10-mL vials

Pharmacologic Actions

All benzodiazepines except clorazepate (Tranxene) are completely absorbed after oral administration and reach peak serum levels within 30 minutes to 2 hours. Metabolism of clorazepate in the stomach converts it to desmethyldiazepam, which is then completely absorbed.

The absorption, the attainment of peak concentrations, and the onset of action are quickest for diazepam (Valium), lorazepam (Ativan), alprazolam (Xanax), triazolam (Halcion), and estazolam (ProSom). The rapid onset of effects is vital to persons who take a single dose of a benzodiazepine to calm an episodic burst of anxiety or to fall asleep rapidly. Several benzodiazepines are effective after intravenous (IV) injection, but only lorazepam and midazolam (Versed) have rapid and reliable absorption after intramuscular (IM) administration.

Diazepam, chlordiazepoxide, clonazepam (Klonopin), clorazepate, flurazepam (Dalmane), and quazepam (Doral) have plasma half-lives of 30 hours to more than 100 hours and are technically described as long-acting benzodiazepines. The plasma half-lives of these compounds can be as high as 200 hours in persons whose metabolism is genetically slow. Because the attainment of steady-state plasma concentrations of the drugs can take up to 2 weeks, persons may experience symptoms and signs of toxicity after only 7 to 10 days of treatment with a dosage that seemed initially to be in the therapeutic range.

Clinically, half-life alone does not necessarily determine the duration of therapeutic action for most benzodiazepines. The fact that all benzodiazepines are lipid-soluble to varying degrees means that benzodiazepines and their active metabolites bind to plasma proteins. The extent of this binding is proportional to their lipid solubility. The amount of protein binding varies from 70 to 99 percent. Distribution, onset, and termination of action after a single dose are thus determined mainly by benzodiazepine lipid solubility, not elimination half-life. Preparations with high lipid solubility, such as diazepam and alprazolam, are absorbed rapidly from the GI tract and distribute rapidly to the brain by passive diffusion along a concentration gradient, resulting in a rapid onset of action. However, as the concentration of the medication increases in the brain and decreases in the bloodstream, the concentration gradient reverses itself, and these medications leave the brain rapidly, resulting in fast cessation of drug effect. Drugs with longer elimination half-lives, such as diazepam, may remain in the bloodstream for a substantially more extended time than their actual pharmacologic action at benzodiazepine receptors because the concentration in the brain decreases rapidly below the level necessary for a noticeable effect.

In contrast, lorazepam, which has a shorter elimination half-life than diazepam but is less lipid-soluble, has a slower onset of action after a single dose because the drug is absorbed and enters the brain more slowly. However, the duration of action after a single dose is longer because it takes longer for lorazepam to leave the brain and for brain levels to decrease below the concentration that produces an effect. In chronic dosing, some of these differences are not as apparent because brain levels are in equilibrium with higher and more consistent steady-state blood levels, but additional doses still produce a more rapid but briefer action with diazepam than with lorazepam. Benzodiazepines are distributed widely in adipose tissue. As a result, medications may persist in the body after discontinuation longer than would be predicted from their elimination half-lives. Also, the dynamic half-life (i.e., duration of action on the receptor) may be longer than the elimination half-life.

The advantages of long–half-life drugs over short–half-life drugs include less frequent dosing, less variation in plasma concentration, and less severe withdrawal phenomena. The disadvantages include drug accumulation, increased risk of daytime psychomotor impairment, and increased daytime sedation.

The half-lives of lorazepam, oxazepam (Serax), temazepam (Restoril), and estazolam are between 8 and 30 hours. Alprazolam has a half-life of 10 to 15 hours, and triazolam has the shortest half-life (2 to 3 hours) of all the orally administered benzodiazepines. Rebound insomnia and anterograde amnesia are thought to be more of a problem with the short–half-life drugs than with the long–half-life drugs.

Because the administration of medications more frequently than the elimination half-life leads to drug accumulation, medications such as diazepam and flurazepam accumulate with daily dosing, eventually resulting in increased daytime sedation.

Some benzodiazepines (e.g., oxazepam) are conjugated directly by glucuronidation and are excreted. Most benzodiazepines are oxidized first by CYP3A4 and CYP2C19, often to active metabolites. These metabolites may then be hydroxylated to another active metabolite. For example, diazepam is oxidized to desmethyldiazepam, which, in turn, is hydroxylated to produce oxazepam. These products undergo glucuronidation to inactive metabolites. Several benzodiazepines (e.g., diazepam, chlordiazepoxide) have the same

active metabolite (desmethyldiazepam), which has an elimination half-life of more than 120 hours. Flurazepam (Dalmane), a lipid-soluble benzodiazepine used as a hypnotic that has a short elimination half-life, has an active metabolite (desalkylflurazepam) with a half-life greater than 100 hours. This is another reason that the duration of action of a benzodiazepine may not correspond to the half-life of the parent drug.

Therapeutic Indications

Insomnia. Because insomnia may be a symptom of a physical or psychiatric disorder, hypnotics should not be used for more than 7 to 10 consecutive days without a thorough investigation of the cause of insomnia. However, many patients have long-standing sleep difficulties and benefit significantly from the long-term use of hypnotic agents. Temazepam, flurazepam, and triazolam are benzodiazepines with a sole indication for insomnia.

Flurazepam, temazepam, quazepam, estazolam, and triazolam are the benzodiazepines approved for use as hypnotics. The benzodiazepine hypnotics differ principally in their half-lives; flurazepam has the most prolonged half-life, and triazolam has the shortest. Flurazepam may be associated with minor cognitive impairment on the day after its administration, and triazolam may be associated with mild rebound anxiety and anterograde amnesia. Quazepam may be associated with daytime impairment when used for a long time. Temazepam or estazolam may be a reasonable compromise for most adults. Estazolam produces rapid onset of sleep and a hypnotic effect for 6 to 8 hours.

Anxiety Disorders

GENERALIZED ANXIETY DISORDER. Benzodiazepines are highly effective for the relief of anxiety associated with GAD. Most persons should be treated for a predetermined, specific, and relatively brief period. However, because GAD is a chronic disorder with a high rate of recurrence, some persons with GAD may warrant long-term maintenance treatment with benzodiazepines.

PANIC DISORDER. Alprazolam and clonazepam, both high-potency benzodiazepines, are commonly used medications for panic disorder with or without agoraphobia. Although the SSRIs are also indicated for the treatment

of panic disorder, benzodiazepines have the advantage of working quickly and not causing significant sexual dysfunction and weight gain. However, the SSRIs are still often preferred because they target common comorbid conditions, such as depression or OCD. Benzodiazepines and SSRIs can be initiated together to treat acute panic symptoms; use of the benzodiazepine can be tapered after 3 to 4 weeks once the therapeutic benefits of the SSRI have emerged.

SOCIAL ANXIETY DISORDER. Clonazepam is an effective treatment for social anxiety disorder. Also, several other benzodiazepines (e.g., diazepam) have been used as adjunctive medications for the treatment of social anxiety disorder.

OTHER ANXIETY DISORDERS. Benzodiazepines are used adjunctively for treatment of adjustment disorder with anxiety, pathologic anxiety associated with life events (e.g., after an accident), OCD, and PTSD.

ANXIETY ASSOCIATED WITH DEPRESSION. Depressed patients often experience significant anxiety, and antidepressant drugs may cause initial exacerbation of these symptoms. Accordingly, benzodiazepines are indicated for the treatment of anxiety associated with depression.

Bipolar I and II Disorders

Clonazepam, lorazepam, and alprazolam are useful in the management of acute manic episodes and as an adjuvant to maintenance therapy instead of antipsychotics. As an adjuvant to lithium (Eskalith) or lamotrigine (Lamictal), clonazepam may result in an increased time between cycles and fewer depressive episodes. Benzodiazepines may help patients with bipolar disorder sleep better.

Catatonia. Lorazepam, sometimes in low doses (less than 5 mg/day) and sometimes in very high doses (12 mg/day or more), is regularly used to treat acute catatonia, which is more frequently associated with bipolar disorder than with schizophrenia. Other benzodiazepines have also been said to be helpful. However, there are no valid controlled trials of benzodiazepines in catatonia. Chronic catatonia does not respond as well to benzodiazepines.

The definitive treatment for catatonia is ECT.

Akathisia. The first-line drug for akathisia is most commonly a β-adrenergic receptor antagonist. However, benzodiazepines are also useful in treating some patients with akathisia.

Other Psychiatric Indications. Chlordiazepoxide (Librium) and clorazepate (Tranxene) are used to manage the symptoms of alcohol withdrawal. The benzodiazepines (especially IM lorazepam) are used to manage substance-induced and psychotic agitation in the emergency department. Benzodiazepines have been used instead of amobarbital (Amytal) for drug-assisted interviewing.

Flumazenil for Benzodiazepine Overdosage. Flumazenil is used to reverse the adverse psychomotor, amnestic, and sedative effects of benzodiazepine receptor agonists. Flumazenil is administered IV and has a half-life of 7 to 15 minutes. The most common adverse effects of flumazenil are nausea, vomiting, dizziness, agitation, emotional lability, cutaneous vasodilation, injection-site pain, fatigue, impaired vision, and headache. The most common serious adverse effect associated with the use of flumazenil is the precipitation of seizures, which is most likely to occur in persons with seizure disorders, those who are physically dependent on benzodiazepines, and those who have ingested large quantities of benzodiazepines. Flumazenil alone may impair memory retrieval.

In mixed-drug overdosage, the toxic effects (e.g., seizures and cardiac arrhythmias) of other drugs (e.g., TCAs) may emerge with the reversal of the benzodiazepine effects of flumazenil. For example, seizures caused by an overdosage of TCAs may have been partially treated in a person who had also taken an overdosage of benzodiazepines. With flumazenil treatment, the tricyclic-induced seizures or cardiac arrhythmias may appear and result in a fatal outcome. Flumazenil does not reverse the effects of ethanol, barbiturates, or opioids.

For the initial management of a known or suspected benzodiazepine overdosage, the recommended initial dosage of flumazenil is 0.2 mg (2 mL) administered IV over 30 seconds. If the desired consciousness is not obtained after 30 seconds, a further dose of 0.3 mg (3 mL) can be administered over 30

seconds. Further doses of 0.5 mg (5 mL) can be administered over 30 seconds at 1-minute intervals up to a cumulative dose of 3.0 mg. The clinician should not rush the administration of flumazenil. A secure airway and IV access should be established before the administration of the drug. Persons should be awakened gradually.

Most persons with a benzodiazepine overdosage respond to a cumulative dose of 1 to 3 mg of flumazenil; doses above 3 mg of flumazenil do not reliably produce additional effects. If a person has not responded 5 minutes after receiving a cumulative dose of 5 mg of flumazenil, the primary cause of sedation is probably not benzodiazepine receptor agonists, and additional flumazenil is unlikely to help.

Sedation can return in 1 to 3 percent of persons treated with flumazenil. It can be prevented or treated by giving repeated dosages of flumazenil at 20-minute intervals. For repeat treatment, no more than 1 mg (given as 0.5 mg a minute) should be given at any one time, and no more than 3 mg should be given in any 1 hour.

Precautions and Adverse Reactions

The most common adverse effect of benzodiazepines is drowsiness, which occurs in about 10 percent of all persons. Because of this adverse effect, persons should be advised to be careful while driving or using dangerous machinery when taking drugs. Drowsiness can be present during the day after the use of a benzodiazepine for insomnia the previous night, the so-called residual daytime sedation. Some persons also experience ataxia (fewer than 2 percent) and dizziness (less than 1 percent). These symptoms can result in falls and hip fractures, especially in elderly persons. The most severe adverse effects of the benzodiazepines occur when other sedative substances, such as alcohol, are taken concurrently. These combinations can result in marked drowsiness, disinhibition, or even respiratory depression. Infrequently, benzodiazepine receptor agonists cause mild cognitive deficits that may impair job performance. Persons taking benzodiazepine receptor agonists should be advised to exercise additional caution when driving or operating dangerous machinery.

High-potency benzodiazepines, especially triazolam, can cause anterograde amnesia. A paradoxical increase in aggression has been reported in persons

with preexisting brain damage. Allergic reactions to the drugs are rare, but a few studies report maculopapular rashes and generalized itching. The symptoms of benzodiazepine intoxication include confusion, slurred speech, ataxia, drowsiness, dyspnea, and hyporeflexia.

Triazolam has received significant attention in the media because of an alleged association with aggression. Therefore, the manufacturer recommends that the drug be used for no more than 10 days for the treatment of insomnia and that physicians carefully evaluate the emergence of any abnormal thinking or behavioral changes in persons treated with triazolam, giving appropriate consideration to all potential causes. Triazolam was banned in Great Britain in 1991.

Persons with hepatic disease and elderly persons are particularly likely to have adverse effects and toxicity from the benzodiazepines, including hepatic coma, especially when the drugs are administered repeatedly or in high dosages. Benzodiazepines can produce clinically significant impairment of respiration in persons with chronic obstructive pulmonary disease and sleep apnea. Alprazolam may exert a direct appetite stimulant effect and may cause weight gain. The benzodiazepines should be used with caution by persons with a history of substance abuse, cognitive disorders, renal disease, hepatic disease, porphyria, CNS depression, or myasthenia gravis.

Some data indicate that benzodiazepines are teratogenic; therefore, their use during pregnancy is not advised. Moreover, the use of benzodiazepines in the third trimester can precipitate a withdrawal syndrome in newborns. The drugs are secreted in the breast milk in sufficient concentrations to affect newborns. Benzodiazepines may cause dyspnea, bradycardia, and drowsiness in nursing babies.

Tolerance, Dependence, and Withdrawal. When benzodiazepines are used for short periods (1 to 2 weeks) in moderate dosages, they usually cause no significant tolerance, dependence, or withdrawal effects. The short-acting benzodiazepines (e.g., triazolam) may be an exception to this rule because some persons have reported increased anxiety the day after taking a single dose of the drug and then stopping its use. Some persons also report a tolerance for the anxiolytic effects of benzodiazepines and require increased doses to maintain the clinical remission of symptoms.

The appearance of a withdrawal syndrome, also called discontinuation

syndrome, depends on how long a person takes the drug, what dose, how quickly they taper it, and the half-life of the compound. Benzodiazepine withdrawal syndrome consists of anxiety, nervousness, diaphoresis, restlessness, irritability, fatigue, lightheadedness, tremor, insomnia, and weakness (Table 21-44). Abrupt discontinuation of benzodiazepines, particularly those with short half-lives, is associated with severe withdrawal symptoms, which may include depression, paranoia, delirium, and seizures. These severe symptoms are more likely to occur if flumazenil is used for the rapid reversal of the benzodiazepine receptor agonist effects. Some features of the syndrome may occur in as many as 90 percent of persons treated with the drugs. The development of severe withdrawal syndrome is seen only in persons who have taken high dosages for long periods. The syndrome may be delayed for 1 or 2 weeks in persons who had been taking benzodiazepines with long half-lives. Alprazolam seems to be significantly associated with an immediate and severe withdrawal syndrome and should be tapered gradually.

When the medication is to be discontinued, the drug must be tapered slowly (25 percent a week); otherwise, recurrence or rebound of symptoms is likely. Monitoring of any withdrawal symptoms (possibly with a standardized rating scale) and psychological support of the person are helpful in the successful accomplishment of benzodiazepine discontinuation. Concurrent use of carbamazepine (Tegretol) during benzodiazepine discontinuation has been reported to permit a more rapid and better-tolerated withdrawal than does a gradual taper alone. The dosage range of carbamazepine used to facilitate withdrawal is 400 to 500 mg a day. Some clinicians report particular difficulty in tapering and discontinuing alprazolam, especially in persons who have been receiving high dosages for long periods. There have been reports of successful discontinuation of alprazolam by switching to clonazepam, which is then gradually withdrawn.

Table 21-44
Signs and Symptoms of Benzodiazepine Withdrawal

Anxiety	Tremor
Irritability	Depersonalization
Insomnia	Hyperesthesia

Hyperacusis	Myoclonus
Nausea	Delirium
Difficulty concentrating	Seizures

Drug Interactions

The most common and potentially severe benzodiazepine receptor agonist interaction is excessive sedation and respiratory depression occurring when benzodiazepines are administered concomitantly with other CNS depressants, such as alcohol, barbiturates, tricyclic and tetracyclic drugs, DRAs, opioids, and antihistamines. Ataxia and dysarthria may be likely to occur when lithium, antipsychotics, and clonazepam are combined. The combination of benzodiazepines and clozapine (Clozaril) has been reported to cause delirium and should be avoided. Cimetidine (Tagamet), disulfiram (Antabuse), isoniazid, estrogen, and oral contraceptives increase the plasma concentration of diazepam, chlordiazepoxide, clorazepate, and flurazepam. However, antacids may reduce the GI absorption of benzodiazepines. The plasma concentrations of triazolam and alprazolam are increased to potentially toxic concentrations by nefazodone (Serzone) and fluvoxamine (Luvox).

The manufacturer of nefazodone recommends that the dosage of triazolam be lowered by 75 percent, and the dosage of alprazolam be lowered by 50 percent, when given concomitantly with nefazodone. Over-the-counter preparations of the kava plant, advertised as a “natural tranquilizer,” can potentiate the action of benzodiazepine receptor agonists through synergistic overactivation of GABA receptors. Carbamazepine can lower the plasma concentration of alprazolam. Antacids and food may decrease the plasma concentrations of benzodiazepines, and smoking may increase the metabolism of benzodiazepines. The benzodiazepines may increase the plasma concentrations of phenytoin and digoxin (Lanoxin). The SSRIs may prolong and exacerbate the severity of zolpidem-induced hallucinations. Deaths have been reported when parental lorazepam is given with parental olanzapine.

Dosage and Clinical Guidelines

The clinical decision to treat an anxious person with a benzodiazepine should be carefully considered. Medical causes of anxiety (e.g., thyroid dysfunction, caffeinism, and prescription medications) should be ruled out. Benzodiazepine use should be started at a low dosage, and the person should be instructed regarding the drug's sedative properties and abuse potential. An estimated length of therapy should be decided at the beginning of therapy, and the need for continued therapy should be reevaluated at least monthly because of the problems associated with long-term use. However, certain persons with anxiety disorders are unresponsive to treatments other than benzodiazepines in long-term use.

Benzodiazepines are available in a wide range of formulations. Clonazepam is available in a wafer formulation that facilitates its use in patients who have trouble swallowing pills. Alprazolam is available in an extended-release form, which reduces the frequency of dosing. Some benzodiazepines are more potent than others in that one compound requires a relatively smaller dosage than another compound to achieve the same effect. For example, clonazepam requires 0.25 mg to achieve the same effect as 5 mg of diazepam; thus, clonazepam is considered a high-potency benzodiazepine. Conversely, oxazepam has an approximate dosage equivalence of 15 mg and is a low-potency drug.

Table 21-43 lists preparations and doses of medications discussed in this chapter.

BUSPIRONE

Buspirone hydrochloride (BuSpar) is classified as an azapirone and is chemically distinct from other psychotropic agents. It acts on two types of receptors, serotonin (5-HT) and dopamine (D). It has a high affinity for the 5-HT_{1A} serotonin receptor, acting as an agonist or partial agonist, and moderate affinity for the D_2 dopamine receptor, acting as both an agonist and an antagonist. The approved indication for this psychotropic drug is for the treatment of GAD. It was initially believed to be a better alternative to the benzodiazepine drug group because buspirone does not possess anticonvulsant and muscle relaxant effects. Reports continue to appear that some patients benefit from the addition of buspirone to their antidepressant regimen. Its use in this role is more common than its use as an anxiolytic.

Interestingly, the antidepressant drug vilazodone (Viibryd) inhibits 5-HT reuptake and acts as a 5-HT_{1A} receptor partial agonist.

Pharmacologic Actions

Buspirone is well absorbed from the GI tract, but absorption is delayed by food ingestion. Peak plasma levels are achieved 40 to 90 minutes after oral administration. At doses of 10 to 40 mg, single-dose linear pharmacokinetics are observed. Nonlinear pharmacokinetics are observed after multiple doses. Because of its short half-life (2 to 11 hours), buspirone is dosed three times daily. An active metabolite of buspirone, 1-pyrimidinylpiperazine (1-PP), is about 20 percent less potent than buspirone but is up to 30 percent more concentrated in the brain than the parent compound. The elimination half-life of 1-PP is 6 hours.

Buspirone does not affect the GABA-associated chloride ion channel or the serotonin reuptake transporter, targets of other drugs that are effective in GAD. Buspirone also has activity at 5-HT_2 and dopamine type 2 (D_2) receptors, although the significance of the effects at these receptors is unknown. At D_2 receptors, it has properties of both an agonist and an antagonist.

Therapeutic Indications

Generalized Anxiety Disorder. Buspirone is a narrow-spectrum antianxiety agent with demonstrated efficacy only in the treatment of GAD. In contrast to the SSRIs or venlafaxine, buspirone is not effective in the treatment of panic disorder, OCD, or social phobia. Buspirone, however, has an advantage over these agents in that it does not typically cause sexual dysfunction or weight gain.

Some evidence suggests that, compared with benzodiazepines, buspirone is generally more useful for symptoms of anger and hostility, equally effective for psychic symptoms of anxiety, and less effective for somatic symptoms of anxiety. The full benefit of buspirone is evident only at dosages above 30 mg a day. Compared with the benzodiazepines, buspirone has a delayed onset of action and lacks any euphoric effect. Unlike benzodiazepines, buspirone has no immediate effects, and patients should be told that a full clinical response

may take 2 to 4 weeks. If an immediate response is needed, patients can be started on a benzodiazepine and then withdrawn from the drug after buspirone's effects begin. Sometimes the sedative effects of benzodiazepines, which are not found with buspirone, are desirable; however, these sedative effects may cause impaired motor performance and cognitive deficits.

Other Disorders. Many other clinical uses of buspirone have been reported, but most have not been confirmed in controlled trials. Evidence of the efficacy of high-dosage buspirone (30 to 90 mg a day) for depressive disorders is mixed. Buspirone appears to have weak antidepressant activity, which has led to its use as an augmenting agent in patients who have failed standard antidepressant therapy. In a large study, buspirone augmentation of SSRIs worked as well as other commonly used strategies. Buspirone is sometimes used to augment SSRIs in the treatment of OCD. There are reports that buspirone may be beneficial against the increased arousal and flashbacks associated with PTSD.

Because buspirone does not act on the GABA–chloride ion channel complex, the drug is not recommended for the treatment of withdrawal from benzodiazepines, alcohol, or sedative-hypnotic drugs, except as treatment of comorbid anxiety symptoms.

Scattered trials suggest that buspirone reduces aggression and anxiety in persons with organic brain disease or traumatic brain injury. It is also used for SSRI-induced bruxism and sexual dysfunction, nicotine craving, and ADHD.

Precautions and Adverse Reactions

Buspirone does not cause weight gain, sexual dysfunction, discontinuation symptoms, or significant sleep disturbance. It does not produce sedation or cognitive and psychomotor impairment. The most common adverse effects of buspirone are headache, nausea, dizziness, and (rarely) insomnia. No sedation is associated with buspirone. Some persons may report a minor feeling of restlessness, although that symptom may reflect an incompletely treated anxiety disorder. No deaths have been reported from overdoses of buspirone, and the median lethal dose is estimated to be 160 to 550 times the recommended daily dose. Buspirone should be used with caution by persons

with hepatic and renal impairment, pregnant women, and nursing mothers. Buspirone can be used safely by the elderly.

Drug Interactions

The coadministration of buspirone and haloperidol (Haldol) results in increased blood concentrations of haloperidol. Buspirone should not be used with MAOIs to avoid hypertensive episodes, and a 2-week washout period should pass between the discontinuation of MAOI use and the initiation of treatment with buspirone. Drugs or foods that inhibit CYP3A4, for example, erythromycin, itraconazole (Sporanox), nefazodone (Serzone), and grapefruit juice, increase buspirone plasma concentrations.

Laboratory Interferences

Single doses of buspirone can cause transient elevations in growth hormone, prolactin, and cortisol concentrations, although the effects are not clinically significant.

Dosage and Clinical Guidelines

Buspirone is available in single-scored 5- and 10-mg tablets and triple-scored 15- and 30-mg tablets; treatment is usually initiated with either 5 mg orally three times daily or 7.5 mg orally twice daily. The dosage can be raised 5 mg every 2 to 4 days to the usual dosage range of 15 to 60 mg a day.

Buspirone should not be used in patients with past hypersensitivity to buspirone, in cases of diabetes-associated metabolic acidosis, or patients with severely compromised liver or renal function.

Switching from a Benzodiazepine to Buspirone. Buspirone is not cross-tolerant with benzodiazepines, barbiturates, or alcohol. A common clinical problem, therefore, is how to initiate buspirone therapy in a person who is currently taking benzodiazepines. There are two alternatives. First, the clinician can start buspirone treatment gradually while the benzodiazepine is being withdrawn. Second, the clinician can start buspirone treatment and bring the person up to a therapeutic dosage for 2 to 3 weeks while the person is still receiving the regular dosage of the benzodiazepine and then slowly taper the benzodiazepine dosage. Patients who have received

benzodiazepines in the past, especially in recent months, may find that buspirone is not as effective as the benzodiazepines in the treatment of their anxiety. This difference might be explained by the absence of the immediate mildly euphoric and sedative effects of benzodiazepines. The coadministration of buspirone and benzodiazepines may be useful in the treatment of persons with anxiety disorders who have not responded to treatment with either drug alone.

β-ADRENERGIC RECEPTOR ANTAGONISTS

Because of the innervations of many, if not most, peripheral organs and vasculature by the sympathetic division of the autonomic nervous system, their functions are ultimately controlled, in part, by one of the two major classes of adrenergic receptors: α-receptors (see Table 33-2) and β-receptors. These receptors are further subdivided based on their action and location, and they are located both peripherally and in the CNS. Shortly after being introduced for cardiac indications, propranolol (Inderal) was reported to be useful for agitation, and its use in psychiatry spread rapidly. The five most commonly used β-receptor antagonists in psychiatry are propranolol, nadolol (Corgard), metoprolol (Lopressor, Toprol), pindolol (Visken), and atenolol (Tenormin) (Table 21-45).

Pharmacologic Actions

The β-receptor antagonists differ concerning lipophilicities, metabolic routes, β-receptor selectivity, and half-lives. The absorption of the β-receptor antagonists from the GI tract is variable. The agents that are most soluble in lipids (i.e., are lipophilic) are likely to cross the blood–brain barrier and enter the brain; those agents that are least lipophilic are less likely to enter the brain. When CNS effects are desired, a lipophilic drug may be preferred; when only peripheral effects are desired, a less lipophilic drug may be indicated.

Table 21-45
β-Adrenergic Drugs Used in Psychiatry

Drug	Pregnancy Category (former FDA classification system)	Protein Binding (%)	Lipophilic	ISA	Metabolism	Receptor Selectivity	Half-Life (hr)	Usual Starting Dosage (mg)	Usual Maximal Dosage (mg)
Atenolol (Tenormin)	D	6–16	No		Renal	$\beta_1 > \beta_2$	6–9	50 OD	50–100 OD
Metoprolol (Lopressor)	C	5–10	Yes		Hepatic	$\beta_1 > \beta_2$	3–4	50 bid	75–150 bid
Nadolol (Corgard)	C	30	No		Renal	$\beta_1 = \beta_2$	14–24	40 OD	80–240 OD
Propranolol (Inderal)	C	>90	Yes		Hepatic	$\beta_1 = \beta_2$	3–6	10–20 bid/tid	80–140 tid
Pindolol (Visken)	B	40	Yes	Minimal	Hepatic	$\beta_1 > \beta_2$	3–4	5 tid/qid	60 bid/tid

Note: In 2015, the FDA changed the pregnancy classification system from a letter-based system to a descriptive system. We refer here to the letter-based system in order to simplify the summary of data into a table.
ISA, intrinsic sympathomimetic activity; OD, once daily; bid, twice a day; tid, three times a day; qid, four times a day.

Whereas propranolol, nadolol, pindolol, and labetalol (Normodyne, Trandate) have nearly equal potency at both the β_1- and β_2-receptors, metoprolol and atenolol have a greater affinity for the β_1-receptor than for the β_2-receptor. Relative β_1-selectivity confers few pulmonary and vascular effects of these drugs, although they must be used with caution in persons with asthma because the drugs retain some activity at the β_2-receptors.

Pindolol has sympathomimetic effects in addition to its β-antagonist effects, which has allowed its use for augmentation of antidepressant drugs. Pindolol, propranolol, and nadolol possess some antagonist activity at the serotonin 5-HT_{1A} receptors.

Therapeutic Indications

Anxiety Disorders. Propranolol is useful for the treatment of social anxiety disorder, primarily of the performance type (e.g., disabling anxiety before a musical performance). Data are also available for its use in the treatment of panic disorder, PTSD, and GAD. In social anxiety disorder, the standard treatment approach is to take 10 to 40 mg of propranolol 20 to 30 minutes before the anxiety-provoking situation. The β-receptor antagonists are less useful for the treatment of panic disorder than are benzodiazepines or SSRIs.

Lithium-Induced Postural Tremor. The β-receptor antagonists are beneficial for lithium-induced postural tremor and other medication-induced postural tremors—for example, those induced by TCAs and valproate

(Depakene). The initial approach to this movement disorder includes lowering the dose of lithium (Eskalith), eliminating aggravating factors, such as caffeine, and administering lithium at bedtime. If these interventions are inadequate, however, propranolol in the range of 20 to 160 mg a day taken two or three times daily is generally sufficient for the treatment of lithium-induced postural tremor.

Neuroleptic-Induced Acute Akathisia. Many studies have shown that β-receptor antagonists can be effective in the treatment of neuroleptic-induced acute akathisia. They are generally more effective for this indication than are anticholinergics and benzodiazepines. The β-receptor antagonists are not effective in the treatment of such neuroleptic-induced movement disorders as acute dystonia and parkinsonism.

Aggression and Violent Behavior. The β-receptor antagonists may be useful in reducing the number of aggressive and violent outbursts in persons with impulse disorders, schizophrenia, and aggression associated with brain injuries such as trauma, tumors, anoxic injury, encephalitis, alcohol use disorders, and degenerative disorders (e.g., Huntington disease).

Alcohol Withdrawal. Propranolol is reported to be useful as an adjuvant to benzodiazepines but not as a sole agent in the treatment of alcohol withdrawal. The following dose schedule is suggested: no propranolol for a pulse rate below 50 beats/min; 50-mg propranolol for a pulse rate between 50 and 79 beats/min; and 100-mg propranolol for a pulse rate of 80 beats/min or above.

Antidepressant Augmentation. Pindolol has been used to augment and hasten the antidepressant effects of SSRIs, tricyclic drugs, and ECT. Small studies have shown that pindolol administered at the onset of antidepressant therapy may shorten the usual 2- to 4-week latency of antidepressant response by several days. Because the β-receptor antagonists may induce depression in some persons, augmentation strategies with these drugs need to be further clarified in controlled trials.

Other Disorders. Several case reports and controlled studies have reported

data indicating that β-receptor antagonists may be of modest benefit for persons with schizophrenia and manic symptoms. They have also been used in some cases of stuttering (see Table 21-46).

Precautions and Adverse Reactions

The β-receptor antagonists are contraindicated for use in people with asthma, insulin-dependent diabetes, congestive heart failure, significant vascular disease, persistent angina, and hyperthyroidism. The contraindication in diabetic persons is because the drugs antagonize the normal physiologic response to hypoglycemia. The β-receptor antagonists can worsen AV conduction defects and lead to complete AV heart block and death. If the clinician decides that the risk-to-benefit ratio warrants a trial of a β-receptor antagonist in a person with one of these coexisting medical conditions, a β_1-selective agent should be the first choice, and the patient should be monitored. All currently available β-receptor antagonists are excreted in breast milk and should be administered with caution to nursing women.

Table 21-46
Psychiatric Uses for β-Adrenergic Receptor Antagonists

Definitely effective
Performance anxiety
Lithium-induced tremor
Neuroleptic-induced akathisia
Probably effective
Adjunctive therapy for alcohol withdrawal and other substance-related disorders
Adjunctive therapy for aggressive or violent behavior
Possibly effective
Antipsychotic augmentation
Antidepressant augmentation

Table 21-47
Adverse Effects and Toxicity of β-Adrenergic Receptor

Antagonists

- Cardiovascular
  - Hypotension
  - Bradycardia
  - Congestive heart failure (in patients with compromised myocardial function)
- Respiratory
  - Asthma (less risk with β_1-selective drugs)
- Metabolic
  - Worsened hypoglycemia in diabetic patients on insulin or oral agents
- Gastrointestinal
  - Nausea
  - Diarrhea
  - Abdominal pain
- Sexual function
  - Impotence
- Neuropsychiatric
  - Lassitude
  - Fatigue
  - Dysphoria
  - Insomnia
  - Vivid nightmares
  - Depression (rare)
  - Psychosis (rare)
- Other (rare)
  - Raynaud phenomenon
  - Peyronie disease
- Withdrawal syndrome
  - Rebound worsening of preexisting angina pectoris when β-adrenergic receptor antagonists are discontinued

The most common adverse effects of β-receptor antagonists are hypotension and bradycardia. In persons at risk for these adverse effects, a test dosage of 20 mg a day of propranolol can be given to assess the reaction to the drug. Depression has been associated with lipophilic β-receptor antagonists, such as propranolol, but it is probably rare. Nausea, vomiting, diarrhea, and constipation can also be caused by treatment with these agents. The β-receptor antagonists may blunt cognition in some people. Other more severe CNS adverse effects (e.g., agitation, confusion, and hallucinations) are rare. Table 21-47 lists the possible adverse effects of β-receptor antagonists.

Drug Interactions

Antipsychotics, anticonvulsants, theophylline (Theo-Dur, Slo-bid), and levothyroxine (Synthroid) have increased plasma concentrations when given with propranolol. Other β-receptor antagonists may have similar effects. The β-receptor antagonists that are eliminated by the kidneys may have similar effects on drugs that are also eliminated by the renal route. Barbiturates, phenytoin (Dilantin), and cigarette smoking increase the elimination of β-receptor antagonists that are metabolized by the liver. Several reports have associated hypertensive crises and bradycardia with the coadministration of β-receptor antagonists and MAOIs. Depressed myocardial contractility and AV nodal conduction can occur from concomitant administration of a β-receptor antagonist and calcium channel inhibitors.

Laboratory Interferences

The β-receptor antagonists do not interfere with standard laboratory tests.

Dosage and Clinical Guidelines

Propranolol is available in 10-, 20-, 40-, 60-, 80-, and 90-mg tablets; 4-, 8-, and 80-mg/mL solutions; and 60-, 80-, 120-, and 160-mg sustained-release capsules. Nadolol is available in 20-, 40-, 80-, 120-, and 160-mg tablets. Pindolol is available in 5- and 10-mg tablets. Metoprolol is available in 50- and 100-mg tablets and 50-, 100-, and 200-mg sustained-release tablets. Atenolol is available in 25-, 50-, and 100-mg tablets. Acebutolol is available in 200- and 400-mg capsules.

For the treatment of chronic disorders, propranolol administration is

usually initiated at 10 mg by mouth three times a day or 20 mg by mouth twice daily. The dosage can be raised by 20 to 30 mg a day until a therapeutic effect emerges. The dosage should be leveled off at the appropriate range for the disorder under treatment. The treatment of aggressive behavior sometimes requires dosages up to 80 mg a day, and therapeutic effects may not be seen until the person has been receiving the maximal dosage for 4 to 8 weeks. For the treatment of social phobia, primarily the performance type, the patient should take 10 to 40 mg of propranolol 20 to 30 minutes before the performance.

Pulse and BP readings should be taken regularly, and the drug should be withheld if the pulse rate is below 50 beats/min or the systolic BP is below 90 mm Hg. The drug should be temporarily discontinued if it produces severe dizziness, ataxia, or wheezing. Treatment with β-receptor antagonists should never be discontinued abruptly. Propranolol should be tapered by 60 mg a day until a dosage of 60 mg a day is reached. After that, the drug should be tapered by 10 to 20 mg a day every 3 or 4 days.

The clinical guidelines for the other drugs listed in this chapter are similar to propranolol, taking into consideration the different doses used. For example, if propranolol is prescribed initially at the lowest available dose (e.g., 10 mg), then metoprolol should be prescribed at its lowest available dose (e.g., 50 mg).

Table 21-48
Barbiturate Dosages (Adult)

Drug	Trade Name	Available Preparations	Hypnotic Dose Range	Anticonvulsant Dose Range
Amobarbital	Amytal	200 mg	50–300 mg	65–500 mg IV
Aprobarbital	Alurate	40 mg/5 mL elixir	40–120 mg	Not established
Butabarbital	Butisol	15-, 30-, and 50-mg tablets 30 mg/5 mL elixir	45–120 mg	Not established
Mephobarbital	Mebaral	32, 50, and 100 mg tablets	100–200 mg	200–600 mg
Methohexital	Brevital	500 mg/50 mL	1 mg/kg for electroconvulsive therapy	Not established
Pentobarbital	Nembutal	50- and 100-mg capsules 50 mg/mL injection or elixir 30, 60, 120, and 200 mg suppository	100–200 mg	100 mg IV, each minute up to 500 mg
Phenobarbital	Luminal	Tablets range from 15–100 mg 20 mg/5 mL elixir 30–130 mg/mL injection	30–150 mg	100–300 mg IV, up to 600 mg/day
Secobarbital	Seconal	100-mg capsule, 50 mg/mL injection	100 mg	5.5 mg/kg IV

IV, intravenous.

BARBITURATES AND SIMILARLY ACTING DRUGS

The first barbiturate to be used in medicine was barbital (Veronal), which was introduced in 1903. It was followed by phenobarbital (Luminal), amobarbital (Amytal), pentobarbital (Nembutal), secobarbital (Seconal), and thiopental (Pentothal). Many others have been synthesized, but only a handful have been used clinically (Table 21-48). Many problems are associated with these drugs, including high abuse and addiction potential, a narrow therapeutic range with low therapeutic index, and unfavorable side effects. The use of barbiturates and similar compounds such as meprobamate (Miltown) has practically been eliminated by the benzodiazepines and hypnotics, such as zolpidem (Ambien), eszopiclone (Lunesta), and zaleplon (Sonata), which have a lower abuse potential and a higher therapeutic index than the barbiturates. Nevertheless, barbiturates still have a role in the treatment of certain mental and convulsive disorders.

Pharmacologic Actions

The barbiturates are well absorbed after oral administration. The binding of barbiturates to plasma proteins is high, but lipid solubility varies. The individual barbiturates are metabolized by the liver and excreted by the kidneys. The half-lives of specific barbiturates range from 1 to 120 hours. The barbiturates may also induce hepatic enzymes (cytochrome P450, CYP), thereby reducing the levels of both the barbiturate and any other concurrently administered drugs metabolized by the liver. The mechanism of action of barbiturates involves the GABA receptor–benzodiazepine receptor–chloride ion channel complex.

Therapeutic Indications

Electroconvulsive Therapy. Methohexital (Brevital) is commonly used as an anesthetic agent for ECT. It has lower cardiac risks than other barbiturate anesthetics. Used intravenously (IV), methohexital produces rapid unconsciousness, and because of its rapid redistribution, it has a brief duration of action (5 to 7 minutes). Typical dosing for ECT is 0.7 to 1.2 mg/kg. Methohexital can also be used to abort prolonged seizures in ECT or to limit postictal agitation.

Seizures. Phenobarbital (Solfoton, Luminal), the most commonly used barbiturate for treatment of seizures, has indications for the treatment of generalized tonic–clonic and simple partial seizures. Parenteral barbiturates are used in the emergency management of seizures independent of cause. Intravenous phenobarbital should be administered slowly at 10 to 20 mg/kg for status epilepticus.

Narcoanalysis. Amobarbital (Amytal) has been used historically as a diagnostic aid in several clinical conditions, including conversion reactions, catatonia, hysterical stupor, and unexplained muteness, and to differentiate stupor of depression, schizophrenia, and structural brain lesions.

The *Amytal interview* is performed by placing the patient in a reclining position and administering amobarbital IV at 50 mg a minute. Infusion is continued until lateral nystagmus is sustained or drowsiness is noted, usually at 75 to 150 mg. After this, 25 to 50 mg can be administered every 5 minutes to maintain narcosis. The patient should be allowed to rest for 15 to 30 minutes after the interview before attempting to walk.

Because of the risk of laryngospasm with IV amobarbital, diazepam has become the drug of choice for narcoanalysis.

Sleep. The barbiturates reduce sleep latency and the number of awakenings during sleep, although tolerance to these effects generally develops within 2 weeks. Discontinuation of barbiturates often leads to rebound increases in electroencephalographic measures of sleep and a worsening of insomnia.

Withdrawal from Sedative-Hypnotics

Barbiturates are sometimes used to determine the extent of tolerance to barbiturates or other hypnotics to guide detoxification. After intoxication has been resolved, a test dose of pentobarbital (200 mg) is given orally. One hour later, the patient is examined. Tolerance and dose requirements are determined by the degree to which the patient is affected. If the patient is not sedated, another 100 mg of pentobarbital can be administered every 2 hours, up to three times (maximum, 500 mg over 6 hours). The amount needed for mild intoxication corresponds to the approximate daily dose of barbiturate used. Phenobarbital (30 mg) may then be substituted for each 100 mg of pentobarbital. This daily dose requirement can be administered in divided

doses and gradually tapered by 10 percent a day, with adjustments made according to withdrawal signs.

Precautions and Adverse Reactions

Some adverse effects of barbiturates are similar to those of benzodiazepines, including paradoxical dysphoria, hyperactivity, and cognitive disorganization. Rare adverse effects associated with barbiturate use include the development of Stevens–Johnson syndrome, megaloblastic anemia, and neutropenia.

Before the advent of benzodiazepines, the widespread use of barbiturates as hypnotics and anxiolytics made them the most common cause of acute porphyria reactions. Severe attacks of porphyria have decreased, mainly because barbiturates are now seldom used and are contraindicated in patients with the disease.

A significant difference between the barbiturates and the benzodiazepines is the low therapeutic index of the barbiturates. An overdose of barbiturates can easily prove fatal. In addition to narrow therapeutic indexes, the barbiturates are associated with a significant risk of abuse potential and the development of tolerance and dependence. Barbiturate intoxication is manifested by confusion, drowsiness, irritability, hyporeflexia or areflexia, ataxia, and nystagmus. The symptoms of barbiturate withdrawal are similar to but more marked than those of benzodiazepine withdrawal.

Ten times the daily dose or 1 g of most barbiturates causes severe toxicity; 2 to 10 g generally proves fatal. Manifestations of barbiturate intoxication may include delirium, confusion, excitement, headache, and CNS and respiratory depression, ranging from somnolence to coma. Other adverse reactions include Cheyne–Stokes respiration, shock, miosis, oliguria, tachycardia, hypotension, hypothermia, irritability, hyporeflexia or areflexia, ataxia, and nystagmus. Treatment of overdose includes induction of emesis or lavage, activated charcoal, and saline cathartics; supportive treatment, including maintaining airway and respiration and treating shock as needed; maintaining vital signs and fluid balance; alkalinizing the urine, which increases excretion; forced diuresis if renal function is typical, or hemodialysis in severe cases.

Because of some evidence of teratogenicity, barbiturates should not be

used by pregnant women or women who are breastfeeding. Barbiturates should be used with caution by patients with a history of substance abuse, depression, diabetes, hepatic impairment, renal disease, severe anemia, pain, hyperthyroidism, or hypoadrenalism. Barbiturates are also contraindicated in patients with acute intermittent porphyria, impaired respiratory drive, or limited respiratory reserve.

Drug Interactions

The primary area for concern about drug interactions is the potentially dangerous effects of respiratory depression. Barbiturates should be used with great caution with other prescribed CNS drugs (including antipsychotic and antidepressant drugs) and nonprescribed CNS agents (e.g., alcohol). Also, caution must be exercised when prescribing barbiturates to patients who are taking other drugs that are metabolized in the liver, especially cardiac drugs and anticonvulsants. Because individual patients have a wide range of sensitivities to barbiturate-induced enzyme induction, it is not possible to predict the degree to which the metabolism of concurrently administered medications may be affected. Drugs that have their metabolism enhanced by barbiturate administration include opioids, antiarrhythmic agents, antibiotics, anticoagulants, anticonvulsants, antidepressants, β-adrenergic receptor antagonists, DRAs, contraceptives, and immunosuppressants.

Laboratory Interferences

No known laboratory interferences are associated with the administration of barbiturates.

Dose and Clinical Guidelines

Barbiturates and other drugs described later begin to act within 1 to 2 hours of administration. The doses of barbiturates vary, and treatment should begin with low doses that are increased to achieve a clinical effect. Children and older people are more sensitive to the effects of barbiturates than are young adults. The most commonly used barbiturates are available in a variety of dose forms. Barbiturates with half-lives in the 15- to 40-hour range are preferable, because long-acting drugs tend to accumulate in the body. Clinicians should instruct patients clearly about the adverse effects and the

potential for dependence associated with barbiturates.

Although determining plasma concentrations of barbiturates is rarely necessary for psychiatry, monitoring of phenobarbital concentrations is standard practice when the drug is used as an anticonvulsant. The therapeutic blood concentrations for phenobarbital in this indication range from 15 to 40 mg/L, although some patients may experience significant adverse effects in that range.

Barbiturates are contained in combination products with which the clinician should be familiar.

Other Similarly Acting Drugs

Several agents that act similarly to the barbiturates have been used in the treatment of anxiety and insomnia. Three such available drugs are paraldehyde (Paral), meprobamate, and chloral hydrate (Noctec). These drugs are rarely used because of their abuse potential and potential toxic effects and some of them are now banned in other countries such as the European Union and Canada.

Paraldehyde. Paraldehyde is a cyclic ether and was first used in 1882 as a hypnotic. It has also been used to treat epilepsy, alcohol withdrawal symptoms, and delirium tremens. Because of its low therapeutic index, it has been supplanted by the benzodiazepines and other anticonvulsants.

PHARMACOLOGIC ACTIONS. Paraldehyde is rapidly absorbed from the GI tract and intramuscular (IM) injections. It is primarily metabolized to acetaldehyde by the liver, and the lungs expire the unmetabolized drug. Reported half-lives range from 3.4 to 9.8 hours. The onset of action is 15 to 30 minutes.

THERAPEUTIC INDICATIONS. Paraldehyde is not indicated as an anxiolytic or a hypnotic and has little place in current psychopharmacology.

PRECAUTIONS AND ADVERSE REACTIONS. Paraldehyde frequently causes foul breath because of the expired unmetabolized drug. It can inflame pulmonary capillaries and cause coughing. It can also cause local thrombophlebitis with IV use. Patients may experience nausea and vomiting with oral use. Overdose leads to metabolic acidosis and decreased renal output. There is a risk of

abuse among drug addicts.

DRUG INTERACTIONS. Disulfiram (Antabuse) inhibits acetaldehyde dehydrogenase and reduces the metabolism of paraldehyde, leading to a possible toxic concentration of paraldehyde. Paraldehyde has additive sedating effects in combination with other CNS depressants such as alcohol or benzodiazepines.

LABORATORY INTERFERENCES. Paraldehyde can interfere with the metyrapone, phentolamine, and urinary 17-hydroxycorticosteroid tests.

DOSING AND CLINICAL GUIDELINES. Paraldehyde is available in 30-mL vials for oral, IV, or rectal use. For seizures in adults, up to 12 mL (diluted to a 10 percent solution) can be administered by gastric tube every 4 hours. For children, the oral dose is 0.3 mg/kg.

Meprobamate. Meprobamate, a carbamate, was introduced shortly before the benzodiazepines, specifically to treat anxiety. It is also used for muscle relaxant effects.

PHARMACOLOGIC ACTIONS. Meprobamate is rapidly absorbed from the GI tract and IM injections. It is metabolized primarily by the liver, and a small portion is excreted unchanged in the urine. The plasma half-life is approximately 10 hours.

THERAPEUTIC INDICATIONS. Meprobamate is indicated for the short-term treatment of anxiety disorders. It has also been used as a hypnotic and is prescribed as a muscle relaxant.

PRECAUTIONS AND ADVERSE REACTIONS. Meprobamate can cause CNS depression and death in overdose and carries the risk of abuse by patients with drug or alcohol use disorders. Abrupt cessation after long-term use can lead to withdrawal syndrome, including seizures and hallucinations. Meprobamate can exacerbate acute intermittent porphyria. Other rare side effects include hypersensitivity reactions, wheezing, hives, paradoxical excitement, and leukopenia. It should not be used in patients with hepatic

compromise.

DRUG INTERACTIONS. Meprobamate has additive sedating effects in combination with other CNS depressants, such as alcohol, barbiturates, or benzodiazepines.

LABORATORY INTERFERENCES. Meprobamate can interfere with the metyrapone, phentolamine, and urinary 17-hydroxycorticosteroid tests.

DOSING AND CLINICAL GUIDELINES. Meprobamate is available in 200-, 400-, and 600-mg tablets; 200- and 400-mg extended-release capsules; and various combinations, for example, aspirin 325 mg and 200 mg of meprobamate (Equagesic) for oral use. For adults, the usual dose is 400 to 800 mg twice daily. Elderly patients and children aged 6 to 12 years require half the adult dose.

Chloral Hydrate. Chloral hydrate is a hypnotic agent rarely used in psychiatry because numerous safer options, such as benzodiazepines, are available.

PHARMACOLOGIC ACTIONS. Chloral hydrate is well absorbed from the GI tract. The parent compound is metabolized within minutes by the liver to the active metabolite trichloroethanol, which has a half-life of 8 to 11 hours. A dose of chloral hydrate induces sleep in about 30 to 60 minutes and maintains sleep for 4 to 8 hours. It probably potentiates GABAergic neurotransmission, which suppresses neuronal excitability.

THERAPEUTIC INDICATIONS. The FDA lists chloral hydrate as an unapproved drug that is still prescribed by clinicians, however it has no FDA-approved indication. The primary use in clinical practice for chloral hydrate is to induce sleep. It should be used for no more than 2 or 3 days because longer-term treatment is associated with an increased incidence and severity of adverse effects. Tolerance develops to the hypnotic effects of chloral hydrate after 2 weeks of treatment. The benzodiazepines are superior to chloral hydrate for all psychiatric uses.

PRECAUTIONS AND ADVERSE REACTIONS. Chloral hydrate has adverse effects on the CNS, GI system, and skin. High doses (>4 g) may be associated with stupor, confusion, ataxia, falls, or coma. The GI effects include nonspecific irritation, nausea, vomiting, flatulence, and an unpleasant taste. With long-term use and overdose, gastritis and gastric ulceration can develop. Along with tolerance, dependence on chloral hydrate can occur. The symptoms are similar to those of alcohol dependence. With a lethal dose between 5,000 and 10,000 mg, chloral hydrate is a particularly poor choice for potentially suicidal persons.

DRUG INTERACTIONS. Because of metabolic interference, chloral hydrate should be strictly avoided with alcohol, a notorious concoction known as a *Mickey Finn*. Chloral hydrate may displace warfarin (Coumadin) from plasma proteins and enhance anticoagulant activity; this combination should be avoided.

LABORATORY INTERFERENCES. Chloral hydrate administration can lead to false-positive results for urine glucose determinations that use cupric sulfate (e.g., Clinitest) but not in tests that use glucose oxidase (e.g., Clinistix and Tes-Tape). Chloral hydrate can also interfere with the determination of urinary catecholamines and 17-hydroxycorticosteroids.

DOSING AND CLINICAL GUIDELINES. Chloral hydrate is available in 500-mg capsules; 500-mg/5-mL solution; and 324-, 500-, and 648-mg rectal suppositories. The standard dose of chloral hydrate is 500 to 2,000 mg at bedtime. Because the drug is a GI irritant, it should be administered with excess water, milk, other liquids, or antacids to decrease gastric irritation.

Propofol. Propofol (Diprivan) is a $GABA_A$ agonist that is used as an anesthetic. It induces the presynaptic release of GABA and dopamine (the latter possibly through action on $GABA_B$ receptors) and is a partial agonist at dopamine D_2 and NMDA receptors. Because it is very lipid-soluble, it crosses the blood–brain barrier readily and induces anesthesia in less than 1 minute. Rapid redistribution from the CNS results in an offset of action within 3 to 8 minutes after the infusion is discontinued. It is well tolerated

when used for conscious sedation, but it has a potential for acute adverse effects, including respiratory depression, apnea, and bradyarrhythmias, and the prolonged infusion can cause acidosis and mitochondrial myopathies. The carrier used for the infusion is a soybean emulsion that can be a culture medium for various organisms. Also, the carrier can impair macrophage function and cause hematologic and lipid abnormalities and anaphylactic reactions.

Etomidate. Etomidate is a carboxylated imidazole that acts at the β_2 and β_3 subunits of the $GABA_A$ receptor. It has a rapid onset (1 minute) and short duration (less than 5 minutes) of action. The propylene glycol vehicle has been linked to hyperosmolar metabolic acidosis. It has both proconvulsant and anticonvulsant properties, and it inhibits cortisol release, with possible adverse consequences after long-term use. It has been used in anesthesia as it is unlikely to affect blood pressure, however it has largely been replaced by newer medications.

21.5 Drugs Used to Treat Sleep Disorders

NONBENZODIAZEPINE GABA AGONISTS

Several of the benzodiazepines are commonly used for sleep, such as flurazepam, temazepam, quazepam, estazolam, and triazolam. Temazepam, flurazepam, and triazolam are benzodiazepines used for insomnia; these are discussed with the other benzodiazepines under the anxiolytic section. Nonbenzodiazepine agonists, such as zolpidem (Ambien), zaleplon (Sonata), and eszopiclone (Lunesta)—the so-called “Z drugs”—are similar to these drugs as they bind at a location close to the benzodiazepine receptor

Pharmacologic Action

Zaleplon, zolpidem, and eszopiclone are structurally distinct and vary in their binding to the GABA receptor subunits. Benzodiazepines activate all three specific GABA–benzodiazepine (GABA–BZ) binding sites of the $GABA_A$-receptor, which opens chloride channels and reduces the rate of neuronal and

muscle firing. Zolpidem, zaleplon, and eszopiclone have selectivity for specific subunits of the GABA receptor. This specificity may account for their selective sedative effects and relative lack of muscle relaxant and anticonvulsant effects.

Zolpidem, zaleplon, and eszopiclone are rapidly and well absorbed after oral administration, although absorption can be delayed by as long as 1 hour if they are taken with food. Zolpidem reaches peak plasma concentrations in 1.6 hours and has a half-life of 2.6 hours. Zaleplon reaches peak plasma concentrations in 1 hour and has a half-life of 1 hour. Eszopiclone reaches peak plasma concentrations in 1 hour. If taken immediately after a high-fat or heavy meal, the peak is delayed by approximately 1 hour, reducing the effects of eszopiclone on sleep onset. The terminal-phase elimination half-life is approximately 6 hours in healthy adults. Eszopiclone is weakly bound to plasma protein (52 to 59 percent).

The rapid metabolism and lack of active metabolites of zolpidem, zaleplon, and eszopiclone avoid the accumulation of plasma concentrations compared with the long-term use of benzodiazepines such as flurazepam or diazepam.

Flumazenil for Benzodiazepine Overdosage. Similar to the benzodiazepines, flumazenil can reverse the adverse psychomotor, amnestic, and sedative effects of zolpidem and zaleplon.

Therapeutic Indications

Insomnia. Zolpidem, zaleplon, and eszopiclone are also indicated only for insomnia. Although these “Z drugs” are not usually associated with rebound insomnia after the discontinuation of their use for short periods, some patients experience increased sleep difficulties the first few nights after discontinuing their use. The use of zolpidem, zaleplon, and eszopiclone for periods more extended than 1 month is not associated with the delayed emergence of adverse effects. No development of tolerance to any parameter of sleep measurement was observed over 6 months in clinical trials of eszopiclone.

γ-Hydroxybutyrate (GHB, Xyrem), which is approved for the treatment of narcolepsy and improves slow-wave sleep, is also an agonist at the $GABA_A$ receptor, where it binds to specific GHB receptors. GHB has the capacity

both to reduce drug craving and to induce dependence, abuse, and absence seizures as a result of complex actions on tegmental dopaminergic systems.

Parkinson Disease. A small number of persons with idiopathic Parkinson disease respond to long-term use of zolpidem with reduced bradykinesia and rigidity. Zolpidem dosages of 10 mg four times daily may be tolerated without sedation for several years.

Precautions and Adverse Reactions

Zolpidem and zaleplon are generally well tolerated. At zolpidem dosages of 10 mg/day and zaleplon dosages above 10 mg/day, a small number of persons will experience dizziness, drowsiness, dyspepsia, or diarrhea. Zolpidem and zaleplon are secreted in breast milk and are therefore contraindicated for use by nursing mothers. The dosage of zolpidem and zaleplon should be reduced in elderly persons and persons with hepatic impairment.

Zolpidem (Ambien) has been associated with automatic behavior and amnesia. In rare cases, zolpidem may cause hallucinations and behavioral changes. The coadministration of zolpidem and SSRIs may extend the duration of hallucinations in susceptible patients. Eszopiclone exhibits a dose–response relationship in elderly adults for the side effects of pain, dry mouth, and unpleasant taste.

Zolpidem and zaleplon can produce a mild withdrawal syndrome lasting 1 day after prolonged use at higher therapeutic dosages. Rarely, a person taking zolpidem has self-titrated up the daily dosage to 30 to 40 mg a day. Abrupt discontinuation of such a high dosage of zolpidem may cause withdrawal symptoms for 4 or more days. Tolerance does not develop to the sedative effects of zolpidem and zaleplon.

Drug Interactions

These agents are most dangerous when used with other CNS depressants, such as alcohol, barbituates, opioids, and similar drugs. Cimetidine increases the plasma concentrations of zaleplon.

Rifampin (Rifadin), phenytoin (Dilantin), carbamazepine, and phenobarbital (Solfoton, Luminal) significantly increase the metabolism of zaleplon.

The CYP3A4 and CYP2E1 enzymes are involved in the metabolism of eszopiclone. Eszopiclone did not show any inhibitory potential on CYP450 1A2, 2A6, 2C9, 2C19, 2D6, 2E1, and 3A4 in cryopreserved human hepatocytes.

Laboratory Interferences

No known laboratory interferences are associated with the use of zolpidem and zaleplon.

Dosage and Clinical Guidelines

Zaleplon is available in 5- and 10-mg capsules. A single 10-mg dose is the usual adult dose. The dose can be increased to a maximum of 20 mg as tolerated. A single dose of zaleplon can be expected to provide 4 hours of sleep with minimal residual impairment. For persons older than age 65 years or persons with hepatic impairment, an initial dose of 5 mg is advised.

Eszopiclone is available in 1-, 2-, and 3-mg tablets. The starting dose should not exceed 1 mg in patients with severe hepatic impairment or those taking potent CYP3A4 inhibitors. The recommended dosing to improve sleep onset or maintenance is 2 or 3 mg for adult patients (ages 18 to 64 years) and 2 mg for older adult patients (ages 65 years and older). The 1-mg dose is for sleep onset in older adult patients whose primary complaint is difficulty falling asleep.

Zolpidem is available in 5- and 10-mg capsules, and 6.25- and 12.5-mg capsules for the controlled-release capsules. There is also a sublingual tablet and an oropharyngeal spray. The controlled-release form is usually for problems with sleep maintenance. The sublingual and oropharyngeal forms are for difficulties with taking the pill, or in particular circumstances. For example, the sublingual can be used for middle of the night awakening. With the oral capsule, the starting dose is 5 mg for females and 5 to 10 mg for males before bedtime. A single 10-mg dose is the usual adult dose (6.25- or 12.5-mg of the controlled release). The capsule should only be taken at the beginning of the night, as the drug can impair a person if they attempt activity within 7 to 8 hours of using the drug. For persons older than age 65 years or persons who are medically frail, 5 mg is the recommended dose.

MELATONIN AGONISTS: RAMELTEON AND MELATONIN

There are two melatonin receptor agonists commercially available in the United States: (1) melatonin, a dietary supplement available in various preparations in health food stores, and not under FDA regulations; (2) and ramelteon (Rozerem), an FDA-approved drug for the treatment of insomnia characterized by difficulties with sleep onset. Both exogenous melatonin and ramelteon are thought to exert their effects by interaction with central melatonin receptors.

Ramelteon

Ramelteon (Rozerem) is a melatonin receptor agonist used to treat sleep-onset insomnia. Unlike the benzodiazepines, ramelteon has no appreciable affinity for the GABA receptor complex.

Pharmacologic Actions. Ramelteon essentially mimics melatonin's sleep-promoting properties and has a high affinity for melatonin MT_1 and MT_2 receptors in the brain. These receptors are thought to be critical in the regulation of the body's sleep–wake cycle.

Ramelteon is rapidly absorbed and eliminated over a dose range of 4 to 64 mg. Maximum plasma concentration (C_{max}) is reached approximately 45 minutes after administration, and the elimination half-life is 1 to 2.6 hours. The total absorption of ramelteon is at least 84 percent, but extensive first-pass metabolism results in a bioavailability of approximately 2 percent. Ramelteon is metabolized primarily through the CYP1A2 pathway and eliminated principally in urine. Repeated once-daily dosing does not appear to result in accumulation, likely because of the compound's short half-life.

Therapeutic Indications. The FDA-approved ramelteon for the treatment of insomnia characterized by difficulty with sleep onset. Potential off-label use is centered on the application in circadian rhythm disorders, predominantly jet lag, delayed sleep phase syndrome, and shift work sleep disorder.

Clinical trials and animal studies have failed to demonstrate evidence of rebound insomnia or withdrawal effects.

Precautions and Adverse Events. Headache is the most common side effect of ramelteon. Other adverse effects may include somnolence, fatigue, dizziness, worsening insomnia, depression, nausea, and diarrhea. We should not use the drug in patients with severe hepatic impairment. It is also not recommended in patients with severe sleep apnea or severe chronic obstructive pulmonary disease. Prolactin levels may be increased in women. The drug should be used with caution, if at all, in nursing mothers and pregnant women.

Ramelteon has been found sometimes to decrease blood cortisol and testosterone and to increase prolactin. Female patients should be monitored for the cessation of menses and galactorrhea, decreased libido, and fertility problems. The safety and effectiveness of ramelteon in children has not been established.

Drug Interactions. CYP1A2 is the major isozyme involved in the hepatic metabolism of ramelteon. Accordingly, fluvoxamine (Luvox) and other CYP1A2 inhibitors may increase the side effects of ramelteon.

Ramelteon should be administered with caution in patients taking CYP1A2 inhibitors, potent CYP3A4 inhibitors such as ketoconazole, and strong CYP2C inhibitors such as fluconazole (Diflucan). No clinically meaningful interactions were found when ramelteon was coadministered with omeprazole, theophylline, dextromethorphan, midazolam, digoxin, and warfarin.

Dosing and Clinical Guidelines. The usual dose of ramelteon is 8 mg within 30 minutes of going to bed. It should not be taken with or immediately after high-fat meals.

Melatonin

Melatonin (*N*-acetyl-5-methoxytryptamine) is a hormone produced mainly at night in the pineal gland. Ingested melatonin can reach and bind to melatonin-binding sites in the brains of mammals and produce somnolence when used at high doses. Melatonin is available as a dietary supplement and is not a medication. Few well-controlled clinical trials have been conducted to determine its effectiveness in treating such conditions as insomnia, jet lag, and sleep disturbances related to shift work.

Pharmacologic Actions. Melatonin's secretion is stimulated by the dark and inhibited by the light. It is naturally synthesized from the amino acid tryptophan, which is converted to serotonin and finally converted to melatonin. The suprachiasmatic nuclei (SCN) of the hypothalamus have melatonin receptors, and melatonin may have a direct action on SCN to influence circadian rhythms, which are relevant for jet lag and sleep disturbances. In addition to the pineal gland, melatonin is also produced in the retina and GI tract.

Melatonin has a very short half-life of 0.5 to 6 minutes. Plasma concentrations are a function of the dose administered and the endogenous rhythm. Approximately 90 percent of melatonin is cleared through the first-pass metabolism by way of the CYP1A1 and CYP1A2 pathways. Elimination occurs principally in urine.

Exogenous melatonin interacts with the melatonin receptors that suppress neuronal firing and promote sleep. There does not appear to be a dose–response relationship between exogenous melatonin administrations and sleep effects.

Therapeutic Indications. Melatonin is approved for insomnia in the European Union and several other countries, however, it is not approved by the FDA for any medical use. It is sold over the counter in the United States and Canada but requires a prescription in some other countries such as the United Kingdom. Individuals have used exogenous melatonin to address sleep difficulties (insomnia, circadian rhythm disorders), cancer (breast, prostate, colorectal), seizures, depression, anxiety, and seasonal affective disorder. Some studies suggest that exogenous melatonin may have some antioxidant effects and antiaging properties.

Precautions and Adverse Reactions. Adverse events associated with melatonin include fatigue, dizziness, headache, irritability, and somnolence. Disorientation, confusion, sleepwalking, vivid dreams, and nightmares have also been observed, often with effects resolving after melatonin administration was suspended.

Melatonin may reduce fertility in both men and women. In men, exogenous melatonin reduces sperm motility, and long-term administration has been shown to inhibit testicular aromatase levels. In women, exogenous

melatonin may inhibit ovarian function, and for that reason, it has been evaluated as a contraceptive, but with inconclusive results.

Drug Interactions. As a dietary supplement preparation, exogenous melatonin is not regulated by the FDA and has not been subjected to the same type of drug interaction studies that were performed for ramelteon. Caution is suggested in coadministering melatonin with blood thinners (e.g., warfarin [Coumadin], aspirin, and heparin), antiseizure medications, and medications that lower BP.

Laboratory Interference. Melatonin is not known to interfere with any commonly used clinical laboratory tests.

Dosage and Administration. Over-the-counter melatonin is available in the following formulations: 1-, 2.5-, 3-, and 5-mg capsules; 1-mg/4-mL liquid; 0.5- and 3-mg lozenges; 2.5-mg sublingual tablets; and 1-, 2-, and 3-mg timed-release tablets.

Standard recommendations are to take the desired melatonin dose at bedtime, but some evidence from clinical trials suggests that dosing up to 2 hours before habitual bedtime may produce a more significant improvement in sleep onset.

Agomelatine (Valdoxan). Agomelatine is structurally related to melatonin and is used in Europe as a treatment for MDD. It acts as an agonist at melatonin (MT_1 and MT_2) receptors. It also acts as a serotonin antagonist. Analysis of agomelatine clinical trial data raised serious questions about the efficacy and safety of the drug. The drug is not being marketed in the United States.

PRAZOSIN

Prazosin (Minipress) is a quinazoline derivative and one of a new chemical class of antihypertensives. It is an α_1-adrenergic receptor antagonist as opposed to the drugs mentioned above, which are α_2-blockers.

Pharmacologic Actions

The exact mechanism of the hypotensive action of prazosin, and how it suppresses nightmares, is unknown. Prazosin causes a decrease in total peripheral resistance that is related to its action as an α_1-adrenergic receptor antagonist. BP is lowered in both the supine and standing positions. This effect is most pronounced on the diastolic BP. After oral administration, human plasma concentrations reach a peak at about 3 hours with a plasma half-life of 2 to 3 hours. The drug is highly bound to plasma protein. Tolerance has not been observed to develop with long-term therapy.

Therapeutic Action

Prazosin is used in psychiatry to suppress nightmares, particularly those associated with PTSD.

Precautions and Adverse Reactions

During clinical trials and subsequent marketing experience, the most frequent reactions were dizziness (10.3 percent); headache (7.8 percent); drowsiness (7.6 percent); lack of energy (6.9 percent); weakness (6.5 percent); palpitations (5.3 percent); and nausea (4.9 percent). In most instances, side effects disappeared with continued therapy or have been tolerated with no decrease in the dose of the drug. Prazosin should not be used in nursing mothers or during pregnancy.

Drug Interactions

No adverse drug interactions have been reported.

Laboratory Interferences

No laboratory interferences have been reported.

Dosage and Clinical Guidelines

The drug is supplied in 1-, 2-, and 5-mg capsules and a nasal spray. The therapeutic dosages most commonly used have ranged from 6 to 15 mg daily given in divided doses. Doses higher than 20 mg do not increase efficacy. When adding a diuretic or other antihypertensive agent, the dose should be reduced to 1 or 2 mg three times a day, and retitration then carried out.

Concomitant use with a PDE-5 inhibitor can result in additive BP-lowering effects and symptomatic hypotension; therefore, PDE-5 inhibitor therapy should be initiated at the lowest dose in patients taking prazosin.

21.6 Stimulants

STIMULANT DRUGS AND ATOMOXETINE

Stimulant drugs increase motivation, mood, energy, and wakefulness. They are also called sympathomimetics because they mimic the physiologic effects of the neurotransmitter epinephrine. Several chemical classes are included in this group.

Currently, these drugs are most commonly used to treat symptoms of poor concentration and hyperactivity in children and adults with ADHD. Paradoxically, many patients with ADHD find that these drugs can have a calming effect. Sympathomimetics are also approved for use in increasing alertness in narcolepsy.

Amphetamines were the first stimulants to be synthesized. They were created in the late 19th century and were used by Bavarian soldiers in the mid-1880s to maintain wakefulness, alertness, energy, and confidence in combat. They have been used similarly in most wars since then. They were not widely used clinically until the 1930s when they were marketed as Benzedrine inhalers for relief of nasal congestion. When their psychostimulant effects were noted, these drugs were used to treat sleepiness associated with narcolepsy. They have been classified as controlled drugs because of their rapid onset, immediate behavioral effects, and propensity to develop tolerance, which leads to the risk of abuse and dependence in vulnerable individuals. State and federal agencies regulate their manufacture, distribution, and use. In 2005, pemoline was withdrawn from the market because of significant risks of treatment-emergent hepatotoxicity.

Sympathomimetics have been widely used in persons with ADHD and narcolepsy because no equally effective agents have been available. They have also been found useful in treating certain cognitive disorders that result in secondary depression or profound apathy (e.g., AIDS, multiple sclerosis,

poststroke depression, dementia, closed head injury) as well as in the augmentation of antidepressant medications in specific treatment-resistant depressions.

Atomoxetine is included in this section because it is used to treat ADHD, even though it is not a psychostimulant.

Pharmacologic Actions

All of these drugs are well absorbed from the GI tract. Amphetamine (Adderall) and dextroamphetamine (Dexedrine, Dextrostat) reach peak plasma concentrations in 2 to 3 hours and have a half-life of about 6 hours, thereby necessitating once- or twice-daily dosing. Methylphenidate is available in immediate-release (Ritalin), sustained-release (Ritalin SR), and extended-release (Concerta) formulations. Immediate-release methylphenidate reaches peak plasma concentrations in 1 to 2 hours and has a short half-life of 2 to 3 hours, thereby necessitating multiple-daily dosing. The sustained-release formulation reaches peak plasma concentrations in 4 to 5 hours and doubles the effective half-life of methylphenidate. The extended-release formulation reaches peak plasma concentrations in 6 to 8 hours and is designed to be effective for 12 hours in once-daily dosing. Dexmethylphenidate (Focalin) reaches peak plasma concentration in about 3 hours and is prescribed twice daily.

Lisdexamfetamine dimesylate, also known as L-lysine D-amphetamine (Vyvanse), is an amphetamine prodrug. In this formulation, dextroamphetamine is coupled with the amino acid L-lysine. Lisdexamfetamine becomes active upon cleavage of the lysine portion of the molecule by enzymes in the red blood cells. This results in the gradual release of dextroamphetamine into the bloodstream. Apart from having an extended duration of action, this formulation reduces its abuse potential. It is the only prodrug of its kind. Lisdexamfetamine is indicated for the treatment of ADHD in children 6 years and up and in adults as an integral part of a total treatment program that may include other measures (i.e., psychological, educational, social). The safety and efficacy of lisdexamfetamine dimesylate in patients 3 to 5 years old has not been established. In contrast to Adderall, which contains approximately 75 percent dextroamphetamine and 25 percent levoamphetamine, lisdexamfetamine is a single, dextro-enantiomer

amphetamine molecule. In most cases, this makes the drug better tolerated, but some patients experience a more significant benefit from the mixed isomer preparation.

Methylphenidate, dextroamphetamine, and amphetamine are indirectly acting sympathomimetics, with the primary effect causing the release of catecholamines from presynaptic neurons. Their clinical effectiveness is associated with increased release of both dopamine and norepinephrine. Dextroamphetamine and methylphenidate are also weak inhibitors of catecholamine reuptake and inhibitors of monoamine oxidase.

In recent years, there has been an explosion of new brand name stimulants. Most of these are variations of the generic methylphenidate or mixed amphetamine salts that provide additional options to customize treatment in terms of dosing and duration of effect.

For modafinil, the specific mechanism of action is unknown. Narcolepsy–cataplexy results from a deficiency of hypocretin, a hypothalamic neuropeptide. Hypocretin-producing neurons are activated after modafinil administration. Modafinil does not appear to work through a dopaminergic mechanism. It does have α_1-adrenergic agonist properties, which may account for its alerting effects, because the wakefulness induced by modafinil can be attenuated by prazosin, an α_1-adrenergic antagonist. Some evidence suggests that modafinil has some norepinephrine reuptake blocking effects. Armodafinil (Nuvigil) is the R-enantiomer of modafinil. Both drugs have similar clinical effects and side effects.

Therapeutic Indications

Attention-Deficit/Hyperactivity Disorder (ADHD). Sympathomimetics are the first-line drugs for the treatment of ADHD in children and are effective about 75 percent of the time. Methylphenidate and dextroamphetamine are equally effective and work within 15 to 30 minutes. Sympathomimetic drugs decrease hyperactivity, increase attentiveness, and reduce impulsivity. They may also reduce comorbid oppositional behaviors associated with ADHD. Many persons take these drugs throughout their schooling and beyond. In responsive persons, the use of a sympathomimetic may be a critical determinant of scholastic success.

Sympathomimetics improve the core ADHD symptoms of hyperactivity,

impulsivity, and inattentiveness and permit improved social interactions with teachers, family, other adults, and peers. The success of long-term treatment of ADHD with sympathomimetics, which are efficacious for most of the various constellations of ADHD symptoms present from childhood to adulthood, supports a model in which ADHD results from a genetically determined neurochemical imbalance that requires lifelong pharmacologic management.

Methylphenidate is the most commonly used initial agent at a dosage of 5 to 10 mg every 3 to 4 hours. Dosages may be increased to a maximum of 20 mg four times daily or 1 mg/kg a day. Use of the 20-mg sustained-release formulation to achieve 6 hours of benefit and eliminate the need for dosing at school is supported by many experts, although other authorities believe it is less effective than the immediate-release formulation. Dextroamphetamine is about twice as potent as methylphenidate on a per milligram basis and provides 6 to 8 hours of benefit. Some 70 percent of nonresponders to one sympathomimetic may benefit from another. All of the sympathomimetic drugs should be tried before switching to drugs of a different class. The previous dictum that sympathomimetics worsen tics and, therefore, should be avoided by persons with comorbid ADHD and tic disorders has been questioned. Small dosages of sympathomimetics do not appear to cause an increase in the frequency and severity of tics. Alternatives to sympathomimetics for ADHD include bupropion (Wellbutrin), venlafaxine (Effexor), guanfacine (Tenex), clonidine (Catapres), and tricyclic drugs. Further studies are needed to determine whether modafinil improves the symptoms of ADHD.

Short-term use of sympathomimetics induces a euphoric feeling; however, tolerance develops for both the euphoric feeling and the sympathomimetic activity.

Narcolepsy and Hypersomnolence. Narcolepsy consists of sudden sleep attacks (*narcolepsy*), sudden loss of postural tone (*cataplexy*), loss of voluntary motor control going into (hypnagogic) or coming out of (hypnopompic) sleep (*sleep paralysis*), and hypnagogic or hypnopompic *hallucinations*. Sympathomimetics reduce narcoleptic sleep attacks and improve wakefulness in other types of hypersomnolent states. Modafinil is approved as an antisomnolence agent for the treatment of narcolepsy, for

people who cannot adjust to night shift work, and for those who do not sleep well because of obstructive sleep apnea.

Other sympathomimetics are also used to maintain wakefulness and accuracy of motor performance in persons subject to sleep deprivation, such as pilots and military personnel. Persons with narcolepsy, unlike persons with ADHD, may develop a tolerance for the therapeutic effects of sympathomimetics.

In direct comparison with amphetamine-like drugs, modafinil is equally useful at maintaining wakefulness, with a lower risk of excessive activation.

Depressive Disorders. Sympathomimetics may be used for treatment-resistant depressive disorders, usually as augmentation of standard antidepressant drug therapy. Possible indications for the use of sympathomimetics as monotherapy include depression in elderly persons, who are at increased risk for adverse effects from standard antidepressant drugs; depression in medically ill persons, especially persons with AIDS; obtundation caused by chronic use of opioids; and clinical situations in which a rapid response is necessary but for which ECT is contraindicated. Depressed patients with abulia and anergia may also benefit.

Dextroamphetamine may be useful in differentiating pseudodementia of depression from dementia. A depressed person generally responds to a 5-mg dose with increased alertness and improved cognition. Sympathomimetics are thought to provide only short-term benefit (2 to 4 weeks) for depression because most persons rapidly develop a tolerance for the antidepressant effects of the drugs. However, some clinicians report that long-term treatment with sympathomimetics can benefit some persons.

Encephalopathy Caused by Brain Injury. Sympathomimetics increase alertness, cognition, motivation, and motor performance in persons with neurologic deficits caused by strokes, trauma, tumors, or chronic infections. Treatment with sympathomimetics may permit earlier and more robust participation in rehabilitative programs. Poststroke lethargy and apathy may respond to long-term use of sympathomimetics.

Obesity. Sympathomimetics are used in the treatment of obesity because of their anorexia-inducing effects. Because tolerance develops for the anorectic

effects and because of the drugs' high abuse potential, their use for this indication is limited. Of the sympathomimetic drugs, phentermine (Adipex-P, Fastin) is the most widely used for appetite suppression. Phentermine was the second half of "fen-phen," an off-label combination of fenfluramine and phentermine, widely used to promote weight loss. Fenfluramine and dexfenfluramine were withdrawn from the market because of their adverse effect, including cardiac valvular insufficiency, primary pulmonary hypertension, and irreversible loss of cerebral serotoninergic nerve fibers. The toxicity of fenfluramine is attributed to the fact that it stimulates the release of massive amounts of serotonin from nerve endings, a mechanism of action not shared by phentermine. The use of phentermine alone has not been reported to cause the same adverse effects like those caused by fenfluramine or dexfenfluramine.

Careful limitations of caloric intake and judicious exercise are at the core of any successful weight loss program. Sympathomimetic drugs facilitate the loss of, at most, an additional fraction of a pound per week. Sympathomimetic drugs are effective appetite suppressants only for the first few weeks of use; then, the anorexigenic effects tend to decrease.

Fatigue. Between 70 and 90 percent of individuals with multiple sclerosis experience fatigue. Modafinil, armodafinil, amphetamines, methylphenidate, and the dopamine receptor agonist amantadine (Symmetrel) are sometimes useful in combating this symptom. Other causes of fatigue, such as chronic fatigue syndrome, respond to stimulants in many cases.

Precautions and Adverse Reactions

The most common adverse effects associated with amphetamine-like drugs are stomach pain, anxiety, irritability, insomnia, tachycardia, cardiac arrhythmias, and dysphoria. Sympathomimetics cause a decreased appetite, although tolerance usually develops for this effect. The treatment of common adverse effects in children with ADHD is usually straightforward (Table 21-49). The drugs can also cause increases in heart rate and BP and may cause palpitations. Less common adverse effects include the possible induction of movement disorders, such as tics, Tourette disorder–like symptoms, and dyskinesias, all of which are often self-limited over 7 to 10 days. If a person

taking a sympathomimetic develops one of these movement disorders, a correlation between the dose of the medication and the severity of the disorder must be firmly established before adjustments are made in the medication dosage. In severe cases, augmentation with risperidone (Risperdal), clonidine (Catapres), or guanfacine (Tenex) is necessary. Methylphenidate may worsen tics in one-third of persons; these persons fall into two groups: those whose methylphenidate-induced tics resolve immediately upon the metabolism of the dosage, and a smaller group in whom methylphenidate appears to trigger tics that persist for several months but eventually resolve spontaneously.

Table 21-49
Management of Common Stimulant-Induced Adverse Effects in Attention-Deficit/Hyperactivity Disorder

Adverse Effect	Management
Anorexia, nausea, weight loss	• Administer stimulant with meals. • Use caloric-enhanced supplements. Discourage forcing meals.
Insomnia, nightmares	• Administer stimulants earlier in day. • Change to short-acting preparations. • Discontinue afternoon or evening dosing. • Consider adjunctive treatment (e.g., antihistamines, clonidine, antidepressants).
Dizziness	• Monitor BP. • Encourage fluid intake. • Change to long-acting form.
Rebound phenomena	• Overlap stimulant dosing. • Change to long-acting preparation or combine long- and short-acting preparations. • Consider adjunctive or alternative treatment (e.g., clonidine, antidepressants).
Irritability	• Assess timing of phenomena (during peak or

	withdrawal phase). • Evaluate comorbid symptoms. • Reduce dose. • Consider adjunctive or alternative treatment (e.g., lithium, antidepressants, anticonvulsants).
Dysphoria, moodiness, agitation	• Consider comorbid diagnosis (e.g., mood disorder). • Reduce dosage or change to long-acting preparation. • Consider adjunctive or alternative treatment (e.g., lithium, anticonvulsants, antidepressants).

BP, blood pressure.

From Wilens TE, Blederman J. The stimulants. In: Shaffer D, ed. *The Psychiatric Clinics of North America: Pediatric Psychopharmacology*. Philadelphia, PA: Saunders; 1992, with permission.

Longitudinal studies do not indicate that sympathomimetics cause growth suppression. Sympathomimetics may exacerbate glaucoma, hypertension, cardiovascular disorders, hyperthyroidism, anxiety disorders, psychotic disorders, and seizure disorders.

High dosages of sympathomimetics can cause dry mouth, pupillary dilation, bruxism, formication, excessive ebullience, restlessness, emotional lability, and occasionally seizures. Long-term use of high dosages can cause a delusional disorder that resembles paranoid schizophrenia. Seizures can be treated with benzodiazepines, cardiac effects with β-adrenergic receptor antagonists, fever with cooling blankets, and delirium with DRAs. Overdosages of sympathomimetics result in hypertension, tachycardia, hyperthermia, toxic psychosis, delirium, hyperpyrexia, convulsions, coma, chest pain, arrhythmia, heart block, hypertension or hypotension, shock, and nausea. Toxic effects of amphetamines can be seen at 30 mg, but idiosyncratic toxicity can occur at doses as low as 2 mg. Conversely, survival has been reported up to 500 mg.

The most limiting adverse effect of sympathomimetics is their association with psychological and physical dependence. At the doses used for the treatment of ADHD, the development of psychological dependence virtually

never occurs. The more considerable concern is the presence of adolescent or adult cohabitants who might confiscate the supply of sympathomimetics for abuse or sale.

The use of sympathomimetics should be avoided during pregnancy, especially during the first trimester. Dextroamphetamine and methylphenidate pass into the breast milk, and it is not known whether modafinil or armodafinil do.

Drug Interactions

Sympathomimetics decrease the metabolism of several drugs, thus increasing their plasma levels. These drugs include tricyclic or tetracyclic antidepressants, warfarin (Coumadin), primidone (Mysoline), phenobarbital (Luminal), phenytoin (Dilantin), or phenylbutazone (Butazolidin). Sympathomimetics decrease the therapeutic efficacy of many antihypertensive drugs, especially guanethidine (Esimil, Ismelin). The sympathomimetics should be used with extreme caution with MAOIs.

Laboratory Interferences

Dextroamphetamine may elevate plasma corticosteroid levels and interfere with some assay methods for urinary corticosteroids.

Dosage and Administration

Many psychiatrists believe that governmental authorities have overly regulated amphetamine use. Amphetamines are listed as schedule II drugs by the Drug Enforcement Agency. Some states keep a registry of patients who receive amphetamines. Such mandates worry both patients and physicians about breaches in confidentiality, and physicians are concerned that official agencies may misinterpret their prescribing practices. Consequently, some physicians may withhold prescription of sympathomimetics, even from persons who may benefit from the medications.

The dosage ranges and the available preparations for sympathomimetics are presented in Table 21-50. Vyvanse dosing is a particular case because many patients are switched to this formulation after being treated with other stimulants. A conversion table is shown in Table 21-51. It is available in 20-, 30-, 40-, 50-, 60-, and 70-mg capsules. Dosage should be individualized

according to the therapeutic needs and response of the patient. Lisdexamfetamine (Vyvanse) should be administered at the lowest effective dosage. In patients who are either starting treatment for the first time or switching from another medication, 30 mg once daily in the morning is the recommended dose. Dosages may go up or down in 10 or 20 mg increments in intervals of approximately 1 week. Patients should avoid taking the drug in the afternoon, as this may cause insomnia. The drug may be taken with or without food.

Dextroamphetamine, methylphenidate, amphetamine, benzphetamine, and methamphetamine are schedule II drugs and, in some states, require triplicate prescriptions. Phendimetrazine (Adipost, Bontril) and phenmetrazine (Prelude) are schedule III drugs, and modafinil, armodafinil, phentermine, diethylpropion (Tenuate), and mazindol (Mazanor, Sanorex) are schedule IV drugs.

Pretreatment evaluation should include an evaluation of the patient's cardiac function, with particular attention to the presence of hypertension or tachyarrhythmias. The clinician should also examine the patient for the presence of movement disorders, such as tics and dyskinesia, because the administration of sympathomimetics can exacerbate these conditions. If tics are present, many experts will not prescribe sympathomimetics but will instead choose clonidine or antidepressants. However, recent data indicate that sympathomimetics may cause only a mild increase in motor tics and may suppress vocal tics. Liver function and renal function should be assessed, and dosages of sympathomimetics should be reduced for persons with impaired metabolism.

Table 21-50
Selected Sympathomimetics Commonly Used in Psychiatry

Generic Name	Trade Name	Preparations	Initial Daily Dose	Usual Daily Dose for ADHD[a]	Usual Daily Dose for Disorders Associated with Excessive Daytime Somnolence	Maximum Daily Dose
Amphetamine–dextroamphetamine	Adderall	5-, 10-, 20-, and 30-mg tablets	5–10 mg	20–30 mg	5–60 mg	Children: 40 mg Adults: 60 mg
Armodafinil	Nuvigil	50-, 150-, and 250-mg tablets	50–150 mg	150–250 mg	250 mg	
Atomoxetine	Strattera	10-, 18-, 25-, 40-, and 60-mg tablets	20 mg	40–80 mg	Not used	Children: 80 mg Adults: 100 mg
Dexmethylphenidate	Focalin	2.5-, 5-, and 10-mg capsules	5 mg	5–20 mg	Not used	20 mg
Dextroamphetamine	Dexedrine, Dextrostat	5-, 10-, and 15-mg ER capsules; 5- and 10-mg tablets	5–10 mg	20–30 mg	5–60 mg	Children: 40 mg Adults: 60 mg
Lisdexamfetamine	Vyvanse	20-, 30-, 40-, 50-, 60-, and 70-mg capsules	20–30 mg			70 mg
Methamphetamine	Desoxyn	5-mg tablets; 5-, 10-, and 15-mg ER tablets	5–10 mg	20–25 mg	Not generally used	45 mg
Methylphenidate	Ritalin, Methidate, Methylin, Attenade	5-, 10-, and 20-mg tablets; 10- and 20-mg SR tablets	5–10 mg	5–60 mg	20–30 mg	Children: 80 mg Adults: 90 mg
	Concerta	18- and 36-mg ER tablets	18 mg	18–54 mg	Not yet established	54 mg
Modafinil*	Provigil	100- and 200-mg tablets	100 mg	Not used	400 mg	400 mg

*Obstructive sleep apnea, narcolepsy, and shift work disorder
[a]For children 6 years of age and older.
ER, extended release; SR, sustained release.

Table 21-51 Lisdexamfetamine (Vyvanse) Dosage Equivalency Conversions

Vyvanse and Adderall XR	
Vyvanse	Adderall XR
20 mg	5 mg
30 mg	10 mg
40 mg	15 mg
50 mg	20 mg
60 mg	25 mg
70 mg	30 mg
Vyvanse, Adderall IR, and Dexedrine	

Vyvanse	Adderall IR	Dexedrine
70 mg	30 mg	22.5 mg
50 mg	20 mg	15 mg
30 mg	10 mg	7.5 mg

XR, extended release; IR, immediate-release.

Persons with ADHD can take immediate-release methylphenidate at 8 AM, 12 noon, and 4 PM. Dextroamphetamine, Adderall, sustained-release methylphenidate, or 18 mg of extended-release methylphenidate may be taken once at 8 AM. The starting dose of methylphenidate ranges from 2.5 mg of regular to 20 mg of the sustained-release formulation. If this is inadequate, it may be increased to a maximum dose of 80 mg in children and 90 mg daily in adults. The dosage of dextroamphetamine is 2.5 to 40 mg a day up to 0.5 mg/kg a day.

The starting dosage of modafinil is 200 mg in the morning in medically healthy individuals and 100 mg in the morning in persons with hepatic impairment. Some persons take a second 100- or 200-mg dose in the afternoon. The maximum recommended daily dosage is 400 mg, although dosages of 600 to 1,200 mg a day have been used safely. Adverse effects become prominent at dosages greater than 400 mg a day. Compared with amphetamine-like drugs, modafinil promotes wakefulness but produces less attentiveness and less irritability. Some persons with excessive daytime sleepiness extend the activity of the morning modafinil dose with an afternoon dose of methylphenidate. Armodafinil is virtually identical to modafinil but is dosed differently, the dosing range being 50 to 250 mg daily.

ATOMOXETINE (STRATTERA)

Atomoxetine is the first nonstimulant drug to be approved by the FDA as a treatment of ADHD in children, adolescents, and adults. It is included in this chapter because it shares this indication with the stimulants described earlier.

Pharmacologic Actions

Atomoxetine is believed to produce a therapeutic effect through selective

inhibition of the presynaptic norepinephrine transporter. It is well absorbed after oral administration and is minimally affected by food. High-fat meals may decrease the rate but not the extent of absorption. Maximum plasma concentrations are reached after approximately 1 to 2 hours. At therapeutic concentrations, 98 percent of atomoxetine in plasma is bound to protein, mainly albumin. Atomoxetine has a half-life of approximately 5 hours and is metabolized principally by the CYP2D6 pathway. Poor metabolizers of this compound reach a fivefold higher area under the curve and fivefold higher peak plasma concentration than normal or extensive metabolizers. This variation is critical to consider in patients receiving medications that inhibit the CYP2D6 enzyme. For example, the antidepressant-like pharmacology of atomoxetine has led to its use as an add-on to SSRIs or other antidepressants. Drugs such as fluoxetine (Prozac), paroxetine (Paxil), and bupropion (Wellbutrin) are CYP2D6 inhibitors and may raise atomoxetine levels.

Therapeutic Indications

Atomoxetine is used for the treatment of ADHD. It should be considered for use in patients who find stimulants too activating or who experience other intolerable side effects. Because atomoxetine has no abuse potential, it is a reasonable choice in the treatment of patients with both ADHD and substance abuse, patients who complain of ADHD symptoms but are suspected of seeking stimulant drugs, and patients who are in recovery.

Atomoxetine may enhance cognition when used to treat patients with schizophrenia. It may also be used as an alternative or add-on to antidepressants in patients who fail to respond to standard therapies.

Precautions and Adverse Reactions

Common side effects of atomoxetine include abdominal discomfort, decreased appetite with resulting weight loss, sexual dysfunction, dizziness, vertigo, irritability, and mood swings. Minor increases in BP and heart rate have also been observed. There have been cases of severe liver injury in a small number of patients taking atomoxetine. The drug should be discontinued in patients with jaundice (yellowing of the skin or whites of the eyes, itching) or laboratory evidence of liver injury. Atomoxetine should not be taken at the same time as, or within 2 weeks of taking, an MAOI or by

patients with narrow-angle glaucoma.

The effects of overdose greater than twice the maximum recommended daily dose in humans are unknown. No specific information is available on the treatment of overdose with atomoxetine.

Dosage and Clinical Guidelines

Atomoxetine is available as 10-, 18-, 25-, 40-, and 60-mg capsules. In children and adolescents who weigh up to 70 kg, atomoxetine should be initiated at a total daily dose of approximately 0.5 mg/kg and increased after a minimum of 3 days to a target total daily dose of approximately 1.2 mg/kg, administered either as a single daily dose in the morning or as evenly divided doses in the morning and late afternoon or early evening. The total daily dose in smaller children and adolescents should not exceed 1.4 mg/kg or 100 mg, whichever is less. Dosing of children and adolescents who weigh more than 70 kg and adults should start at a total daily dose of 40 mg and then be increased after a minimum of 3 days to a target total daily dose of approximately 80 mg. The doses can be administered either as a single daily dose in the morning or as evenly divided doses in the morning and late afternoon or early evening. After 2 to 4 additional weeks, the dose may be increased to a maximum of 100 mg in patients who have not achieved an optimal response. The maximum recommended total daily dose in children and adolescents over 70 kg and adults is 100 mg.

▲ 21.7 Drugs Used to Treat Substance Use Disorders

OPIOID RECEPTOR AGONISTS

Opioid receptor agonists are a structurally diverse group of compounds that are used for pain management. These drugs are also called narcotics. Although highly effective as analgesics, they often cause dependence and are frequently diverted for recreational use. Commonly used opioid agonists for pain relief include morphine, hydromorphone (Dilaudid), codeine, meperidine (Demerol), oxycodone (OxyContin), buprenorphine (Buprenex),

hydrocodone (Robidone), tramadol (Ultram), and fentanyl (Durogesic). Heroin is used as a street drug. Methadone is used both for pain management and for the treatment of opiate addiction. This chapter focuses on the μ-opioid receptor agonists that are most likely to be used in the treatment of psychiatric disorders instead of pain management.

It is now recognized that the pharmacology of the opioid system is complex. There are multiple types of opioid receptors, with μ- and κ-opioid receptors representing functionally opposing endogenous systems (Table 21-52). All of the compounds above, which represent the most extensively used narcotic analgesics, are agonists at μ-opioid receptors. However, analgesic effects also result from agonist effects on the κ-opioid receptor. Buprenorphine has mixed receptor effects, being primarily a μ-opioid receptor agonist as well as a κ-opioid antagonist.

There is growing interest in the use of some drugs that act on opioid receptors as alternative treatments for a subpopulation of patients with refractory depression, as well as treatment for cutting behavior in patients with borderline personality disorder.

Ongoing, regular use of opioids produces dependence and tolerance and may lead to maladaptive use, functional impairment, and withdrawal symptoms. This well-known fact tempers consideration of such off-label use. The prevalence of opioid use, abuse, and dependence, particularly with prescription opioids, has risen in recent years.

Table 21-52
μ- and κ-Opiate Receptors

Receptor	Agonist Effects	Antagonist Effects
Mu (μ)	Analgesia Euphoria Antidepressant Anxiety	Anxiety Hostility
Kappa (κ)	Analgesia Dysphoria Depression	Antidepressant

Before using opioid receptor agonists with patients who have failed on multiple conventional therapeutic agents, screen carefully for a history of drug use disorders, document the rationale for off-label use, establish treatment ground rules, obtain written consent, consult with primary care physician, and monitor closely. Avoid replacing “lost” prescriptions and providing early prescription renewals.

Pharmacologic Actions

Methadone and buprenorphine are absorbed rapidly from the GI tract. Hepatic first-pass metabolism significantly affects the bioavailability of each of the drugs but in markedly different ways. For methadone, hepatic enzymes reduce the bioavailability of an oral dosage by about half, an effect that is easily managed with dosage adjustments.

For buprenorphine, first-pass intestinal and hepatic metabolism eliminates oral bioavailability almost wholly. When used in opioid detoxification, buprenorphine is given sublingually in either a liquid or a tablet formulation.

The peak plasma concentrations of oral methadone are reached within 2 to 6 hours, and the plasma half-life initially is 4 to 6 hours in opioid-naive persons and 24 to 36 hours after steady dosing of any type of opioid. Methadone is highly protein-bound and equilibrates widely throughout the body, which ensures little post dosage variation in steady-state plasma concentrations.

Elimination of a sublingual dosage of buprenorphine occurs in two phases: an initial phase with a half-life of 3 to 5 hours and a terminal phase with a half-life of more than 24 hours. Buprenorphine dissociates from its receptor binding site slowly, which permits an every-other-day dosing schedule.

Methadone acts as a pure agonist at μ-opioid receptors and has negligible agonist or antagonist activity at κ- or δ-opioid receptors. Buprenorphine is a partial agonist at μ-receptors, a potent antagonist at κ-receptors, and neither an agonist nor an antagonist at δ-receptors.

Therapeutic Indications

Methadone. Methadone is used for short-term detoxification (7 to 30 days),

long-term detoxification (up to 180 days), and maintenance (treatment beyond 180 days) of opioid-dependent individuals. For these purposes, it is only available through designated clinics called methadone maintenance treatment programs (MMTPs) and in hospitals and prisons. Methadone is a schedule II drug, which means that specific federal laws and regulations tightly govern its administration.

Enrollment in a methadone program reduces the risk of death by 70 percent; reduces illicit use of opioids and other substances of abuse; reduces criminal activity; reduces the risk of infectious diseases of all types, most importantly HIV and hepatitis B and C infection; and in pregnant women, reduces the risk of fetal and neonatal morbidity and mortality. The use of methadone maintenance frequently requires lifelong treatment.

Some opioid-dependence treatment programs use a stepwise detoxification protocol in which a person addicted to heroin switches first to the potent agonist methadone; then to the weaker agonist buprenorphine; and finally to maintenance on an opioid receptor antagonist, such as naltrexone (ReVia). This approach minimizes the appearance of opioid withdrawal effects, which, if they occur, are mitigated with clonidine (Catapres). However, compliance with opioid receptor antagonist treatment is low outside of settings using intensive cognitive-behavioral techniques. In contrast, noncompliance with methadone maintenance precipitates opioid withdrawal symptoms, which serve to reinforce the use of methadone and make cognitive-behavioral therapy less than essential. Thus, some well-motivated, socially integrated former heroin addicts can use methadone for years without participation in a psychosocial support program.

Data pooled from many reports indicate that methadone is more effective when taken at dosages above 60 mg a day. The analgesic effects of methadone are sometimes used in the management of chronic pain when less addictive agents are ineffective.

PREGNANCY. Methadone maintenance, combined with effective psychosocial services and regular obstetric monitoring, significantly improves obstetric and neonatal outcomes for women addicted to heroin. Enrollment of a heroin-addicted pregnant woman in such a maintenance program reduces the risk of malnutrition, infection, preterm labor, spontaneous abortion, preeclampsia, eclampsia, abruptio placenta, and septic thrombophlebitis.

The dosage of methadone during pregnancy should be the lowest effective dosage, and no withdrawal to abstinence should be attempted during pregnancy. Methadone is metabolized more rapidly in the third trimester, which may necessitate higher dosages. The daily dose can be administered in two divided doses during the third trimester to avoid potentially sedating postdose peak plasma concentrations. Methadone treatment has no known teratogenic effects.

NEONATAL METHADONE WITHDRAWAL SYMPTOMS. Withdrawal symptoms in newborns frequently include tremor, a high-pitched cry, increased muscle tone and activity, poor sleep and eating, mottling, yawning, perspiration, and skin excoriation. Convulsions that require aggressive anticonvulsant therapy may also occur. Withdrawal symptoms may be delayed in onset and prolonged in neonates because of their immature hepatic metabolism. Women taking methadone are sometimes counseled to initiate breastfeeding as a means of gently weaning their infants from methadone dependence, but they should not breastfeed their babies while still taking methadone.

Buprenorphine. The analgesic effects of buprenorphine are sometimes used in the management of chronic pain when less addictive agents are ineffective. Because buprenorphine is a partial agonist rather than a full agonist at the μ-receptor and is a weak antagonist at the κ-receptor, this agent produces a milder withdrawal syndrome and has a wider margin of safety than the full μ-agonist compounds generally used in treatment. Buprenorphine has a ceiling effect beyond which dose increases prolong the duration of action of the drug without further increasing the agonist effects. Because of this, buprenorphine has a high clinical safety profile, with limited respiratory depression, therefore decreasing the likelihood of lethal overdose. Buprenorphine does have the capacity to cause typical side effects associated with opioids, including sedation, nausea and vomiting, constipation, dizziness, headache, and sweating. A relevant pharmacokinetic consideration when using buprenorphine is the fact that it requires hepatic conversion to become analgesic (*N*-dealkylation catalyzed by CYP3A4). This may explain why some patients do not benefit from buprenorphine. Genetics, grapefruit juice, and many medications (including fluoxetine and fluvoxamine) can reduce a person’s ability to metabolize buprenorphine into its bioactive form.

Buprenorphine has been combined with the narcotic antagonist naloxone for sublingual administration (Suboxone). This combination reduces the likelihood of abusing buprenorphine via the IV route. Because the sublingual route poorly absorbs naloxone, when the combination drug is taken sublingually, there is no effect of the naloxone on the efficacy of buprenorphine. If an opioid-dependent individual injects the combination medication, the naloxone precipitates a withdrawal reaction, therefore reducing the likelihood of illicit injection use of the sublingual preparation.

Inducting and stabilizing a patient on buprenorphine is analogous to inducting and stabilizing a patient on methadone except that, as a partial agonist, buprenorphine has the potential to cause precipitated withdrawal in patients who have recently taken full agonist opioids. Thus, a patient must avoid short-acting opioids for 12 to 24 hours before starting buprenorphine. Similarly, they should abstain from longer-acting opioids such as methadone for 24 to 48 hours or longer. The physician must assess the patient clinically and determine that the patient is in mild to moderate opioid withdrawal with objectively observable withdrawal signs before initiating buprenorphine.

In most instances, a relatively low dose of buprenorphine (2 to 4 mg) can then be administered, with additional doses given in 1 to 2 hours if withdrawal signs persist. The goal for the first 24 hours is to suppress withdrawal signs and symptoms, and the total 24-hour dose to do so can range from 2 to 16 mg on the first day. In subsequent days, the dose can be adjusted upward or downward to resolve withdrawal fully and, as with methadone, to achieve an absence of craving, adequate tolerance to prevent reinforcement from the use of other opioids, and ultimately abstinence from other opioids while minimizing side effects. Dose-ranging studies have demonstrated that dosages of 6 to 16 mg/day are associated with improved treatment outcomes compared with lower doses of buprenorphine (1 to 4 mg). Sometimes patients seem to need dosages higher than 16 mg/day, although there is no evidence for any benefit of dosages beyond 32 mg/day. For the treatment of opioid dependence, a dose of approximately 4 mg of sublingual buprenorphine is the equivalent of a daily dose of 40 mg of oral methadone. It has also been demonstrated that daily, alternate-day or three-times-per-week administration has equivalent effects in suppressing the symptoms of opioid withdrawal for dependent individuals. The combination tablet is recommended for most clinical purposes, including induction and

maintenance. The buprenorphine mono (Subutex) should be used only for pregnant patients (although recent studies are investigating whether the combination of buprenorphine/naloxone is safe in pregnancy) or for patients who have a documented anaphylactic reaction to naloxone.

Newer forms of buprenorphine delivery, including a transdermal skin patch, a long-acting depot intramuscular injection that provides therapeutic plasma levels for several weeks (Sublocade), and subcutaneous buprenorphine implants that may provide therapeutic plasma levels for 6 months (Probuphine), are also FDA approved, although the latter treatment requires special training to administer.

Tramadol. There are multiple reports of tramadol's antidepressant effects, both as monotherapy and augmentation agent in treatment-resistant depression. Clinical and experimental data suggest that tramadol has an inherent antidepressant-like activity. Tramadol has complex pharmacology. It is a weak μ-opioid receptor agonist, a 5-HT releasing agent, a DA-releasing agent, a 5-HT_{2C} receptor antagonist, a norepinephrine reuptake inhibitor, an NMDA receptor antagonist, a nicotinic acetylcholine receptor antagonist, a $TRPV_1$ receptor agonist, and an M_1 and M_3 muscarinic acetylcholine receptor antagonist. Consistent with the evidence of its antidepressant effects is the fact that tramadol has a close structural similarity to the antidepressant venlafaxine.

Both venlafaxine and tramadol inhibit norepinephrine/serotonin reuptake and inhibit the reserpine-induced syndrome completely. Both compounds also have an analgesic effect on chronic pain. Venlafaxine may have an opioid component, and naloxone reverses the antipain effect of venlafaxine. Nonopioid activity is demonstrated by the fact that the μ-opioid receptor antagonist naloxone does not fully antagonize its analgesic effect. Indicative of their structural similarities, venlafaxine may cause false-positive results on liquid chromatography tests to detect urinary tramadol levels.

Another relevant property of tramadol is its relatively long half-life, which reduces the potential for misuse. Its habituating effects are found to be much less than other opiate agonists, but abuse, withdrawal, and dependence are risks. Tramadol requires metabolism to become analgesic: individuals who are CYP2D6 "poor metabolizers" or use drugs that are CYP2D6 inhibitors

reduce the efficacy of tramadol (the same is true of codeine).

Precautions and Adverse Reactions

The most common adverse effects of opioid receptor agonists are lightheadedness, dizziness, sedation, nausea, constipation, vomiting, perspiration, weight gain, decreased libido, inhibition of orgasm, and insomnia or sleep irregularities. Opioid receptor agonists are capable of inducing tolerance as well as producing physiologic and psychological dependence. Other CNS adverse effects include depression, sedation, euphoria, dysphoria, agitation, and seizures. Delirium has been reported in rare cases. Occasional non-CNS adverse effects include peripheral edema, urinary retention, rash, arthralgia, dry mouth, anorexia, biliary tract spasm, bradycardia, hypotension, hypoventilation, syncope, antidiuretic hormone-like activity, pruritus, urticaria, and visual disturbances. Menstrual irregularities are frequent in women, especially in the first 6 months of use. Various abnormal endocrine laboratory indexes of little clinical significance may also be seen.

Most persons develop tolerance to the pharmacologic adverse effects of opioid agonists during long-term maintenance, and relatively few adverse effects are experienced after the induction period.

Overdosage. The acute effects of opioid receptor agonist overdosage include sedation, hypotension, bradycardia, hypothermia, respiratory suppression, miosis, and decreased GI motility. Severe effects include coma, cardiac arrest, shock, and death. The risk of overdosage is most significant in the induction stage of treatment and in persons with slow drug metabolism caused by preexisting hepatic insufficiency. Deaths have been caused during the first week of induction by methadone dosages of only 50 to 60 mg a day.

The risk of overdosage with buprenorphine appears to be lower than with methadone. However, deaths have been caused by the use of buprenorphine in combination with benzodiazepines.

Withdrawal Symptoms. Abrupt cessation of methadone use triggers withdrawal symptoms within 3 to 4 days, which usually reaches peak intensity on the sixth day. Withdrawal symptoms include weakness, anxiety, anorexia, insomnia, gastric distress, headache, sweating, and hot and cold

flashes. The withdrawal symptoms usually resolve after 2 weeks. However, a protracted methadone abstinence syndrome is possible that may include restlessness and insomnia.

The withdrawal symptoms associated with buprenorphine are similar to but less marked than those caused by methadone. In particular, buprenorphine is sometimes used to ease the transition from methadone to opioid receptor antagonists or abstinence because of the relatively mild withdrawal reaction associated with discontinuation of buprenorphine.

Drug–Drug Interactions

Opioid receptor agonists can potentiate the CNS-depressant effects of alcohol, barbiturates, benzodiazepines, other opioids, low-potency DRAs, tricyclic and tetracyclic drugs, and MAOIs. Carbamazepine (Tegretol), phenytoin (Dilantin), barbiturates, rifampin (Rimactane, Rifadin), and heavy long-term consumption of alcohol may induce hepatic enzymes, which may lower the plasma concentration of methadone or buprenorphine and thereby precipitate withdrawal symptoms. In contrast, however, hepatic enzyme induction may increase the plasma concentration of active levomethadyl metabolites and cause toxicity.

Acute opioid withdrawal symptoms may be precipitated in persons on methadone maintenance therapy who take pure opioid receptor antagonists such as naltrexone, nalmefene (Revex, Selincro), and naloxone (Narcan); partial agonists such as buprenorphine; or mixed agonist–antagonists such as pentazocine (Talwin). These symptoms may be mitigated by the use of clonidine, a benzodiazepine, or both.

Competitive inhibition of methadone or buprenorphine metabolism after short-term use of alcohol or administration of cimetidine (Tagamet), erythromycin, ketoconazole (Nizoral), fluoxetine (Prozac), fluvoxamine (Luvox), loratadine (Claritin), quinidine (Quinidex), and alprazolam (Xanax) may lead to higher plasma concentrations or a prolonged duration of action of methadone or buprenorphine. Medications that alkalinize the urine may reduce methadone excretion.

Methadone maintenance may also increase plasma concentrations of desipramine (Norpramin, Pertofrane) and fluvoxamine. The use of methadone may increase zidovudine (Retrovir) concentrations, which

increases the possibility of zidovudine toxicity at otherwise standard dosages. Moreover, in vitro human liver microsome studies demonstrate competitive inhibition of methadone demethylation by several protease inhibitors, including ritonavir (Norvir), indinavir (Crixivan), and saquinavir (Invirase). The clinical relevance of this finding is unknown.

Fatal drug–drug interactions with the MAOIs are associated with the use of the opioids fentanyl (Sublimaze) and meperidine (Demerol) but not with the use of methadone, levomethadyl, or buprenorphine.

Tramadol may interact with drugs that inhibit serotonin reuptake. Such combinations can trigger seizures and serotonin syndrome. These events may also develop during tramadol monotherapy, either at routine or excessive doses. The risk of interactions is increased when tramadol is combined with virtually all classes of antidepressants and with drugs that lower the seizure threshold, especially the antidepressant bupropion.

Laboratory Interferences

Methadone and buprenorphine can be tested separately in urine toxicology to distinguish them from other opioids. No known laboratory interferences are associated with the use of methadone or buprenorphine.

Dosage and Clinical Guidelines

Methadone. Methadone is supplied in 5-, 10-, and 40-mg dispersible scored tablets; 40-mg scored wafers; 5-mg/5-mL, 10-mg/5-mL, and 10-mg/mL solutions; and a 10-mg/mL parenteral form. In maintenance programs, methadone is usually dissolved in water or juice, and dose administration is directly observed to ensure compliance. For induction of opioid detoxification, an initial methadone dose of 15 to 20 mg will usually suppress craving and withdrawal symptoms. However, some individuals may require up to 40 mg a day in single or divided doses. Higher dosages should be avoided during induction of treatment to reduce the risk of acute toxicity from overdosage.

Over several weeks, the dosage should be raised to at least 70 mg a day. The maximum dosage is usually 120 mg a day, and higher dosages require prior approval from regulatory agencies. Dosages above 60 mg a day are associated with much more complete abstinence from the use of illicit opioids

than are dosages less than 60 mg a day.

The duration of treatment should not be predetermined but should be based on response to treatment and assessment of psychosocial factors. All studies of methadone maintenance programs endorse long-term treatment (i.e., several years) as more effective than short-term programs (i.e., less than 1 year) for the prevention of relapse into opioid abuse. In actual practice, however, a minority of programs are permitted by policy or approved by insurers to provide even 6 months of continuous maintenance treatment. Moreover, some programs encourage withdrawal from methadone in less than 6 months after induction. This practice is quite ill-conceived, because more than 80 percent of persons who terminate methadone maintenance treatment eventually return to illicit drug use within 2 years. In programs that offer both maintenance and withdrawal treatments, the overwhelming majority of participants enroll in the maintenance treatment.

Buprenorphine. Buprenorphine is supplied as a 0.3-mg/mL solution in 1-mL ampules. Sublingual tablet formulations of buprenorphine containing buprenorphine only or buprenorphine combined with naloxone in a 4:1 ratio are used for opioid maintenance treatment. Physicians must be trained and certified to carry out this therapy in their private offices. There are several approved training programs in the United States. As noted above, an extended release and subcutaneous extended formulation are also available but require some special skill and training.

Tramadol. No controlled trials exist that establish the appropriate dosing schedule for tramadol when used for conditions other than pain. Tramadol is available in many formulations. These range from capsules (regular and extended-release) to tablets (regular, extended-release, chewable tablets) that can be taken sublingually, suppositories, and injectable ampules. It also comes as tablets and capsules containing acetaminophen or aspirin. Doses in case reports of treatment for depression or OCD range from 50 to 200 mg a day and involve short-term use. The long-term use of tramadol in the treatment of psychiatric disorders has not been studied.

OPIOID RECEPTOR ANTAGONISTS: NALTREXONE, NALMEFENE, AND NALOXONE

Naltrexone (Revia, Depade) and naloxone (Narcan) are competitive opioid antagonists. They bind to opioid receptors without causing their activation. Because these drugs induce opioid withdrawal effects in people using full opioid agonists, these drugs are classified as opioid antagonists.

Naltrexone is the most widely used of these drugs. It has a relatively long half-life, is orally effective, is not associated with dysphoria, and is administered once daily. Naloxone, which predated naltrexone to treat narcotic overdose, became less widely used for preventing relapse to opiate use in detoxified opiate addicts. Since its introduction, naltrexone has been tried for the treatment of a wide range of psychiatric disorders, including, among others, eating disorders, autism, self-injurious behavior, cocaine dependence, gambling, and alcoholism. Naltrexone was approved for the treatment of alcohol dependence in 1994. Several generic formulations are also available. An extended-release, once-a-month injectable suspension (Vivitrol) was also approved in 2006. Nalmefene (Revex) is indicated for the complete or partial reversal of opioid drug effects and in the management of known or suspected opioid overdose. An oral formulation of nalmefene is available in some countries but not in the United States. Nalmefene (Revex, Selincro) is an opioid receptor antagonist that is sometimes used in the management of alcohol dependence.

Pharmacologic Actions

The GI tract rapidly absorbs oral opioid receptor antagonists. However, because of first-pass hepatic metabolism, only 60 percent of a dose of naltrexone and 40 to 50 percent of a dose of nalmefene reach the systemic circulation unchanged. Peak concentrations of naltrexone and its active metabolite, 6-β-naltrexol, are achieved within 1 hour of ingestion. The half-life of naltrexone is 1 to 3 hours, and the half-life of 6-β-naltrexol is 13 hours. Peak concentrations of nalmefene are achieved in about 1 to 2 hours, and the half-life is 8 to 10 hours. Clinically, a single dose of naltrexone effectively blocks the rewarding effects of opioids for 72 hours. Traces of 6-β-naltrexol may linger for up to 125 hours after a single dose.

Naltrexone and nalmefene are competitive antagonists of opioid receptors. Understanding the pharmacology of opioid receptors can explain the difference in adverse effects caused by naltrexone and nalmefene. Opioid

receptors in the body are typed pharmacologically as μ, κ, or δ. Whereas activation of the κ- and δ-receptors is thought to reinforce opioid and alcohol consumption centrally, activation of μ-receptors is more closely associated with central and peripheral antiemetic effects. Because naltrexone is a relatively weak antagonist of κ- and δ-receptors and a potent μ-receptor antagonist, dosages of naltrexone that effectively reduce opioid and alcohol consumption also strongly block μ-receptors and, therefore, may cause nausea. Nalmefene, in contrast, is an equally potent antagonist of all three opioid receptor types, and dosages of nalmefene that effectively reduce opioid and alcohol consumption have no significantly increased effect on μ-receptors. Thus, nalmefene is associated clinically with few GI adverse effects.

Naloxone has the highest affinity for the μ-receptor but is a competitive antagonist at the μ-, κ-, and δ-receptors.

Whereas the effects of opioid receptor antagonists on opioid use are easily understood in terms of competitive inhibition of opioid receptors, the effects of opioid receptor antagonists on alcohol dependence are less straightforward. That likely relates to the fact that the desire for and the effects of alcohol consumption appear to be regulated by several neurotransmitter systems, both opioid and nonopioid.

Therapeutic Indications

The combination of a cognitive-behavioral program plus the use of opioid receptor antagonists is more successful than either the cognitive-behavioral program or the use of opioid receptor antagonists alone. Naloxone is used as a screening test to ensure that the patient is opioid-free before the induction of therapy with naltrexone (see “Naloxone Challenge Test” in Table 21-53).

Table 21-53
Naloxone (Narcan) Challenge Test

The naloxone challenge test should not be performed in a patient showing clinical signs or symptoms of opioid withdrawal or in a patient whose urine contains opioids. The naloxone challenge test may be administered by either the intravenous (IV) or the

subcutaneous route.

IV challenge: After appropriate screening of the patient, 0.8 mg of naloxone should be drawn into a sterile syringe. If the IV route of administration is selected, 0.2 mg of naloxone should be injected, and while the needle is still in the patient's vein, the patient should be observed for 30 s for evidence of withdrawal signs or symptoms. If there is no evidence of withdrawal, the remaining 0.6 mg of naloxone should be injected and the patient observed for an additional 20 min for signs and symptoms of withdrawal.

Subcutaneous challenge: If the subcutaneous route is selected, 0.8 mg should be administered subcutaneously and the patient observed for signs and symptoms of withdrawal for 20 min.

Conditions and technique for observation of patient: During the appropriate period of observation, the patient's vital signs should be monitored, and the patient should be monitored for signs of withdrawal. It is also important to question the patient carefully. The signs and symptoms of opioid withdrawal include, but are not limited to, the following:

- **Withdrawal signs:** Stuffiness or running nose, tearing, yawning, sweating, tremor, vomiting, or piloerection
- **Withdrawal symptoms:** Feeling of temperature change, joint or bone and muscle pain, abdominal cramps, and formication (feeling of bugs crawling under skin)

Interpretation of the challenge: Warning—the elicitation of the enumerated signs or symptoms indicates a potential risk for the subject, and naltrexone should not be administered. If no signs or symptoms of withdrawal are observed, elicited, or reported, naltrexone may be administered. If there is any doubt in the observer's mind that the patient is not in an opioid-free state or is in continuing withdrawal, naltrexone should be withheld for 24 hr and the challenge repeated.

Opioid Dependence. Patients in detoxification programs are usually weaned from potent opioid agonists such as heroin over days to weeks, during which emergent adrenergic withdrawal effects are treated as needed

with clonidine (Catapres). A serial protocol is sometimes used in which potent agonists are gradually replaced by weaker agonists followed by mixed agonist–antagonists and then finally by pure antagonists. For example, an abuser of the potent agonist heroin would switch first to the weaker agonist methadone (Dolophine), then to the partial agonist buprenorphine (Buprenex) or levomethadyl acetate (ORLAAM)—commonly called LAAM—and finally, after a 7- to 10-day washout period, to a pure antagonist, such as naltrexone or nalmefene. However, even with gradual detoxification, some persons continue to experience mild adverse effects or opioid withdrawal symptoms for the first several weeks of treatment with naltrexone.

As the opioid receptor agonist potency diminishes, so do the adverse consequences of discontinuing the drug. Thus, because there are no pharmacologic barriers to discontinuation of pure opioid receptor antagonists, the social environment and frequent cognitive-behavioral intervention become significant factors supporting continued opioid abstinence. Because of poorly tolerated adverse symptoms, most persons not simultaneously enrolled in a cognitive-behavioral program stop taking opioid receptor antagonists within 3 months. Compliance with the administration of an opioid receptor antagonist regimen can also be increased with participation in a well-conceived voucher program.

Issues of medication compliance should be a central focus of treatment. If a person with a history of opioid addiction stops taking a pure opioid receptor antagonist, the person’s risk of relapse into opioid abuse is exceedingly high, because the reintroduction of a potent opioid agonist would yield a very rewarding subjective “high.” In contrast, compliant persons do not develop tolerance to the therapeutic benefits of naltrexone even if it is administered continuously for 1 year or longer. Individuals may undergo several relapses and remissions before achieving long-term abstinence.

Persons taking opioid receptor antagonists should also be warned that sufficiently high dosages of opioid agonists can overcome the receptor antagonism of naltrexone or nalmefene, which may lead to hazardous and unpredictable levels of receptor activation (see “Precautions and Adverse Reactions”).

Rapid Detoxification. The recommended period of opioid abstinence before starting opioid receptor antagonists is 7 to 10 days. However, to avoid

this, rapid detoxification protocols have been developed. Continuous administration of adjunct clonidine—to reduce the adrenergic withdrawal symptoms—and adjunct benzodiazepines, such as oxazepam (Serax)—to reduce muscle spasms and insomnia—can permit the use of oral opioid receptor antagonists on the first day of opioid cessation. Detoxification can thus be completed within 48 to 72 hours, at which point opioid receptor antagonist maintenance is initiated. Moderately severe withdrawal symptoms may be experienced on the first day, but they taper off rapidly after that.

Because of the potential hypotensive effects of clonidine, the BP of persons undergoing rapid detoxification must be closely monitored for the first 8 hours. Outpatient rapid detoxification settings must therefore be adequately prepared to administer emergency care.

The main advantage of rapid detoxification is that the transition from opioid abuse to maintenance treatment occurs over just 2 or 3 days. The completion of detoxification in as little time as possible minimizes the risk that the person will relapse into opioid abuse during the detoxification protocol.

Alcohol Use Disorder. Opioid receptor antagonists are also used as adjuncts to cognitive-behavioral programs for the treatment of alcohol use disorder. Opioid receptor antagonists reduce alcohol craving and alcohol consumption, and they ameliorate the severity of relapses. Concomitant opioid receptor antagonist treatment added to an effective cognitive-behavioral program may halve the risk of relapse into heavy alcohol consumption.

The newer agent, nalmefene, has several potential pharmacologic and clinical advantages over its predecessor, naltrexone, for the treatment of alcohol use disorder. Whereas naltrexone may cause reversible transaminase elevations in persons who take dosages of 300 mg a day (which is six times the recommended dosage for treatment of alcohol and opioid dependence [50 mg a day]), nalmefene has not been associated with any hepatotoxicity. Clinically effective dosages of naltrexone are discontinued by 10 to 15 percent of persons because of adverse effects, most commonly nausea. In contrast, discontinuation of nalmefene because of an adverse event is rare at the clinically effective dosage of 20 mg a day and in the range of 10 percent at excessive dosages—that is, 80 mg a day. Because of its pharmacokinetic

profile, a given dosage of nalmefene may also produce a more sustained opioid antagonist effect than does naltrexone.

The efficacy of opioid receptor antagonists in reducing alcohol craving may be augmented with an SSRI, although data from large trials are needed to assess this potential synergistic effect more fully.

Precautions and Adverse Reactions

Because opioid receptor antagonists are used for sustaining a drug-free state after opioid detoxification, great care must be taken to ensure that an adequate washout period elapses. This detox requires at least 5 days for a short-acting opioid such as heroin and at least 10 days for longer-acting opioids such as methadone—after the last dose of opioids and before the first dose of an opioid receptor antagonist is taken. Self-report and urine toxicology screens should determine the opioid-free state. If any question persists of whether opioids are in the body despite a negative urine screen result, then a *naloxone challenge test* should be performed. Naloxone challenge is used because its opioid antagonism lasts less than 1 hour, but those of naltrexone and nalmefene may persist for more than 24 hours. Thus, any withdrawal effects elicited by naloxone will be relatively short-lived (see "Dosage and Clinical Guidelines"). Symptoms of acute opioid withdrawal include drug craving, a feeling of temperature change, musculoskeletal pain, and GI distress. Signs of opioid withdrawal include confusion, drowsiness, vomiting, and diarrhea. Naltrexone and nalmefene should not be taken if naloxone infusion causes any signs of opioid withdrawal except as part of a supervised rapid detoxification protocol.

A set of adverse effects resembling a vestigial withdrawal syndrome tends to affect up to 10 percent of persons who take opioid receptor antagonists. Up to 15 percent of persons taking naltrexone may experience abdominal pain, cramps, nausea, and vomiting, which may be limited by transiently halving the dosage or altering the time of administration. Adverse CNS effects of naltrexone, experienced by up to 10 percent of persons, include headache, low energy, insomnia, anxiety, and nervousness. Joint and muscle pains may occur in up to 10 percent of persons taking naltrexone, as may rash.

Naltrexone may cause dosage-related hepatic toxicity at dosages well above 50 mg a day; 20 percent of persons taking 300 mg a day of naltrexone

may experience serum aminotransferase concentrations 3 to 19 times the upper limit of normal. The hepatocellular injury of naltrexone appears to be a dose-related toxic effect rather than an idiosyncratic reaction. At the lowest dosages of naltrexone required for significant opioid antagonism, hepatocellular injury is not typically observed. However, naltrexone dosages as low as 50 mg a day may be hepatotoxic in persons with underlying liver disease, such as persons with cirrhosis of the liver caused by chronic alcohol abuse. Serum aminotransferase concentrations should be monitored monthly for the first 6 months of naltrexone therapy and after that based on clinical suspicion. Hepatic enzyme concentrations usually return to normal after discontinuation of naltrexone therapy.

If analgesia is required while a dose of an opioid receptor antagonist is pharmacologically active, opioid agonists should be avoided in favor of benzodiazepines or other nonopioid analgesics. Persons taking opioid receptor antagonists should be instructed that low dosages of opioids will not affect them. However, larger dosages could overcome the receptor blockade and suddenly produce symptoms of profound opioid overdosage, with sedation possibly progressing to coma or death. Use of opioid receptor antagonists is contraindicated in persons who are taking opioid agonists, small amounts of which may be present in over-the-counter antiemetic and antitussive preparations; in persons with acute hepatitis or hepatic failure; and in persons who are hypersensitive to the drugs.

Because naltrexone is transported across the placenta, opioid receptor antagonists should only be taken by pregnant women if a compelling need outweighs the potential risks to the fetus. It is not known whether opioid receptor antagonists are distributed into breast milk.

Opioid receptor antagonists are relatively safe drugs, and the ingestion of high doses of opioid receptor antagonists should be treated with supportive measures combined with efforts to decrease GI absorption.

Because buprenorphine has a high affinity and slow displacement from the opioid receptors, nalmefene may not wholly reverse buprenorphine-induced respiratory depression.

Drug Interactions

Many drug interactions involving opioid receptor antagonists have been

discussed earlier, including those with opioid agonists associated with drug abuse as well as those involving antiemetics and antitussives. Because of its extensive hepatic metabolism, naltrexone may affect or be affected by other drugs that influence hepatic enzyme levels. However, the clinical importance of these potential interactions is not known.

One potentially hepatotoxic drug that has been used in some cases with opioid receptor antagonists is disulfiram (Antabuse). Although no adverse effects were observed, frequent laboratory monitoring is indicated when such combination therapy is contemplated. Opioid receptor antagonists have been reported to potentiate the sedation associated with the use of thioridazine (Mellaril), an interaction that probably applies equally to all low-potency DRAs.

Intravenous nalmefene has been administered after benzodiazepines, inhalational anesthetics, muscle relaxants, and muscle relaxant antagonists were administered in conjunction with general anesthetics without any adverse reactions. Care should be taken when using flumazenil (Romazicon) and nalmefene together because both of these agents have been shown to induce seizures in preclinical studies.

Laboratory Interferences

The potential for false-positive urine for opiates using less specific urine screens such as enzyme-multiplied immunoassay technique (EMIT) may exist, given that naltrexone and nalmefene are derivatives of oxymorphone. Naltrexone does not interefere with thin-layer, gas-liquid, and high-pressure liquid chromatographic methods used for the detection of opiates in the urine.

Dosage and Clinical Guidelines

We should take several steps to ensure that the person is opioid-free. These steps are meant to avoid the possibility of precipitating an acute opioid withdrawal syndrome. Within a supervised detoxification setting, at least 5 days should elapse after the last dose of short-acting opioids, such as heroin, hydromorphone (Dilaudid), meperidine (Demerol), or morphine, and at least 10 days should elapse after the last dose of longer-acting opioids, such as methadone, before opioid antagonists are initiated. Some rapid detoxification protocols use shorter abstinence periods, however these require special

expertise to do safely. Urine toxicologic screens should demonstrate no opioid metabolites, and detoxification should be complete. However, an individual may have a negative urine opioid screen result, yet still be physically dependent on opioids and thus susceptible to antagonist-induced withdrawal effects. Therefore, after the urine screen result is negative, a naloxone challenge test is recommended unless an adequate period of opioid abstinence can be reliably confirmed by observers (Table 21-53).

The initial dosage of naltrexone for the treatment of opioid or alcohol dependence is 50 mg a day, which should be achieved through a gradual introduction, even when the naloxone challenge test result is negative. Various authorities begin with 5, 10, 12.5, or 25 mg and titrate up to the 50-mg dosage over a period ranging from 1 hour to 2 weeks while continually monitoring for evidence of opioid withdrawal. When a daily dose of 50 mg is well tolerated, it may be averaged over a week by giving 100 mg on alternate days or 150 mg every third day. Such schedules may increase compliance. The corresponding therapeutic dosage of nalmefene is 20 mg a day, divided into two equal doses. Gradual titration of nalmefene to this daily dose is probably a wise strategy, although clinical data on dosage strategies for nalmefene are not yet available.

It is recommended that family members directly observe the ingestion of each dose. This strategy helps to maximize compliance. Random urine tests for opioid receptor antagonists and their metabolites, as well as for ethanol or opioid metabolites, should also be taken. Opioid receptor antagonists should be continued until the person is no longer considered psychologically at risk for relapse into opioid or alcohol abuse. This treatment generally requires at least 6 months but may take longer, mainly if there are external stresses.

Nalmefene is available as a sterile solution for intravenous, intramuscular, and subcutaneous administration in two concentrations, containing 100 µg or 1.0 mg of nalmefene free base per milliliter. The 100 µg/mL concentration contains 110.8 µg of nalmefene hydrochloride, and the 1.0 mg/mL concentration contains 1.108 mg of nalmefene hydrochloride per milliliter. Both concentrations contain 9.0 mg of sodium chloride per milliliter, and the pH is adjusted to 3.9 with hydrochloric acid. Pharmacodynamic studies have shown that nalmefene has a longer duration of action than naloxone at fully reversing opiate activity.

Rapid Detoxification. Rapid detoxification has been standardized using naltrexone, although nalmefene would be expected to be equally effective with fewer adverse effects. In rapid detoxification protocols, the addicted person stops opioid use abruptly and begins the first opioid-free day by taking clonidine 0.2 mg orally every 2 hours for nine doses, to a maximum dose of 1.8 mg, during which time the BP is monitored every 30 to 60 minutes for the first 8 hours. Naltrexone 12.5 mg is administered 1 to 3 hours after the first dose of clonidine. To reduce muscle cramps and later insomnia, a short-acting benzodiazepine, such as oxazepam 30 to 60 mg, is administered simultaneously with the first dose of clonidine, and half of the initial dose is readministered every 4 to 6 hours as needed. The maximum daily dosage of oxazepam should not exceed 180 mg. The person undergoing rapid detoxification should be accompanied home by a reliable escort. On the second day, similar doses of clonidine and the benzodiazepine are administered but with a single dose of naltrexone 25 mg taken in the morning. Relatively asymptomatic persons may return home after 3 to 4 hours. Administration of the daily maintenance dose of 50 mg of naltrexone is begun on the third day, and the dosages of clonidine and the benzodiazepine are gradually tapered off over 5 to 10 days.

DISULFIRAM AND ACAMPROSATE

Disulfiram (Antabuse) and acamprosate (Campral) are drugs used to treat alcohol use disorder. Disulfiram has suffered from a reputation as a dangerous medication only suitable for highly motivated and strictly supervised drinkers because of the severe physical reactions the drug causes after drinking. Experience has shown, however, that at recommended doses, it is an acceptable and safe medication for dependent drinkers seeking to sustain abstinence. The properties that constitute disulfiram's main therapeutic effect (i.e., the ability to produce unpleasant symptoms after alcohol intake, also known as disulfiram–alcohol reaction) have created that perception of dangerousness.

In the most severe cases, when disulfiram is combined with alcohol, severe clinical conditions can occur. These include respiratory depression, cardiovascular collapse, acute heart failure, convulsions, loss of consciousness, and death in rare cases. These potential complications, as well

as the development of alternative antialcohol medications, have been the limiting factors for the broader use of disulfiram. Unlike disulfiram, acamprosate, the other drug discussed in this section, does not produce aversive side effects. Acamprosate is now prescribed more commonly than disulfiram in outpatient settings, but disulfiram is prescribed more often in inpatient settings because it helps facilitate initial abstinence.

Other drugs that are useful in reducing alcohol consumption include naltrexone (ReVia, Trexan), nalmefene (Revex), topiramate (Topamax), and gabapentin (Neurontin). These agents are discussed in their respective sections.

Disulfiram

Pharmacologic Actions. Disulfiram is almost completely absorbed from the GI tract after oral administration. Its half-life is estimated to be 60 to 120 hours. Therefore, it may take 1 or 2 weeks to eliminate disulfiram from the body after taking the last dose.

The metabolism of ethanol proceeds through oxidation via alcohol dehydrogenase to the formation of acetaldehyde, which is further metabolized to acetyl-coenzyme A (acetyl-CoA) by aldehyde dehydrogenase. Disulfiram is an aldehyde dehydrogenase inhibitor that interferes with the metabolism of alcohol by producing a marked increase in blood acetaldehyde concentration. The accumulation of acetaldehyde (to a level up to 10 times higher than occurs in the normal metabolism of alcohol) produces a wide array of unpleasant reactions, called the *disulfiram–alcohol reaction,* characterized by nausea, throbbing headache, vomiting, hypertension, flushing, sweating, thirst, dyspnea, tachycardia, chest pain, vertigo, and blurred vision. The reaction occurs almost immediately after the ingestion of one alcoholic drink and may last from 30 minutes to 2 hours.

BLOOD CONCENTRATIONS IN RELATION TO ACTION. Plasma concentrations of disulfiram vary among individuals because of several factors, most notably age and hepatic function. In general, the severity of disulfiram–alcohol reaction is proportional to the amount of the ingested disulfiram and alcohol. Nevertheless, disulfiram plasma levels are rarely obtained in clinical practice. The positive correlation between plasma concentrations of alcohol and the

intensity of the reaction is described as follows: in sensitive individuals, as little as a 5 to 10 mg/100 mL increase of the plasma alcohol level may produce mild symptoms; fully developed symptoms occur at alcohol levels of 50 mg/100 mL, and levels as high as 125 to 150 mg/100 mL result in loss of consciousness and coma.

Therapeutic Indications. The primary indication for disulfiram use is as an aversive conditioning treatment for alcohol use disorder. Either the fear of having a disulfiram–alcohol reaction or the memory of having had one is meant to condition the person not to use alcohol. Usually, describing the severity and the unpleasantness of the disulfiram–alcohol reaction graphically enough discourages the person from imbibing alcohol. Disulfiram treatment should be combined with such treatments as psychotherapy, group therapy, and support groups such as Alcoholics Anonymous (AA). Treatment with disulfiram requires careful monitoring because a person can decide not to take the medication.

Precautions and Adverse Reactions

WITH ALCOHOL CONSUMPTION. The intensity of the disulfiram–alcohol reaction varies with each person. In extreme cases, it is marked by respiratory depression, cardiovascular collapse, myocardial infarction, convulsions, and death. Therefore, disulfiram is contraindicated for persons with significant pulmonary or cardiovascular disease. Also, disulfiram should be used with caution, if at all, by persons with nephritis, brain damage, hypothyroidism, diabetes, hepatic disease, seizures, polydrug dependence, or an abnormal electroencephalogram. Most fatal reactions occur in persons who take more than 500 mg a day of disulfiram and who consume more than 3 oz of alcohol. The treatment of a severe disulfiram–alcohol reaction is primarily supportive to prevent shock. The use of oxygen, intravenous vitamin C, ephedrine, and antihistamines have been reported to aid in recovery.

WITHOUT ALCOHOL CONSUMPTION. The adverse effects of disulfiram in the absence of alcohol consumption include fatigue, dermatitis, impotence, optic neuritis, a variety of mental changes, and hepatic damage. A metabolite of disulfiram inhibits dopamine-

β-hydroxylase, the enzyme that metabolizes dopamine into norepinephrine and epinephrine, and thus may exacerbate psychosis in persons with psychotic disorders. Catatonic reactions may also occur.

Drug Interactions. Disulfiram increases the blood concentration of diazepam (Valium), paraldehyde, phenytoin (Dilantin), caffeine, tetrahydrocannabinol (the active ingredient in marijuana), barbiturates, anticoagulants, isoniazid (Nydrazid), and tricyclic drugs. Disulfiram should not be administered concomitantly with paraldehyde because paraldehyde is metabolized to acetaldehyde in the liver.

Laboratory Interferences. In rare instances, disulfiram has been reported to interfere with the incorporation of iodine-131 into protein-bound iodine. Disulfiram may reduce urinary concentrations of homovanillic acid, the major metabolite of dopamine, because it inhibits dopamine hydroxylase.

Dosage and Clinical Guidelines. Disulfiram is supplied in 250- and 500-mg tablets. The usual initial dosage is 500 mg a day, taken by mouth for the first 1 or 2 weeks, followed by a maintenance dosage of 250 mg a day. The dosage should not exceed 500 mg a day. The maintenance dosage range is 125 to 500 mg a day.

Persons taking disulfiram must be instructed that the ingestion of even the smallest amount of alcohol will bring on a disulfiram–alcohol reaction, with all of its unpleasant effects. Also, persons should be warned against ingesting any alcohol-containing preparations, such as cough drops, tonics of any kind, and alcohol-containing foods and sauces. Some reactions have occurred in patients who used alcohol-based lotions, toilet water, colognes, or perfumes and inhaled the fumes; therefore, precautions must be explicit and should include any topically applied preparations containing alcohol, such as perfume.

Disulfiram should not be administered until the person has abstained from alcohol for at least 12 hours. Persons should be warned that the disulfiram–alcohol reaction may occur as long as 1 or 2 weeks after the last dose of disulfiram. Persons taking disulfiram should carry identification cards describing the disulfiram–alcohol reaction and listing the name and telephone number of the physician to be called.

Acamprosate

Pharmacologic Actions. Acamprosate's mechanism of action is not fully understood, but it is thought to antagonize neuronal overactivity related to the actions of the excitatory neurotransmitter glutamate. In part, this may result from antagonism of NMDA receptors.

Indications. Acamprosate is used for treating alcohol-dependent individuals seeking to continue to remain alcohol-free after they have stopped drinking. Its efficacy in promoting abstinence has not been demonstrated in persons who have not undergone detoxification and who have not achieved alcohol abstinence before beginning treatment.

Precautions and Adverse Effects. Side effects are mostly seen early in treatment and are usually mild and transient. The most common side effects are headache, diarrhea, flatulence, abdominal pain, paresthesias, and various skin reactions. No adverse events occur after abrupt withdrawal of acamprosate, even after long-term use. There is no evidence of addiction to the drug. Patients with severe renal impairment (creatinine clearance of less than 30 mL/min) should not be given acamprosate.

Drug Interactions. Alcohol and acamprosate do not affect each other's pharmacokinetics. The same is true when adding disulfiram or diazepam to acamprosate. Coadministration of naltrexone with acamprosate produces an increase in concentrations of acamprosate. No adjustment of dosage is recommended in such patients. The pharmacokinetics of naltrexone and its major metabolite 6-β-naltrexol were unaffected after coadministration with acamprosate. During clinical trials, patients taking acamprosate concomitantly with antidepressants more commonly reported both weight gain and weight loss compared with patients taking either medication alone.

Laboratory Interferences. Acamprosate has not been shown to interfere with commonly performed laboratory tests.

Dosage and Clinical Guidelines. It is important to remember that acamprosate should not be used to treat alcohol withdrawal symptoms. It should only be started after the individual has been successfully weaned off

alcohol. Patients should show a commitment to remaining abstinent, and treatment should be part of a comprehensive management program that includes counseling or support group attendance.

Each tablet contains acamprosate calcium 333 mg, which is equivalent to 300 mg of acamprosate. The dose of acamprosate is different for different patients. The recommended dosage is two 333-mg tablets (each dose should total 666 mg) taken three times daily. Although dosing may be done without regard to meals, dosing with meals was used during clinical trials and is suggested as an aid to compliance in patients who regularly eat three meals daily. A lower dose may be useful in some patients. A missed dose should be taken as soon as possible. However, if it is almost time for the next dose, the missed dose should be skipped, and then the regular dosing schedule should be resumed. Doses should not be doubled up. For patients with moderate renal impairment (creatinine clearance of 30 to 50 mL/min), a starting dosage of one 333-mg tablet taken three times daily is recommended. People with severe renal insufficiency should not take acamprosate.

CLONIDINE AND GUANFACINE

Clonidine and guanfacine are marketed as hypertension treatments. Guanfacine is more selective and less potent than clonidine, but clonidine is the most widely used α_2-agonist.

Pharmacologic Actions

Clonidine and guanfacine are presynaptic α_2-receptor agonists. They inhibit sympathetic outflow and cause vasodilation of blood vessels. Clonidine and guanfacine are well absorbed from the GI tract and reach peak plasma levels 1 to 3 hours after oral administration. The half-life of clonidine is 6 to 20 hours, and that of guanfacine is 10 to 30 hours.

The agonist effects of clonidine and guanfacine on presynaptic α_2-adrenergic receptors in the sympathetic nuclei of the brain result in a decrease in the amount of norepinephrine released from the presynaptic nerve terminals. This decrease serves to reset the body's sympathetic tone at a lower level and decrease arousal. Table 21-54 provides a summary of α_2-adrenergic receptor agonists used in psychiatry.

Therapeutic Indications

There is considerably more experience in clinical psychiatry with clonidine than with guanfacine. There is recent interest in the use of guanfacine for the same indications that respond to clonidine due to guanfacine's longer half-life and relative lack of sedative effects.

Withdrawal from Opioids, Alcohol, Benzodiazepines, or Nicotine. Clonidine and guanfacine are effective in reducing the autonomic symptoms of rapid opioid withdrawal (e.g., hypertension, tachycardia, dilated pupils, sweating, lacrimation, and rhinorrhea) but not the associated subjective sensations. Clonidine administration (0.1 to 0.2 mg two to four times a day) is initiated before detoxification and is then tapered off over 1 to 2 weeks (Table 21-55).

Clonidine and guanfacine can reduce symptoms of alcohol and benzodiazepine withdrawal, including anxiety, diarrhea, and tachycardia. They can reduce craving, anxiety, and irritability symptoms of nicotine withdrawal. The transdermal patch formulation of clonidine is associated with better long-term compliance for purposes of detoxification than is the tablet formulation.

Tourette Disorder. Clonidine and guanfacine are effective drugs for the treatment of Tourette disorder. Most clinicians begin treatment for Tourette disorder with the standard DRAs haloperidol (Haldol) and pimozide (Orap) and the SDAs risperidone (Risperdal) and olanzapine (Zyprexa). However, if concerned about the adverse effects of these drugs, the clinician may begin treatment with clonidine or guanfacine. The starting dose of clonidine for children is 0.05 mg a day; it can be increased to 0.3 mg a day in divided doses. Clonidine may take long periods (e.g., 4 to 6 months) to positively effect the symptoms of the disorder. The response rate has been reported to be up to 70 percent.

Table 21-54
α_2-Adrenergic Receptor Agonists Used in Psychiatry[a]

Drug	Preparations	Usual Child Starting Dosage	Usual Child Dosage Range	Usual Adult Starting Dosage	Usual Adult Dosage
Clonidine tablets (Catapres)	0.1, 0.2, 0.3 mg	0.05 mg/day	Up to 0.3 mg/day tablets in divided doses	0.1–0.2 mg, two to four times a day (0.2–0.8 mg/day)	0.3–1.2 mg/day, two to three times a day (1.2 mg/day maximal dosage)
Clonidine transdermal system (Catapres-TTS)	0.1, 0.2, 0.3 mg/day	0.05 mg/day	Up to 0.3 mg/day patch every 5 days (0.5 mg/day every 5 days maximal dosage)	0.1 mg/day every 7 days	0.1 mg/day patch per week (0.6 mg/day every 7 days)
Guanfacine (Tenex)	1- and 2-mg tablets	1 mg/day at bedtime	1–2 mg/day at bedtime (3 mg/day maximal dosage)	1 mg/day at bedtime	1–2 mg at bedtime (3 mg/day maximal dosage)

*Dosages for medical indications, such as hypertension, vary.

Other Tic Disorders. Clonidine and guanfacine reduce the frequency and severity of tics in persons with tic disorder with or without comorbid ADHD.

Hyperactivity and Aggression in Children. Clonidine and guanfacine can be useful alternatives for the treatment of ADHD. They are used in place of sympathomimetics and antidepressants, which may produce a paradoxical worsening of hyperactivity in some children with intellectual disability, aggression, or features on the spectrum of autism. Clonidine and guanfacine can improve mood, reduce activity level, and improve social adaptation. Some impaired children may respond favorably to clonidine, but others may become sedated. The starting dose is 0.05 mg a day; it can be raised to 0.3 mg a day in divided doses. The efficacy of clonidine and guanfacine for control of hyperactivity and aggression often diminishes over several months of use.

Table 21-55
Oral Clonidine Protocols for Opioid Detoxification

Clonidine 0.1–0.2 mg PO four times a day; hold for systolic BP <90 mm Hg or bradycardia; stabilize for 2–3 days, then taper over 5–10 days

OR

Clonidine 0.1–0.2 mg PO q4–6h as needed for withdrawal signs or symptoms; stabilize for 2–3 days, then taper over 5–10 days

OR

Test dose with clonidine 0.1–0.2 mg PO or SL (for patients weighing

over 200 lb); check BP after 1 hr. If diastolic BP >70 mm Hg and no symptoms of hypotension, begin treatment as follows:	
Weight (lb)	Number of Clonidine Patches
<110	1 patch
110–160	2 patches
160–200	2 patches
>200	2 patches
OR	
Test dose of oral clonidine 0.1 mg; check BP after 1 hr (if systolic BP <90 mm Hg, do not give patch)	
Place two TTS-2 clonidine patches (or three patches if patient weighs >150 lb) on hairless area of upper body; then	
For first 23 hr after patch application, give oral clonidine 0.2 mg q6h; then	
For next 24 hr, give oral clonidine 0.1 mg q6h	
Change patches weekly	
After 2 wk of two patches, switch to one patch (or two patches if patient weighs >150 lb)	
After 1 wk of one patch, discontinue patches	

BP, blood pressure; PO, oral; q, every; SL, sublingual; TTS, through the skin.

From American Society of Addiction Medicine. Detoxification: principle and protocols. In: *The Principles Update Series: Topics in Addiction Medicine*, Section 11. American Society of Addiction; 1997, with permission.

Clonidine and guanfacine can be combined with methylphenidate (Ritalin) or dextroamphetamine (Dexedrine) to treat hyperactivity and inattentiveness, respectively. A small number of cases have been reported of the sudden death of children taking clonidine together with methylphenidate; however, it has not been conclusively demonstrated that these medications contributed to these deaths. The clinician should explain to the family that the efficacy and

safety of this combination have not been investigated in controlled trials. Periodic cardiovascular assessments, including vital signs and electrocardiograms, are warranted if this combination is used.

Posttraumatic Stress Disorder. Acute exacerbations of PTSD may be associated with hyperadrenergic symptoms such as hyperarousal, exaggerated startle response, insomnia, vivid nightmares, tachycardia, agitation, hypertension, and perspiration. Preliminary reports suggested that these symptoms may respond to the use of clonidine or, especially for an overnight benefit, to the use of guanfacine. More recent studies have failed to demonstrate that guanfacine produces an improvement in PTSD symptoms.

Other Disorders. Other potential indications for clonidine include other anxiety disorders (panic disorder, phobias, obsessive-compulsive disorder, and GAD) and mania, in which it may be synergistic with lithium (Eskalith) or carbamazepine (Tegretol). There are anecdotal accounts suggesting the efficacy of clonidine in schizophrenia and tardive dyskinesia. A clonidine patch can reduce the hypersalivation and dysphagia caused by clozapine. Low-dose use has been reported effective in hallucinogen-persisting perceptive disorders.

Precautions and Adverse Reactions

The most common adverse effects associated with clonidine are dry mouth and eyes, fatigue, sedation, dizziness, nausea, hypotension, and constipation, which result in discontinuation of therapy by about 10 percent of all persons taking the drug. Some persons also experience sexual dysfunction. Tolerance may develop to these adverse effects. A similar but milder adverse profile is seen with guanfacine, especially in doses of 3 mg or more per day. Adults should not take clonidine and guanfacine if their BP is below 90/60 mm Hg or if they have cardiac arrhythmias, especially bradycardia. Development of bradycardia warrants gradual, tapered discontinuation of the drug. Clonidine, in particular, is associated with sedation, and tolerance does not usually develop to this adverse effect. Uncommon CNS adverse effects of clonidine include insomnia, anxiety, and depression; rare CNS adverse effects include vivid dreams, nightmares, and hallucinations. Fluid retention associated with clonidine treatment can be treated with diuretics.

The transdermal patch formulation of clonidine may cause local skin irritation, which can be minimized by rotating the sites of application.

Overdose. Persons who take an overdose of clonidine may present with coma and constricted pupils, symptoms similar to those of an opioid overdose. Other symptoms of overdose are decreased BP, pulse, and respiratory rate. Guanfacine overdose produces a milder version of these symptoms. Clonidine and guanfacine should be avoided during pregnancy and by nursing mothers. Elderly persons are more sensitive to the drug than are younger adults. Children are susceptible to the same adverse effects as are adults.

Withdrawal. Abrupt discontinuation of clonidine can cause anxiety, restlessness, perspiration, tremor, abdominal pain, palpitations, headache, and a dramatic increase in BP. These symptoms may appear about 20 hours after the last dose of clonidine, and these may also be seen if one or two doses are skipped. A similar set of symptoms occasionally occurs 2 to 4 days after discontinuation of guanfacine, but the usual course is a gradual return to baseline BP over 2 to 4 days. Because of the possibility of discontinuation symptoms, doses of clonidine and guanfacine should be tapered slowly.

Drug Interactions

Clonidine and guanfacine cause sedation, especially early in therapy, and when administered with other centrally active depressants, such as barbiturates, alcohol, and benzodiazepines, the potential for additive sedative effects should be considered. Dose reduction may be required in patients receiving agents that interfere with AV node and sinus node conduction such as β-blockers, CCBs, and digitalis. This combination increases the risk of AV block and bradycardia. Clonidine should not be given with TCAs, which can inhibit the hypotensive effects of clonidine.

Laboratory Interferences

No known laboratory interferences are associated with the use of clonidine or guanfacine.

Dosage and Clinical Guidelines

Clonidine is available in 0.1-, 0.2-, and 0.3-mg tablets. The usual starting dosage is 0.1 mg orally twice a day; the dosage can be raised by 0.1 mg a day to an appropriate level (up to 1.2 mg/day). Clonidine must always be tapered when it is discontinued to avoid rebound hypertension, which may occur about 20 hours after the last clonidine dose. A weekly transdermal formulation of clonidine is available at doses of 0.1, 0.2, and 0.3 mg/day. The usual starting dosage is the 0.1-mg-a-day patch, which is changed each week for adults and every 5 days for children; the dose can be increased, as needed, every 1 to 2 weeks. The transition from the oral to the transdermal formulations should be accomplished gradually by overlapping them for 3 to 4 days.

Guanfacine is available in 1- and 2-mg tablets. The usual starting dosage is 1 mg before sleep, and this can be increased to 2 mg before sleep after 3 to 4 weeks, if necessary. Regardless of the indication for which clonidine or guanfacine is being used, the drug should be withheld if a person becomes hypotensive (BP below 90/60 mm Hg).

An extended-release preparation of guanfacine (Intuniv) is also available. Extended-release guanfacine should be dosed once daily. Tablets should not be crushed, chewed, or broken before swallowing because this will increase the rate of guanfacine release. It should not be administered with high-fat meals due to increased exposure. The extended-release formulation should not be substituted for immediate-release guanfacine tablets on a milligram-per-milligram basis because of differing pharmacokinetic profiles. If switching from immediate-release guanfacine, discontinue that treatment, and titrate with extended-release guanfacine according to the following recommended schedule:

1. ;Begin at a dose of 1 mg/day, and adjust in increments of no more than 1 mg/wk for both monotherapy and adjunctive therapy to a psychostimulant.
2. For both monotherapy and adjunctive therapy (with a stimulant), maintain the dose within the range of 1 to 4 mg once daily, depending on clinical response and tolerability. In clinical trials, patients were randomized or dose optimized to doses of 1, 2, 3, or 4 mg and received extended-release guanfacine once daily in the morning in monotherapy trials and once daily in the morning or the evening in the adjunctive

therapy trial.

3. In monotherapy trials, clinically relevant improvements were observed beginning at doses in the range 0.05 to 0.08 mg/kg once daily. Efficacy increased with increasing weight-adjusted dose (mg/kg). If well tolerated, doses up to 0.12 mg/kg once daily may provide additional benefit. Doses above 4 mg/day have not been systematically studied in controlled clinical trials.
4. In the adjunctive trial, the majority of subjects reached optimal doses in the 0.05 to 0.12 mg/kg/day range.

In clinical trials, there were dose-related and exposure-related risks for several clinically significant adverse reactions (e.g., hypotension, bradycardia, sedative events). Thus, consideration should be given to dosing an extended-release preparation of guanfacine on a milligram-per-kilogram basis in order to balance the exposure-related potential benefits and risks of treatment.

▲ 21.8 Drugs Used for Cognitive Enhancement

CHOLINESTERASE INHIBITORS

Donepezil (Aricept), rivastigmine (Exelon), and galantamine (Reminyl) are cholinesterase inhibitors used to treat mild to moderate cognitive impairment in dementia of the Alzheimer type. They reduce the inactivation of the neurotransmitter acetylcholine and, thus, potentiate cholinergic neurotransmission, which in turn produces a modest improvement in memory and goal-directed thought. Memantine (Namenda) is not a cholinesterase inhibitor, producing its effects through blockade of NMDA receptors. Unlike the cholinesterase inhibitors, which are indicated for the mild to moderate stages of Alzheimer disease, memantine is indicated for the moderate to severe stages of the disease. Tacrine (Cognex), the first cholinesterase inhibitor to be introduced, is no longer used because of its multiple-daily dosing regimens, its potential for hepatotoxicity, and the consequent need for

frequent laboratory monitoring. Clinicians often combine a cholinesterase inhibitor with memantine, as this combination may provide a beneficial response compared with only cholinesterase inhibitor pharmacotherapy.

Pharmacologic Actions

Donepezil is entirely absorbed from the GI tract. Peak plasma concentrations are reached about 3 to 4 hours after oral dosing. The half-life of donepezil is 70 hours in elderly persons, and it is taken only once daily. Steady-state levels are achieved within about 2 weeks. The presence of stable alcoholic cirrhosis reduces the clearance of donepezil by 20 percent. Rivastigmine (Exelon) is rapidly and completely absorbed from the GI tract and reaches peak plasma concentrations in 1 hour, but this is delayed by up to 90 minutes if rivastigmine is taken with food. The half-life of rivastigmine is 1 hour, but because it remains bound to cholinesterases, a single dose is therapeutically active for 10 hours, and it is taken twice daily. Galantamine (Reminyl) is an alkaloid similar to codeine and is extracted from daffodils of the plant *Galanthus nivalis*. It is readily absorbed, with maximum concentrations reached after 30 minutes to 2 hours. Food decreases the maximum concentration by 25 percent. The elimination half-life of galantamine is approximately 6 hours.

Tacrine (Cognex) is absorbed rapidly from the GI tract. Peak plasma concentrations are reached about 90 minutes after oral dosing. The half-life of tacrine is about 2 to 4 hours, thereby necessitating four-times-daily dosing.

Cholinesterase inhibitors are reversible, nonacylating inhibitors of either acetylcholinesterase or butyrylcholinesterase, the enzymes that catabolize choline-based esthers in the CNS. The enzyme inhibition increases synaptic concentrations of acetylcholine, especially in the hippocampus and cerebral cortex. Unlike tacrine, which is nonselective for all forms of acetylcholinesterase, donepezil appears to be selectively active within the CNS and has little activity in the periphery. Donepezil’s favorable side effect profile appears to correlate with its lack of inhibition of cholinesterases in the GI tract. Rivastigmine appears to have somewhat more peripheral activity than donepezil and is thus more likely to cause GI adverse effects than is donepezil.

Therapeutic Indications

Cholinesterase inhibitors are effective for the treatment of mild to moderate cognitive impairment in dementia of the Alzheimer type. In long-term use, they slow the progression of memory loss and diminish apathy, depression, hallucinations, anxiety, euphoria, and purposeless motor behaviors. Functional autonomy is less well preserved. Some persons note an immediate improvement in memory, mood, psychotic symptoms, and interpersonal skills. Others note little initial benefit but can retain their cognitive and adaptive faculties at a relatively stable level for many months. A practical benefit of cholinesterase inhibitor use is a delay or reduction of the need for nursing home placement.

Donepezil and rivastigmine may be beneficial for patients with Parkinson disease and Lewy body disease and treatment of cognitive deficits caused by traumatic brain injury. Donepezil is under study for the treatment of mild cognitive impairment that is less severe than that caused by Alzheimer disease. People with vascular dementia may respond to acetylcholinesterase inhibitors. Occasionally, cholinesterase inhibitors elicit an idiosyncratic catastrophic reaction, with signs of grief and agitation, which is self-limited after the drug is discontinued. The use of cholinesterase inhibitors to improve cognition by nondemented individuals should be discouraged.

Precautions and Adverse Reactions

Donepezil. Donepezil is generally well tolerated at recommended dosages. Fewer than 3 percent of those taking donepezil experience nausea, diarrhea, and vomiting. These mild symptoms are more frequent with a 10-mg dose than with a 5-mg dose, and when present, they tend to resolve after 3 weeks of continued use. Donepezil may cause weight loss. Donepezil treatment has been infrequently associated with bradyarrhythmias, especially in those with underlying cardiac disease. A small number of persons experience syncope.

Rivastigmine. Rivastigmine is generally well tolerated but recommended dosages may need to be scaled back in the initial period of treatment to limit GI and CNS adverse effects. These mild symptoms are more common at dosages above 6 mg a day, and when present, they tend to resolve after the dosage is lowered. The most common adverse effects associated with

rivastigmine are nausea, vomiting, dizziness, headache, diarrhea, abdominal pain, anorexia, fatigue, and somnolence. Rivastigmine may cause weight loss, but it does not appear to cause hepatic, renal, hematologic, or electrolyte abnormalities.

Galantamine. The most common side effects of galantamine are dizziness, headache, nausea, vomiting, diarrhea, and anorexia. These side effects tend to be mild and transient.

Tacrine. Tacrine is the least used of the cholinesterase inhibitors but requires more discussion than the others because it is cumbersome to titrate and use, and it poses the risk of potentially significant elevations in hepatic transaminase levels. These increases occur in 25 to 30 percent of persons. Aside from elevated transaminase levels, the most common specific adverse effects associated with tacrine treatment are nausea, vomiting, myalgia, anorexia, and rash, but only nausea, vomiting, and anorexia have been found to have a clear relation to the dosage. Transaminase elevations characteristically develop during the first 6 to 12 weeks of treatment, and cholinergically mediated events are dosage related.

HEPATOTOXICITY. Tacrine is associated with increases in the plasma activities of alanine aminotransferase (ALT) and aspartate aminotransferase (AST). The ALT measurement is the more sensitive indicator of the hepatic effects of tacrine. About 95 percent of patients who develop elevated ALT serum levels do so in the first 18 weeks of treatment. The average length of time for elevated ALT concentrations to return to normal after stopping tacrine treatment is 4 weeks.

For routine monitoring of hepatic enzymes, AST and ALT activities should be measured weekly for the first 18 weeks, every month for the second 4 months, and every 3 months after that. Weekly assessments of AST and ALT should be performed for at least 6 weeks after an increase in dosage. Patients with mildly elevated ALT activity should be monitored weekly and not be rechallenged with tacrine until the ALT activity returns to the normal range. For any patient with elevated ALT activity and jaundice, tacrine treatment should be stopped, and the patient should not be given the drug again.

Table 21-56
Incidence of Major Adverse Side Effects with Cholinesterase Inhibitors (%)

Drug	Dose (mg/day)	Nausea	Vomiting	Diarrhea	Dizziness	Muscle Cramps	Insomnia
Donepezil	5	4	3	9	15	9	7
Donepezil	10	17	10	17	13	12	8
Rivastigmine	1–4	14	7	10	15	NR	NR
Rivastigmine	6–12	48	27	17	24	NR	NR
Galantamine	8	5.7	3.6	5	NR	NR	NR
Galantamine	16	13.3	6.1	12.2	NR	NR	NR
Galantamine	24	16.5	9.9	5.5	NR	NR	NR

NR, not reported from clinical trial data; incidence less than 5%.

Table 21-56 summarizes the incidence of significant adverse side effects associated with each of the cholinesterase inhibitors.

Drug Interactions. All cholinesterase inhibitors should be used cautiously with drugs that also possess cholinomimetic activity. Such drugs include succinylcholine (Anectine) and bethanechol (Urecholine). The coadministration of cholinesterase inhibitors and drugs that have cholinergic antagonist activity (e.g., tricyclic drugs) is probably counterproductive. Paroxetine is the most anticholinergic of the SSRIs, and we avoid it in patients taking cholinesterase inhibitors.

Donepezil undergoes extensive metabolism via both CYP2D6 and 3A4 isozymes. The metabolism of donepezil may be increased by phenytoin (Dilantin), carbamazepine (Tegretol), dexamethasone (Decadron), rifampin (Rifadin), and phenobarbital (Solfoton). Commonly used agents such as paroxetine, ketoconazole (Nizoral), and erythromycin can significantly increase donepezil concentrations. Donepezil is highly protein-bound, but it does not displace other protein-bound drugs, such as furosemide (Lasix), digoxin (Lanoxin), or warfarin (Coumadin). Rivastigmine circulates mostly unbound to serum proteins and has no significant drug interactions.

Similar to donepezil, galantamine is metabolized by both CYP2D6 and 3A4 isozymes and thus may interact with drugs that inhibit these pathways. Paroxetine and ketoconazole should be used with great caution.

Laboratory Interferences. No laboratory interferences have been associated with the use of cholinesterase inhibitors.

Dosage and Clinical Guidelines. Before initiation of cholinesterase inhibitor therapy, potentially treatable causes of dementia should be ruled out, and the diagnosis of dementia of the Alzheimer type established.

Donepezil is available in 5- and 10-mg tablets. Treatment should be initiated at 5 mg each night. If well tolerated and of some discernible benefit after 4 weeks, the dosage should be increased to a maintenance dosage of 10-mg each night. Donepezil absorption is unaffected by meals.

Rivastigmine is available in 1.5-, 3-, 4.5-, and 6-mg capsules. The recommended initial dosage is 1.5 mg twice daily for a minimum of 2 weeks, after which increases of 1.5 mg a day can be made at intervals of at least 2 weeks to a target dosage of 6 mg a day, taken in two equal dosages. If tolerated, the dosage may be further titrated upward to a maximum of 6 mg twice daily. The administration of rivastigmine with food can reduce the risk of adverse GI events.

Galantamine is available in 4-, 8-, and 16-mg tablets. The suggested dose range is 16 to 32 mg/day given twice a day. The higher dose is better tolerated than lower doses. The initial dosage is 8 mg/day, and after a minimum of 4 weeks, the dose can be raised. All subsequent dosage increases should occur at 4-week intervals and should be based on tolerability.

Tacrine is available in 10-, 20-, 30-, and 40-mg capsules. Before the initiation of tacrine treatment, a complete physical and laboratory examination should be conducted, with particular attention to liver function tests and baseline hematologic indexes. Treatment should be initiated at 10 mg four times a day and then raised by increments of 10 mg a dose every 6 weeks up to 160 mg a day; the person’s tolerance of each dosage is indicated by the absence of unacceptable side effects and lack of elevation of ALT activity. Tacrine should be given four times daily—ideally 1 hour before meals because the absorption of tacrine is reduced by about 25 percent when it is taken during the first 2 hours after meals. If tacrine is used, the specific guidelines for tacrine-induced ALT listed above should be followed.

MEMANTINE

Pharmacologic Actions

Memantine is well absorbed after oral administration. It reaches peak

concentrations in about 3 to 7 hours. Food does not affect the absorption of memantine. Memantine has linear pharmacokinetics over the therapeutic dosage range and has a terminal elimination half-life of about 60 to 80 hours. Plasma protein binding is 45 percent.

Memantine undergoes little metabolism, with the majority (57 to 82 percent) of an administered dose excreted unchanged in the urine; the remainder is converted primarily to three polar metabolites: the *N*-gludantan conjugate, 6-hydroxy memantine, and 1-nitroso-deaminated memantine. These metabolites possess minimal NMDA receptor antagonist activity. Memantine is a low- to moderate-affinity NMDA receptor antagonist. It is thought that the overexcitation of NMDA receptors by the neurotransmitter glutamate may play a role in Alzheimer disease because glutamate plays an integral role in the neural pathways associated with learning and memory. Excess glutamate overstimulates NMDA receptors to allow too much calcium into nerve cells, leading to the eventual cell death observed in Alzheimer disease. Memantine may protect cells against excess glutamate by partially blocking NMDA receptors associated with the abnormal transmission of glutamate while allowing for physiologic transmission associated with normal cell functioning.

Therapeutic Indications

Memantine is the only approved therapy in the United States for moderate to severe Alzheimer disease.

Precautions and Adverse Reactions

Memantine is safe and well tolerated. The most common adverse effects are dizziness, headache, constipation, and confusion. The use of memantine in patients with severe renal impairment is not recommended. In a documented case of an overdose with up to 400 mg of memantine, the patient experienced restlessness, psychosis, visual hallucinations, somnolence, stupor, and loss of consciousness. The patient recovered without permanent sequelae.

Drug Interactions

In vitro studies conducted with marker substrates of CYP450 enzymes (CYP1A2, 2A6, 2C9, 2D6, 2E1, and 3A4) showed minimal inhibition of

these enzymes by memantine. No pharmacokinetic interactions with drugs metabolized by these enzymes are expected.

Because memantine is eliminated in part by tubular secretion, coadministration of drugs that use the same renal cationic system, including hydrochlorothiazide triamterene (Dyrenium), cimetidine (Tagamet), ranitidine (Zantac), quinidine, and nicotine, could potentially result in altered plasma levels of both agents. Coadministration of memantine with a combination of hydrochlorothiazide and triamterene did not affect the bioavailability of either memantine or triamterene, and the bioavailability of hydrochlorothiazide decreased by 20 percent.

Urine pH is altered by diet, drugs (e.g., carbonic anhydrase inhibitors, topiramate [Topamax], sodium bicarbonate), and the clinical state of the patient (e.g., renal tubular acidosis or severe infections of the urinary tract). The clearance of memantine is reduced by about 80 percent under alkaline urine conditions at pH 8. Therefore, alterations of urine pH toward the alkaline condition may lead to an accumulation of the drug with a possible increase in adverse effects. Hence, memantine should be used with caution under these conditions.

Laboratory Interferences

No laboratory interferences have been associated with the use of memantine.

Dosage and Clinical Guidelines

Memantine is available in 5- and 10-mg tablets, with a recommended starting dose of 5 mg daily. The recommended target dose is 20 mg/day. The drug is administered twice daily in separate doses with 5-mg increment increases weekly depending on tolerability.

Patients with mild to moderate disease receiving memantine in combination with a cholinesterase inhibitor have not been found to experience significantly greater benefit in cognition or overall function than those who receive a cholinesterase inhibitor alone.

21.9 Drugs Used to Treat Sexual

Disorders

PHOSPHODIESTERASE-5 INHIBITORS

Phosphodiesterase (PDE)-5 inhibitors, such as sildenafil (Viagra), which was developed in 1998, revolutionized the treatment of erectile disorder. Two congeners have since come on the market—vardenafil (Levitra) and tadalafil (Cialis). All have a similar method of action and have changed people's expectations of sexual functioning. Although indicated only for the treatment of male erectile dysfunction, there is anecdotal evidence of these drugs being effective in women. They are also being misused as recreational drugs to enhance sexual performance. These drugs have been used by more than 20 million men around the world.

The development of sildenafil provided important information about the physiology of erection. Sexual stimulation causes the release of the neurotransmitter nitric oxide (NO), which increases the synthesis of cyclic guanosine monophosphate (cGMP), causing smooth muscle relaxation in the corpus cavernosum that allows blood to flow into the penis and results in turgidity and tumescence. The concentration of cGMP is regulated by the enzyme PDE-5, which, when inhibited, allows cGMP to increase and enhance erectile function. Because sexual stimulation is required to cause the release of NO, PDE-5 inhibitors do not affect in the absence of such stimulation, an important point to understand when providing information to patients about their use. The congeners vardenafil and tadalafil work in the same way, by inhibiting PDE-5, thus allowing an increase in cGMP and enhancing the vasodilatory effects of NO. For this reason, these drugs are sometimes referred to as NO enhancers.

Pharmacologic Actions

All three substances are relatively rapidly absorbed from the GI tract, with maximum plasma concentrations reached in 30 to 120 minutes (median, 60 minutes) in the fasting state. Because it is lipophilic, concomitant ingestion of a high-fat meal delays the rate of absorption by up to 60 minutes and reduces the peak concentration by one-quarter. These drugs are principally metabolized by the CYP3A4 system, which may lead to clinically significant

drug–drug interactions, not all of which have been documented. Excretion of 80 percent of the dose is via feces, and another 13 percent is eliminated in the urine. Elimination is reduced in persons older than age 65 years, which results in plasma concentrations 40 percent higher than in persons ages 18 to 45 years. Elimination is also reduced in the presence of severe renal or hepatic insufficiency.

The mean half-lives of sildenafil and vardenafil are 3 to 4 hours, and that of tadalafil is about 18 hours. Tadalafil can be detected in the bloodstream 5 days after ingestion, and because of its long half-life, it has been marketed as effective for up to 36 hours—the so-called weekend pill. The onset of sildenafil occurs about 30 minutes after ingestion on an empty stomach; tadalafil and vardenafil act somewhat more quickly.

Clinicians need to be aware of the crucial clinical observation that these drugs do not by themselves create an erection. Instead, the mental state of sexual arousal brought on by erotic stimulation must first lead to activity in the penile nerves, which then release NO into the cavernosum, triggering the erectile cascade, the resulting erection being prolonged by the NO enhancers. Thus, a full advantage may be taken of a sexually exciting stimulus, but the drug is not a substitute for foreplay and emotional arousal.

Therapeutic Indications

Erectile dysfunctions have traditionally been classified as organic, psychogenic, or mixed. Over the past 20 years, the prevailing view of the cause of erectile dysfunction has shifted away from psychological causes toward organic causes. The latter include diabetes mellitus, hypertension, hypercholesterolemia, cigarette smoking, peripheral vascular disease, pelvic or spinal cord injury, pelvic or abdominal surgery (especially prostate surgery), multiple sclerosis, peripheral neuropathy, and Parkinson disease. Erectile dysfunction is often induced by alcohol, nicotine, and other substances of abuse and prescription drugs.

These drugs are effective regardless of the baseline severity of erectile dysfunction, race, or age. Among those responding to sildenafil are men with coronary artery disease, hypertension, other cardiac diseases, peripheral vascular disease, diabetes mellitus, depression, coronary artery bypass graft surgery, radical prostatectomy, transurethral resection of the prostate, spina

bifida, and spinal cord injury, as well as persons taking antidepressants, antipsychotics, antihypertensives, and diuretics. However, the response rate is variable.

Sildenafil has been reported to reverse SSRI-induced anorgasmia in men. There are anecdotal reports of sildenafil having a therapeutic effect on sexual inhibition in women as well.

Precautions and Adverse Reactions

A significant potential adverse effect associated with the use of these drugs is myocardial infarction (MI). The U.S. FDA distinguished the risk of MI caused directly by these drugs from that caused by underlying conditions such as hypertension, atherosclerotic heart disease, diabetes mellitus, and other atherogenic conditions. The FDA concluded that when used according to the approved labeling, the drugs do not by themselves confer an increased risk of death. However, there is increased oxygen demand and stress placed on the cardiac muscle by sexual intercourse. Thus, coronary perfusion may be severely compromised, and cardiac failure may occur as a result. For that reason, any person with a history of MI, stroke, renal failure, hypertension, or diabetes mellitus and any person older than the age of 70 years should discuss plans to use these drugs with an internist or a cardiologist. The cardiac evaluation should specifically address exercise tolerance and the use of nitrates.

The use of PDE-5 inhibitors is contraindicated in persons who are taking organic nitrates in any form. Also, amyl nitrate (poppers), a popular substance of abuse used by gay men to enhance the intensity of orgasm, should not be used with any of the erection-enhancing drugs. The combination of organic nitrates and PDE inhibitors can cause a precipitous lowering of BP and can reduce coronary perfusion to the point of causing MI and death.

Adverse effects are dose-dependent, occurring at higher rates with higher dosages. The most common adverse effects are headache, flushing, and stomach pain. Other less common adverse effects include nasal congestion, urinary tract infection, abnormal vision (colored tinge [usually blue], increased sensitivity to light, or blurred vision), diarrhea, dizziness, and rash. No cases of priapism were reported in premarketing trials. Supportive

management is indicated in cases of overdosage. Tadalafil has been associated with back and muscle pain in about 10 percent of patients.

Recently, there have been 50 reports and 14 verified cases of a severe condition in men taking sildenafil called nonarteritic anterior ischemic optic neuropathy. This condition is an eye ailment that causes restriction of blood flow to the optic nerve and can result in permanent vision loss. The first symptoms appear within 24 hours after the use of sildenafil and include blurred vision and some degree of vision loss. The incidence of this effect is infrequent—1 in 1 million. In the reported cases, many patients had preexisting eye problems that may have increased their risk, and many had a history of heart disease and diabetes, which may indicate vulnerability in these men to endothelial damage.

In 2010, possible hearing loss was reported based on 29 incidents of the problem since the introduction of these drugs. Hearing loss usually occurs within hours or days of using the drug. In some cases, the loss is both unilateral and temporary.

No data are available on the effects on human fetal growth and development or testicular morphologic or functional changes. However, because these drugs are not considered an essential treatment, they should not be used during pregnancy.

Treatment of Priapism

Phenylephrine (Neo-Synephrine) is the drug of choice and first-line treatment of priapism, because the drug has almost pure α-agonist effects and minimal β activity. In short-term priapism (less than 6 hours), especially for drug-induced priapism, intracavernosal injection of phenylephrine can be used to cause detumescence. A mixture of 1 ampule of phenylephrine (1 mL/1,000 µg) should be diluted with an additional 9 mL of normal saline. 0.3 to 0.5 mL should be injected into the corpora cavernosa, using a 29-gauge needle with 10 to 15 minutes between injections. Vital signs should be monitored, and compression should be applied to the area of injection to help prevent hematoma formation.

Phenylephrine can also be used orally, 10 to 20 mg every 4 hours as needed, but it may not be as effective or act as rapidly as the injectable route.

Drug Interactions

The primary route of PDE-5 metabolism is through CYP3A4, and the minor route is through CYP2C9. Inducers or inhibitors of these enzymes will therefore affect the plasma concentration and half-life of sildenafil. For example, 800 mg of cimetidine (Tagamet), a nonspecific CYP inhibitor, increases plasma sildenafil concentrations by 56 percent, and erythromycin (E-mycin) increases plasma sildenafil concentrations by 182 percent. Other, more potent inhibitors of CYP3A4 include ketoconazole (Nizoral), itraconazole (Sporanox), and mibefradil (Posicor). In contrast, rifampicin, a CYP3A4 inducer, decreases plasma concentrations of sildenafil.

Laboratory Interferences

No laboratory interferences have been described.

Dosage and Clinical Guidelines

Sildenafil is available as 25-, 50-, and 100-mg tablets. The recommended dose of sildenafil is 50 mg taken by mouth 1 hour before intercourse. However, sildenafil may take effect within 30 minutes. The duration of the effect is usually 4 hours, but in healthy young men, the effect may persist for 8 to 12 hours. Based on effectiveness and adverse effects, the dose should be titrated between 25 and 100 mg. Sildenafil is recommended for use no more than once a day. The dosing guidelines for use by women as off-label use are the same as those for men.

Increased plasma concentrations of sildenafil may occur in persons older than 65 years of age and those with cirrhosis or severe renal impairment or using CYP3A4 inhibitors. A starting dose of 25 mg should be used in these circumstances.

An investigational nasal spray formulation of sildenafil has been developed that acts within 5 to 15 minutes of administration. This formulation is highly water-soluble, and it is rapidly absorbed directly into the bloodstream. Such a formulation would permit more ease of use.

Vardenafil is supplied in 2.5-, 5-, 10-, and 20-mg tablets. The initial dose is usually 10 mg taken with or without food about 1 hour before sexual activity. The dose can be increased to a maximum of 20 mg or decreased to 5 mg based on efficacy and side effects. The maximum dosing frequency is once

per day. As with sildenafil, dosages may have to be adjusted in patients with hepatic impairment or patients using specific CYP3A4 inhibitors. A 10 mg orally disintegrating form of vardenafil (Staxyn) is available. It is placed on the tongue approximately 60 minutes before sexual activity and should not be used more than once a day.

Tadalafil is available in 2.5-, 5-, or 20-mg tablets for oral administration. The recommended dose of tadalafil is 10 mg before sexual activity, which may be increased to 20 mg or decreased to 5 mg depending on efficacy and side effects. Once-a-day use of the 2.5- or 5-mg pill is acceptable for most patients. Similar cautions apply as mentioned earlier in patients with hepatic impairment and those taking concomitant potent inhibitors of CYP3A4. As with other PDE-5 inhibitors, concomitant use of nitrates in any form is contraindicated.

YOHIMBINE

Yohimbine (Yocon) is an α_2-adrenergic receptor antagonist that is used as a treatment for both idiopathic and medication-induced erectile disorder. Currently, sildenafil (Viagra) and its congeners and alprostadil (Impulse, Edex) are considered more efficacious for this indication than yohimbine. Yohimbine is derived from an alkaloid found in *Rubiaceae* and related trees and the *Rauwolfia serpentina* plant.

Pharmacologic Actions

Yohimbine is erratically absorbed after oral administration, with bioavailability ranging from 7 to 87 percent. There is extensive hepatic first-pass metabolism. Yohimbine affects the sympathomimetic autonomic nervous system by increasing plasma concentrations of norepinephrine. The half-life of yohimbine is 0.5 to 2 hours. Clinically, yohimbine produces increased parasympathetic (cholinergic) tone.

Therapeutic Indications

Yohimbine has been used to treat erectile dysfunction. Penile erection has been linked to cholinergic activity and to the α_2-adrenergic blockade, which theoretically results in an increased penile inflow of blood, decreased penile

outflow of blood, or both. Yohimbine is reported to help counteract the loss of sexual desire and the orgasmic inhibition caused by some serotonergic antidepressants (e.g., SSRIs). It has not been found useful in women for these indications.

Precautions

The side effects of yohimbine include anxiety, elevated BP and heart rate, increased psychomotor activity, irritability, tremor, headache, skin flushing, dizziness, urinary frequency, nausea, vomiting, and sweating. Patients with panic disorder show heightened sensitivity to yohimbine and experience increased anxiety, increased BP, and increased plasma 3-methoxy-4-hydroxyphenylglycol (MHPG).

Yohimbine should be used with caution in female patients and should not be used in patients with renal disease, cardiac disease, glaucoma, or a history of gastric or duodenal ulcers.

Drug Interactions

Yohimbine blocks the effects of clonidine, guanfacine, and other α_2-receptor agonists.

Laboratory Interferences

No known laboratory interferences are associated with yohimbine use.

Dosage and Clinical Guidelines

Yohimbine is available in 5.4-mg tablets. The dosage of yohimbine in the treatment of erectile disorder is approximately 16 mg a day, given in doses that range from 2.7 to 5.4 mg three times a day. In the event of significant adverse effects, the dose should first be reduced and then gradually increased again. Yohimbine should be used judiciously in psychiatric patients because it may worsen their mental status. Because yohimbine has no consistent effect on erectile dysfunction, its use remains controversial. Phosphodiesterase-5 (PDE-5) inhibitors are the preferred medication for this disorder.

21.10 Drugs Used to Treat the Side Effects of Psychotropic Drugs

ANTICHOLINERGIC AGENTS

Anticholinergic drugs block the actions of atropine. In the clinical practice of psychiatry, the anticholinergic drugs are primarily used to treat medication-induced movement disorders, particularly neuroleptic-induced parkinsonism, neuroleptic-induced acute dystonia, and medication-induced postural tremor.

Anticholinergics

Pharmacologic Actions. All anticholinergic drugs are well absorbed from the GI tract after oral administration, and all are sufficiently lipophilic to enter the CNS. Trihexyphenidyl (Artane) and benztropine (Cogentin) reach peak plasma concentrations in 2 to 3 hours after oral administration, and their duration of action is 1 to 12 hours. Benztropine is absorbed equally rapidly by intramuscular (IM) and intravenous (IV) administration; IM administration is preferred because of its low risk for adverse effects.

All six anticholinergic drugs listed in this section (Table 21-57) block muscarinic acetylcholine receptors, and benztropine has some antihistaminergic effects. None of the available anticholinergic drugs has any effect on the nicotinic acetylcholine receptors. Of these drugs, trihexyphenidyl is the most stimulating agent, perhaps acting through dopaminergic neurons, and benztropine is the least stimulating and thus is least associated with abuse potential.

Table 21-57
Anticholinergic Drugs

Generic Name	Brand Name	Tablet Size	Injectable	Usual Daily Oral Dosage	Short-Term Intramuscular or Intravenous Dosage
Benztropine	Cogentin	0.5, 1, 2 mg	1 mg/mL	1–4 mg one to three times	1–2 mg
Biperiden	Akineton	2 mg	5 mg/mL	2 mg one to three times	2 mg
Ethopropazine	Parsidol	10, 50 mg	—	50–100 mg one to three times	—
Orphenadrine	Norflex, Disipal	100 mg	30 mg/mL	50–100 mg three times	60 mg IV given over 5 min
Procyclidine	Kemadrin	5 mg	—	2.5–5 mg three times	—
Trihexyphenidyl	Artane, Trihexane, Trihexy-5	2, 5 mg elixir 2 mg/5 mL	—	2–5 mg two to four times	—

IV, intravenous.

Therapeutic Indications. The primary indication for the use of anticholinergics in psychiatric practice is for the treatment of *neuroleptic-induced parkinsonism*, characterized by tremor, rigidity, cogwheeling, bradykinesia, sialorrhea, stooped posture, and festination. All of the available anticholinergics are equally effective in the treatment of parkinsonian symptoms. Neuroleptic-induced parkinsonism is most common in elderly persons and is most frequently seen with high-potency DRAs, for example, haloperidol (Haldol). The onset of symptoms usually occurs after 2 or 3 weeks of treatment. The incidence of neuroleptic-induced parkinsonism is lower with the newer antipsychotic drugs of the SDA class.

Another indication for the use of anticholinergics is for the treatment of *neuroleptic-induced acute dystonia*, which is most common in young men. The syndrome often occurs early in the course of treatment; it is commonly associated with high-potency DRAs (e.g., haloperidol); and most commonly affects the muscles of the neck, tongue, face, and back. Anticholinergic drugs are useful both in the short-term treatment of dystonias and in prophylaxis against neuroleptic-induced acute dystonias.

Akathisia is characterized by a subjective and objective sense of restlessness, anxiety, and agitation. Although a trial of anticholinergics for the treatment of neuroleptic-induced acute akathisia is reasonable, these drugs are not generally considered as effective as the β-adrenergic receptor antagonists, the benzodiazepines, and clonidine (Catapres).

Precautions and Adverse Reactions. The adverse effects of the anticholinergic drugs result from the blockade of muscarinic acetylcholine receptors. Anticholinergic drugs should be used cautiously, if at all, by persons with prostatic hypertrophy, urinary retention, and narrow-angle glaucoma. The anticholinergics are occasionally used as drugs of abuse

because of their mild mood-elevating properties, most notably, trihexyphenidyl.

The most severe adverse effect associated with anticholinergic toxicity is anticholinergic intoxication. The intoxication includes symptoms of delirium, coma, seizures, agitation, hallucinations, severe hypotension, supraventricular tachycardia, and peripheral manifestations (flushing, mydriasis, dry skin, hyperthermia, and decreased bowel sounds). Treatment should begin with the immediate discontinuation of all anticholinergic drugs. We can both diagnose and treat anticholinergic intoxication with physostigmine (Antilirium, Eserine), an inhibitor of anticholinesterase, 1 to 2 mg IV (1 mg every 2 minutes) or IM every 30 or 60 minutes. Because physostigmine can lead to severe hypotension and bronchial constriction, it should be used only in severe cases, and only when emergency cardiac monitoring and life-support services are available.

Drug Interactions. The most common drug–drug interactions with the anticholinergics occur when they are coadministered with psychotropics that also have high anticholinergic activity, such as DRAs, tricyclic and tetracyclic drugs, and MAOIs. Many other prescription drugs and over-the-counter cold preparations also induce significant anticholinergic activity. The coadministration of those drugs can result in a life-threatening anticholinergic intoxication syndrome. Also, anticholinergic drugs can delay gastric emptying, thereby decreasing the absorption of drugs that are broken down in the stomach and usually absorbed in the duodenum (e.g., levodopa [Larodopa] and DRAs).

Laboratory Interferences. No known laboratory interferences have been associated with anticholinergics.

Dosage and Clinical Guidelines. The six anticholinergic drugs discussed in this chapter are available in a range of preparations (see Table 21-57).

NEUROLEPTIC-INDUCED PARKINSONISM. For the treatment of neuroleptic-induced parkinsonism, the equivalent of 1 to 3 mg of benztropine should be given one to two times daily. The anticholinergic drug should be administered for 4 to 8 weeks, and then it should be discontinued to assess

whether the person still requires the drug. Anticholinergic drugs should be tapered over 1 to 2 weeks.

Treatment with anticholinergics as prophylaxis against the development of neuroleptic-induced parkinsonism is usually not indicated because the onset of its symptoms is usually sufficiently mild and gradual to allow the clinician to initiate treatment only after it is indicated. In young men, prophylaxis may be indicated, however, mainly if a high-potency DRA is being used. The clinician should attempt to discontinue the antiparkinsonian agent in 4 to 6 weeks to assess whether its continued use is necessary.

NEUROLEPTIC-INDUCED ACUTE DYSTONIA. For the short-term treatment and prophylaxis of neuroleptic-induced acute dystonia, 1 to 2 mg of benztropine or its equivalent in another drug should be given IM. The dose can be repeated in 20 to 30 minutes, as needed. If the person still does not improve in another 20 to 30 minutes, a benzodiazepine (e.g., 1 mg IM or IV lorazepam [Ativan]) should be given. Laryngeal dystonia is a medical emergency and should be treated with benztropine, up to 4 mg in 10 minutes, followed by 1 to 2 mg of lorazepam, administered slowly by the IV route.

Prophylaxis against dystonias is indicated in persons who have had one episode or in persons at high risk (young men taking high-potency DRAs). Prophylactic treatment is given for 4 to 8 weeks and then gradually tapered over 1 to 2 weeks to allow assessment of its continued need. The prophylactic use of anticholinergics in persons requiring antipsychotic drugs has mostly become a moot issue because of the availability of SDAs, which are relatively free of parkinsonian effects.

AKATHISIA. As mentioned, anticholinergics are not the drugs of choice for this syndrome. The β-adrenergic receptor antagonists and perhaps the benzodiazepines and clonidine are preferable drugs to try initially.

ANTIHISTAMINES

Antihistamines are frequently used in the treatment of a variety of psychiatric disorders because of their sedative and anticholinergic activities. Certain antihistamines (antagonists of histamine H_1 receptors) are used to treat neuroleptic-induced parkinsonism and neuroleptic-induced acute dystonia

and as hypnotics and anxiolytics. Diphenhydramine (Benadryl) is used to treat neuroleptic-induced parkinsonism and neuroleptic-induced acute dystonia and sometimes as a hypnotic. Hydroxyzine hydrochloride (Atarax) and hydroxyzine pamoate (Vistaril) are used as anxiolytics. Promethazine (Phenergan) is used for its sedative and anxiolytic effects. Cyproheptadine (Periactin) has been used for the treatment of anorexia nervosa and inhibited male and female orgasms caused by serotonergic agents. The antihistamines most commonly used in psychiatry are listed in Table 21-58. Second-generation, "nonsedating" H_1 blockers, such as fexofenadine (Allegra), loratadine (Claritin), and cetirizine (Zyrtec) are less commonly used in psychiatric practice. The H_2-receptor antagonists, such as cimetidine, work primarily on gastric mucosa, inhibiting gastric secretion.

Table 21-59 lists antihistaminic drugs not used in psychiatry, but that may have psychiatric adverse effects or drug–drug interactions.

Pharmacologic Actions

The H_1 antagonists used in psychiatry are well absorbed from the GI tract. The antiparkinsonian effects of intramuscular (IM) diphenhydramine have their onset in 15 to 30 minutes and the sedative effects of diphenhydramine peak in 1 to 3 hours. The sedative effects of hydroxyzine and promethazine begin after 20 to 60 minutes and last for 4 to 6 hours. Because all three drugs are metabolized in the liver, persons with hepatic disease, such as cirrhosis, may attain high plasma concentrations with long-term administration. Cyproheptadine is well absorbed after oral administration, and its metabolites are excreted in the urine.

Table 21-58
Histamine Antagonists Commonly Used in Psychiatry

Generic Name	Trade Name	Duration of Action (hr)
Diphenhydramine	Benadryl	4–6
Hydroxyzine	Atarax, Vistaril	6–24
Promethazine	Phenergan	4–6

Cyproheptadine	Periactin	4–6

Table 21-59
Other Histamine Antagonists often Prescribed

Class	Generic Name	Trade Name
Second-generation histamine 1 receptor antagonists	Cetirizine	Zyrtec
	Loratadine	Claritin
	Fexofenadine	Allegra
Histamine 2 receptor antagonists	Nizatidine	Axid
	Famotidine	Pepcid
	Ranitidine	Zantac
	Cimetidine	Tagamet

Activation of H_1 receptors stimulates wakefulness; therefore, receptor antagonism causes sedation. All four agents also possess some antimuscarinic cholinergic activity. Cyproheptadine is unique among the drugs because it has both potent antihistamine and serotonin 5-HT_2-receptor antagonist properties.

Therapeutic Indications

Antihistamines are useful as a treatment for neuroleptic-induced parkinsonism, neuroleptic-induced acute dystonia, and neuroleptic-induced akathisia. They are an alternative to anticholinergics and amantadine for these purposes. The antihistamines are relatively safe hypnotics, but they are not superior to the benzodiazepines, which have been much better studied in terms of efficacy and safety. The antihistamines have not been proven effective for long-term anxiolytic therapy; therefore, the benzodiazepines, buspirone (BuSpar), or SSRIs are preferable for such treatment. Cyproheptadine is sometimes used to treat impaired orgasms, especially

delayed orgasm resulting from treatment with serotonergic drugs.

Because it promotes weight gain, cyproheptadine may be of some use in the treatment of eating disorders, such as anorexia nervosa. Cyproheptadine can reduce recurrent nightmares with posttraumatic themes. The antiserotonergic activity of cyproheptadine may counteract the serotonin syndrome caused by concomitant use of multiple serotonin-activating drugs, such as SSRIs and MAOIs.

Precautions and Adverse Reactions

Antihistamines are commonly associated with sedation, dizziness, and hypotension, all of which can be severe in elderly persons, who are also likely to experience the anticholinergic effects of those drugs. Paradoxical excitement and agitation is an adverse effect seen in a small number of persons. Poor motor coordination can result in accidents; therefore, persons should be warned about driving and operating dangerous machinery. Other common adverse effects include epigastric distress, nausea, vomiting, diarrhea, and constipation. Because of mild anticholinergic activity, some people experience dry mouth, urinary retention, blurred vision, and constipation.

For this reason, also, antihistamines should be used only at very low doses, if at all, by persons with narrow-angle glaucoma or obstructive GI, prostate, or bladder conditions. Either cyproheptadine or diphenhydramine may induce a central anticholinergic syndrome with psychosis. The use of cyproheptadine in some persons has been associated with weight gain, which may contribute to its reported efficacy in some persons with anorexia nervosa.

In addition to the above adverse effects, antihistamines have some potential for abuse. The coadministration of antihistamines and opioids can increase the euphoria experienced by persons with substance use disorders. Overdoses of antihistamines can be fatal. Antihistamines are excreted in breast milk, so nursing mothers should avoid their use. Because of some potential for teratogenicity, pregnant women should avoid the use of antihistamines.

Drug Interactions

The sedative property of antihistamines can be additive with other CNS

depressants, such as alcohol, other sedative-hypnotic drugs, and many psychotropic drugs, including tricyclic drugs and DRAs. Anticholinergic activity can be cumulative when using other anticholinergic drugs and may sometimes result in severe anticholinergic symptoms or intoxication.

Laboratory Interferences

H_1 antagonists may eliminate the wheal and induration that form the basis of allergy skin tests. Promethazine may interfere with pregnancy tests and may increase blood glucose concentrations. Diphenhydramine may yield a false-positive urine test result for phencyclidine (PCP). Hydroxyzine use can falsely elevate the results of specific tests for urinary 17-hydroxycorticosteroids.

Dosage and Clinical Guidelines

The antihistamines are available in a variety of preparations (Table 21-60). IM injections should be deep because superficial administration can cause local irritation.

Table 21-60
Dosage and Administration of Common Histamine Antagonists

Medication	Route	Preparation	Common Dosage
Diphenhydramine (Benadryl)	PO	Capsules and tablets: 25 mg, 50 mg	Adults: 25–50 mg three to four times per day
		Liquid: 12.5 mg/5.0 mL	Children: 5 mg/kg three to four times per day, not to exceed 300 mg/day
	Deep IM or IV	Solution: 10 or 50 mg/mL	Same as oral

Hydroxyzine Hydrochloride (Atarax)	PO	Tablets: 10, 25, 50, and 100 mg	Adults: 50–100 mg three to four times daily
		Syrup: 10 mg/5 mL	Children younger than 6 yr of age: 2 mg/kg/day in divided doses
			Children older than 6 yr of age: 12.5–25.0 mg three to four times daily
	IM	Solution: 25 or 50 mg/mL	Same as oral
Hydroxyzine Pamoate (Vistaril)	PO	Suspension: 25 mg/mL	Same as dosages for hydroxyzine hydrochloride
		Capsules: 25, 50, and 100 mg	
Promethazine (Phenergan)	PO	Tablets: 15.2, 25.0, and 50.0 mg	Adults: 50–100 mg three to four times daily for sedation
		Syrup: 3.25 mg/5 mL	Children: 12.5–25.0 mg at night for sedation
	Rectal	Suppositories: 12.5, 25.0, and 50.0 mg	
	IM	Solution: 25 and 50 mg/mL	

Cyproheptadine (Periactin)	PO	Tablets: 4 mg Syrup: 2 mg/5 mL	Adults: 4–20 mg/day Children 2–7 yr of age: 2 mg two to three times daily (maximum, 12 mg/day) Children 7–14 yr of age: 4 mg two to three times daily (maximum of 16 mg/day)

IM, intramuscular; IV, intravenous; PO, oral.

Intravenous (IV) administration of 25 to 50 mg of diphenhydramine is an effective treatment for neuroleptic-induced acute dystonia, which may immediately disappear. Treatment with 25 mg three times a day—up to 50 mg four times a day, if necessary—can be used to treat neuroleptic-induced parkinsonism, akinesia, and buccal movements. Diphenhydramine can be used as a hypnotic at a 50-mg dose for mild transient insomnia. Doses of 100 mg are not superior to doses of 50 mg, but they produce more anticholinergic effects than doses of 50 mg.

Hydroxyzine is most commonly used as a short-term anxiolytic. Hydroxyzine should not be given IV because it is irritating to the blood vessels. Dosages of 50 to 100 mg given orally four times a day for long-term treatment or 50 to 100 mg IM every 4 to 6 hours for short-term treatment are usually effective.

SSRI-induced anorgasmia may sometimes be reversed with 4 to 16 mg a day of cyproheptadine taken by mouth 1 or 2 hours before anticipated sexual activity. Several case reports and small studies have also reported that cyproheptadine may be of some use in the treatment of eating disorders, such as anorexia nervosa. Cyproheptadine is available in 4-mg tablets and a 2-mg/5-mL solution. Children and elderly patients are more sensitive to the effects of antihistamines than are young adults.

DOPAMINE RECEPTOR AGONISTS AND PRECURSORS

Dopamine agonists activate dopamine receptors in the absence of endogenous dopamine and have been widely used to treat idiopathic Parkinson disease, hyperprolactinemia, and certain pituitary tumors (prolactinoma). Because dopamine stimulates the heart and increases blood flow to the liver, kidneys, and other organs, low levels of dopamine are associated with low BP and low cardiac input. Dopamine agonist drugs are also administered to treat shock and congestive heart failure.

Their use in psychiatry has been limited to treat such adverse effects of antipsychotic drugs as parkinsonism, extrapyramidal symptoms, akinesia, focal perioral tremors, hyperprolactinemia, galactorrhea, and neuroleptic malignant syndrome. The drugs in this class most commonly prescribed are bromocriptine (Parlodel), levodopa (also called L-Dopa; Larodopa), carbidopa-levodopa (Sinemet), and amantadine (Symmetrel). Amantadine is used primarily for the treatment of medication-induced movement disorders, such as neuroleptic-induced parkinsonism. It is also used as an antiviral agent for the prophylaxis and treatment of influenza A infection and Cotard syndrome, a rare neuropsychiatric disorder in which a person holds a delusional belief that he or she is dead. There are also a few reports of amantadine's role in augmenting antidepressant medications in patients with treatment-resistant depression.

New dopamine receptor agonists include ropinirole (Requip), pramipexole (Mirapex), apomorphine (Apokyn), and pergolide (Permax). Of these drugs, pramipexole is the most widely prescribed in psychiatry as an augmenter of antidepressants. In 2007, pergolide was removed from the market because of the risk of severe damage to patients' heart valves. In 2012, the U.S. FDA notified health care professionals about a possible increased risk of heart failure with pramipexole. This warning was based on studies that suggested a potential risk of heart failure; however, further review is required because of study limitations.

Pharmacologic Actions

L-Dopa is rapidly absorbed after oral administration, and peak plasma levels are reached after 30 to 120 minutes. The half-life of L-Dopa is 90 minutes.

Absorption of L-Dopa can be significantly reduced by changes in gastric pH and by ingestion with meals. Bromocriptine and ropinirole are rapidly absorbed but undergo first-pass metabolism such that only about 30 to 55 percent of the dose is bioavailable. Peak concentrations are achieved 1.5 to 3 hours after oral administration. The half-life of ropinirole is 6 hours. Pramipexole is rapidly absorbed with little first-pass metabolism and reaches peak concentrations in 2 hours. Its half-life is 8 hours. Oral forms of apomorphine have been studied, but this form is not available in the United States. Subcutaneous apomorphine injection results in rapid and controlled systemic delivery, with linear pharmacokinetics over a dose ranging from 2 to 8 mg.

After L-Dopa enters the dopaminergic neurons of the CNS, it is converted into the neurotransmitter dopamine. Apomorphine, bromocriptine, ropinirole, and pramipexole act directly on dopamine receptors. L-Dopa, pramipexole, and ropinirole bind about 20 times more selectively to dopamine D_3 than D_2 receptors; the corresponding ratio for bromocriptine is less than 2 to 1. Apomorphine binds selectively to D_1 and D_2 receptors, with little affinity for D_3 and D_4 receptors. L-Dopa, pramipexole, and ropinirole have no significant activity at nondopaminergic receptors. However, bromocriptine binds to serotonin 5-HT_1 and 5-HT_2 and α_1-, α_2-, and β-adrenergic receptors.

Therapeutic Indications

Medication-Induced Movement Disorders. In present-day clinical psychiatry, dopamine receptor agonists are used for the treatment of medication-induced parkinsonism, extrapyramidal symptoms, akinesia, and focal perioral tremors. Their use has diminished sharply, however, because the incidence of medication-induced movement disorders is much lower with the use of the newer, atypical antipsychotics (SDAs). Dopamine receptor agonists are effective in treating idiopathic restless legs syndrome and may also be helpful when this is a medication side effect. Ropinirole can treat restless legs syndrome.

For the treatment of medication-induced movement disorders, most clinicians rely on anticholinergics, amantadine, and antihistamines because they are equally effective and have few adverse effects. Bromocriptine

remains in use in the treatment of neuroleptic malignant syndrome; however, the incidence of this disorder is diminishing with the decreased use of DRAs.

Dopamine receptor agonists are also used to counteract the hyperprolactinemic effects of DRAs, which result in the side effects of amenorrhea and galactorrhea.

Mood Disorders. Bromocriptine has long been used to enhance response to antidepressant drugs in refractory patients. Ropinirole has been reported to be useful as an augmentation of antidepressant therapy and as a treatment for medication-resistant bipolar II depression. Ropinirole may also be helpful in the treatment of antidepressant-induced sexual dysfunction. Pramipexole is often used in the augmentation of antidepressants in treatment-resistant depression. Some studies have found pramipexole to be superior to sertraline (Zoloft) in the treatment of depression in Parkinson disease, as well as in reducing anhedonia in Parkinson patients.

Sexual Dysfunction. Dopamine receptor agonists improve erectile dysfunction in some patients. However, they are rarely used because they frequently cause adverse effects at therapeutic dosages. Phosphodiesterase-5 inhibitor agents are better tolerated and more effective (see Chapter 16).

Precautions and Adverse Reactions

Adverse effects are common with dopamine receptor agonists, thus limiting the usefulness of these drugs. Adverse effects are dosage-dependent and include nausea, vomiting, orthostatic hypotension, headache, dizziness, and cardiac arrhythmias. To reduce the risk of orthostatic hypotension, the initial dosage of all dopamine receptor agonists should be relatively low, with incremental increases at intervals of at least 1 week. These drugs should be used with caution in persons with hypertension, cardiovascular disease, and hepatic disease. After long-term use, persons, particularly elderly persons, may experience choreiform and dystonic movements and psychiatric disturbances—including hallucinations, delusions, confusion, depression, and mania—and other behavioral changes.

Long-term use of bromocriptine can produce retroperitoneal and pulmonary fibrosis, pleural effusions, and pleural thickening.

In general, ropinirole and pramipexole have a similar but milder adverse

effect profile than L-Dopa and bromocriptine. Pramipexole and ropinirole may cause irresistible sleep attacks that occur suddenly without warning and have caused motor vehicle accidents.

The most common adverse effects of apomorphine are yawning, dizziness, nausea, vomiting, drowsiness, bradycardia, syncope, and perspiration. Hallucinations have also been reported. Apomorphine's sedative effects are exacerbated with concurrent use of alcohol or other CNS depressants.

Dopamine receptor agonists are contraindicated during pregnancy, especially for nursing mothers, because they inhibit lactation.

Drug Interactions

DRAs are capable of reversing the effects of dopamine receptor agonists, but this is not usually clinically significant. The concurrent use of tricyclic drugs and dopamine receptor agonists has been reported to cause symptoms of neurotoxicity, such as rigidity, agitation, and tremor. They may also potentiate the hypotensive effects of diuretics and other antihypertensive medications. Dopamine receptor agonists should not be used in conjunction with MAOIs, including selegiline (Eldepryl), and MAOIs should be discontinued at least 2 weeks before the initiation of dopamine receptor agonist therapy.

Benzodiazepines, phenytoin (Dilantin), and pyridoxine may interfere with the therapeutic effects of dopamine receptor agonists. We should not combine ergot alkaloids and bromocriptine because they may cause hypertension and myocardial infarction. Progestins, estrogens, and oral contraceptives may interfere with the effects of bromocriptine and may raise plasma concentrations of ropinirole. Ciprofloxacin (Cipro) can raise plasma concentrations of ropinirole, and cimetidine (Tagamet) can raise plasma concentrations of pramipexole.

Laboratory Interferences

L-Dopa administration has been associated with false reports of elevated serum and urinary uric acid concentrations, urinary glucose test results, urinary ketone test results, and urinary catecholamine concentrations. No laboratory interferences have been associated with the administration of the other dopamine receptor agonists.

Dosage and Clinical Guidelines

Table 21-61 lists the various dopamine receptor agonists and their formulations. For the treatment of antipsychotic-induced parkinsonism, the clinician should start with a 100-mg dose of levodopa three times a day, which may be increased until the person is functionally improved. The maximum dosage of L-Dopa is 2,000 mg a day, but most persons respond to dosages below 1,000 mg/day. The dosage of the carbidopa component of the L-Dopa-carbidopa formulation should total at least 75 mg a day.

The dosage of bromocriptine for mental disorders is uncertain, although it seems prudent to begin with low dosages (1.25 mg twice daily) and to increase the dosage gradually. Bromocriptine is usually taken with meals to help reduce the likelihood of nausea.

The starting dosage of pramipexole is 0.125 mg three times daily, which is increased to 0.25 mg three times daily in the second week and is increased by 0.25 mg/dose each week until therapeutic benefit or adverse effects emerge. Persons with idiopathic Parkinson disease usually experience benefits at total daily doses of 1.5 mg, and the maximum daily dose is 4.5 mg.

For ropinirole, the starting dosage is 0.25 mg three times daily and is increased by 0.25 mg/dose each week to a total daily dose of 3 mg, then by 0.5 mg/dose each week to a total daily dose of 9 mg, and then by 1 mg/dose each week to a maximum dosage of 24 mg a day until therapeutic benefit or adverse effects emerge. The average daily dose for persons with idiopathic Parkinson disease is about 16 mg.

The recommended subcutaneous dose of apomorphine in Parkinson disease is 0.2 to 0.6 mL subcutaneously during acute hypomobility episodes delivered via metered injector pen. Apomorphine can be administered three times daily, with a maximum dose of 0.6 mL five times daily.

Table 21-61
Available Preparations of Dopamine Receptor Agonists and Carbidopa

Generic Name	Trade Name	Preparations
Amantadine	Symmetrel	100-mg capsule, 50-mg/5-mL

Bromocriptine	Parlodel	syrup (teaspoon) 2.5-, 5-mg tablets
Carbidopa	Lodosyn	25 mg[a]
Levodopa (L-Dopa)	Larodopa	100-, 250-, 500-mg tablets
Levodopa-carbidopa (co-careldopa)	Sinemet, Atamet	100/10-mg, 100/25-mg, 250/25-mg tablets; 100/25-, 200/50-mg extended-release tablets
Pramipexole	Mirapex	0.125-, 0.375-, 0.75-, 1.5-, 3-, 4-mg extended-release tablets
Ropinirole	Requip	0.25-, 0.5-, 1-, 2-, 5-mg tablets

[a]Drug only available directly through the manufacturer.

Amantadine

Amantadine is an antiviral drug used for the prophylaxis and treatment of influenza. It was found to have antiparkinsonian properties and is now used to treat that disorder as well as akinesias and other extrapyramidal signs, including focal perioral tremors (rabbit syndrome).

Pharmacologic Actions. Amantadine is well absorbed from the GI tract after oral administration, reaches peak plasma concentrations in approximately 2 to 3 hours, has a half-life of about 12 to 18 hours, and attains steady-state concentrations after approximately 4 to 5 days of therapy. Amantadine is excreted unmetabolized in the urine. Amantadine plasma concentrations can be twice as high in elderly persons as in younger adults. Patients with renal failure accumulate amantadine in their bodies.

Amantadine augments dopaminergic neurotransmission in the CNS; however, the precise mechanism is unknown. The mechanism may involve dopamine release from presynaptic vesicles, blocking the reuptake of dopamine into presynaptic nerve terminals, or an agonist effect on postsynaptic dopamine receptors.

Therapeutic Indications. The primary indication for amantadine use in

psychiatry is to treat extrapyramidal signs and symptoms, such as parkinsonism, akinesia, and rabbit syndrome (focal perioral tremor of the choreoathetoid type) caused by the administration of DRA or SDA drugs. Amantadine is as effective as the anticholinergics (e.g., benztropine [Cogentin]) for these indications and results in an improvement in approximately half of all persons who take it. Amantadine, however, is not generally considered as effective as the anticholinergics for the treatment of acute dystonic reactions and is not effective in treating tardive dyskinesia and akathisia.

Amantadine is a reasonable compromise for persons with extrapyramidal symptoms who would be sensitive to additional anticholinergic effects, particularly those taking a low-potency DRA or the elderly. Elderly persons are susceptible to anticholinergic adverse effects, both in the CNS, such as anticholinergic delirium, and in the peripheral nervous system, such as urinary retention. Amantadine is associated with less memory impairment than are the anticholinergics.

Amantadine has been reported to be of benefit in treating some SSRI-associated side effects, such as lethargy, fatigue, anorgasmia, and ejaculatory inhibition.

Amantadine is used in general medical practice for the treatment of parkinsonism of all causes, including idiopathic parkinsonism.

Precautions and Adverse Effects. The most common CNS effects of amantadine are mild dizziness, insomnia, and impaired concentration (dosage related), which occur in 5 to 10 percent of all persons. Irritability, depression, anxiety, dysarthria, and ataxia occur in 1 to 5 percent of all persons. More severe CNS adverse effects, including seizures and psychotic symptoms, have been reported. Nausea is the most common peripheral adverse effect of amantadine. Headache, loss of appetite, and blotchy spots on the skin have also been reported.

Livedo reticularis of the legs (a purple discoloration of the skin caused by dilation of blood vessels) has been reported in up to 5 percent of persons who take the drug for longer than 1 month. It usually diminishes with the elevation of the legs and resolves in almost all cases when drug use is terminated.

Amantadine is relatively contraindicated in persons with renal disease or a

seizure disorder. Amantadine should be used with caution in persons with edema or cardiovascular disease. Some evidence indicates that amantadine is teratogenic and, therefore, should not be taken by pregnant women. Because amantadine is excreted in breast milk, breastfeeding women should not take the drug.

Suicide attempts with amantadine overdosages are life-threatening. Symptoms can include toxic psychoses (confusion, hallucinations, aggressiveness) and cardiopulmonary arrest. Emergency treatment beginning with gastric lavage is indicated.

Drug Interactions. Coadministration of amantadine with phenelzine (Nardil) or other MAOIs can result in a significant increase in resting BP. The coadministration of amantadine with CNS stimulants can result in insomnia, irritability, nervousness, and possibly seizures or irregular heartbeat. Amantadine should not be coadministered with anticholinergics because unwanted side effects—such as confusion, hallucinations, nightmares, dry mouth, and blurred vision—may be exacerbated.

Dosage and Clinical Guidelines. Amantadine is available in 100-mg capsules and as a 50-mg/5-mL syrup. The usual starting dosage of amantadine is 100 mg given twice a day orally, although the dosage can be cautiously increased up to 200 mg given twice a day orally if indicated. Amantadine should be used in persons with renal impairment *only* in consultation with the physician treating the renal condition. If amantadine is successful in the treatment of the drug-induced extrapyramidal symptoms, it should be continued for 4 to 6 weeks and then discontinued to see whether the person has become tolerant to the neurologic adverse effects of the antipsychotic medication. Amantadine should be tapered over 1 to 2 weeks after a decision has been made to discontinue the drug. Persons taking amantadine should not drink alcoholic beverages.

DRUGS TO TREAT PSYCHOTROPIC-INDUCED WEIGHT GAIN

Weight management is a critical element of psychotropic drug treatment because obesity is common among persons with mental disorders. Thus,

medical conditions such as hypertension, diabetes mellitus, and hyperlipidemia need to be taken into account when selecting medications. With few exceptions, most psychotropic drugs used to manage mood disorders, anxiety disorders, and psychosis are associated with a significant risk of weight gain as a side effect. Many patients may refuse or discontinue treatment if weight gain occurs, even if the drug is effective in treating their symptoms. For this and other reasons, clinicians need to be well informed about treatment strategies for mitigating drug-induced weight gain and obesity in general.

The standard recommendation for weight loss regimens consists of attempting to manage body weight through consistent dietary modifications and regular physical activity. This behavioral approach may be difficult for patients struggling with psychiatric symptoms, because their mental disorder can compromise their ability to be disciplined in this effort. Also, the physiologic effects of some psychotropic drugs on the regulation of satiety and body metabolism are difficult, if not impossible, to overcome through diet and exercise alone. For these reasons, it may be necessary to use prescription medications to facilitate weight loss.

In this section, drugs used to manage obesity are categorized in two ways: (1) drugs approved by the U.S. FDA as diet pills; and (2) drugs with primary indications other than weight loss but produce weight loss as a side effect.

Drugs with U.S. Food and Drug Administration Approval for Weight Loss

All of the drugs approved by the FDA as weight loss agents are specifically indicated as an adjunct to a reduced-calorie diet and increased physical activity for chronic weight management in adult patients with an initial body mass index (BMI) of 30 kg/m^2 or greater (obese) or 27 kg/m^2 or greater (overweight) in the presence of at least one weight-related comorbidity such as hypertension, type 2 diabetes mellitus, or dyslipidemia.

Phentermine. Phentermine hydrochloride (Adipex-P) is a sympathomimetic amine with pharmacologic activity similar to the amphetamines. It is indicated as a short-term adjunct in a regimen of weight reduction, but in fact, many patients use the drug for extended periods. As

with all sympathomimetics, contraindications include advanced arteriosclerosis, cardiovascular disease, moderate to severe hypertension, hyperthyroidism, known hypersensitivity or idiosyncrasy to the sympathomimetic amines, agitated states, and glaucoma.

The drug should be prescribed with caution to patients with a history of drug abuse. Hypertensive crises may result if phentermine is used during or within 14 days following the administration of MAOIs. Insulin requirements in diabetes mellitus may be altered in association with the use of phentermine hydrochloride and the concomitant dietary regimen. Phentermine hydrochloride may decrease the hypotensive effect of guanethidine. Phentermine was pregnancy Category X in the former FDA classification system and thus contraindicated during pregnancy. Studies have not been performed with phentermine hydrochloride to determine the potential for carcinogenesis, mutagenesis, or impairment of fertility.

Phentermine should be taken on an empty stomach once daily, before breakfast. Tablets may be broken or cut in half but should not be crushed. It should be dosed early in the day to avoid disrupting normal sleep patterns. If taking more than one dose a day, the last dose should be taken approximately 4 to 6 hours before going to bed. The recommended dose of phentermine may be different for different patients. Adults under age 60 taking phentermine using 15- to 37.5-mg capsules should take them once per day before breakfast or 1 to 2 hours after breakfast. Those using 15- to 37.5-mg tablets should take them once per day before breakfast or 1 to 2 hours after breakfast. Instead of taking it once a day, some patients may take 15 to 37.5 mg in divided doses a half hour before meals. An oral resin formulation is available in 15- and 30-mg capsules, which should be taken once per day before breakfast.

Phentermine/Topiramate Extended Release (Qsymia).

This drug is a combination of phentermine and topiramate (Topamax). The FDA approved the phentermine/topiramate combination in 2012 as an extended-release formulation. Both active agents in this formulation are associated with weight loss through separate mechanisms.

Adverse events associated with the use of this drug may include, but are not limited to, paresthesia, dizziness, dysgeusia, insomnia, constipation, dry mouth, kidney stones, metabolic acidosis, and secondary angle-closure glaucoma. The use of this drug is associated with a fivefold increased risk of

infants with cleft palate and was classified as pregnancy Category X in the former FDA classification system. It can only be prescribed by clinicians who have been certified in the use of this drug.

It is available as a tablet and should be administered once daily in the morning with or without food. Avoid dosing with the drug in the evening due to the possibility of insomnia. The recommended dose is as follows: Start treatment with 3.75 mg/
23 mg (phentermine/topiramate extended-release) daily for 14 days; after 14 days, increase the dose to 7.5 mg/46 mg once daily. Evaluate for weight loss after 12 weeks of treatment at the 7.5 mg/
46 mg dose. If at least 3 percent of baseline body weight has not been lost on 7.5 mg/46 mg, discontinue the drug or escalate the dose. To escalate the dose, increase to 11.25 mg/69 mg daily for 14 days, followed by dosing 15 mg/92 mg daily. Evaluate weight loss following dose escalation to 15 mg/92 mg after an additional 12 weeks of treatment. If at least 5 percent of baseline body weight has not been lost on 15 mg/92 mg, discontinue the medication gradually.

Phendimetrazine (Bontril PDM, Adipost, Phendiet, Statobex). Phendimetrazine is a sympathomimetic amine that is closely related to the amphetamines. It is classified by the Drug Enforcement Agency (DEA) as a Schedule III controlled substance.

The overall prescribing of this agent is limited. The most commonly used formulation is the 105-mg extended-release capsule, which approximates the action of three 35-mg immediate-release doses taken at 4-hour intervals. The average half-life of elimination, when studied under controlled conditions, is about 3.7 hours for both the extended-release and immediate-release forms. The absorption half-life of the drug from the immediate-release 35-mg phendimetrazine tablets is appreciably more rapid than the absorption rate of the drug from the extended-release formulation. The primary route of elimination is via the kidneys, where most of the drug and metabolites are excreted.

Phendimetrazine contraindications are similar to those of phentermine. They include a history of cardiovascular disease (e.g., coronary artery disease, stroke, arrhythmias, congestive heart failure, uncontrolled hypertension, pulmonary hypertension); use during or within 14 days

following the administration of MAOIs; hyperthyroidism; glaucoma; agitated states; a history of drug abuse; pregnancy; nursing; use in combination with other anorectic agents or CNS stimulants; and known hypersensitivity or idiosyncratic reactions to sympathomimetics. Given the lack of systematic research, phendimetrazine should not be used in combination with over-the-counter preparations and herbal products that claim to promote weight loss.

Phendimetrazine tartrate was considered pregnancy Category X in the former FDA classification system and is contraindicated during pregnancy because weight loss offers no potential benefit to a pregnant woman and may result in fetal harm. Studies with phendimetrazine tartrate sustained release have not been performed to evaluate carcinogenic potential, mutagenic potential, or effects on fertility.

Interactions may occur with MAOIs, alcohol, insulin, and oral hypoglycemic agents. Phendimetrazine may decrease the hypotensive effect of adrenergic neuron blocking drugs. The effectiveness and safety of phendimetrazine in pediatric patients have not been established. It is not recommended in patients less than 17 years of age.

Adverse reactions reported with phendimetrazine include sweating, flushing, tremor, insomnia, agitation, dizziness, headache, psychosis, and blurred vision. Elevated BP, palpitations, and tachycardia are frequent. GI side effects include dry mouth, nausea, stomach pain, diarrhea, and constipation. Genitourinary side effects include frequency, dysuria, and changes in libido.

Phendimetrazine tartrate is related chemically and pharmacologically to the amphetamines. Amphetamines and related stimulant drugs have been extensively abused, and the possibility of abuse of phendimetrazine should be kept in mind when evaluating the desirability of including a drug as part of a weight reduction program.

Acute overdose with phendimetrazine may manifest itself by restlessness, confusion, belligerence, hallucinations, and panic states. Fatigue and depression usually follow central stimulation. Cardiovascular effects include tachycardia, arrhythmias, hypertension or hypotension, and circulatory collapse. GI symptoms include nausea, vomiting, diarrhea, and abdominal cramps. Poisoning may result in convulsions, coma, and death. The management of acute overdose is mainly symptomatic. It includes lavage and sedation with a barbiturate. If hypertension is marked, the use of a nitrate or

rapid-acting α-receptor–blocking agent should be considered.

Diethylpropion (Tenuate). Diethylpropion preceded its analog, the antidepressant drug bupropion (Wellbutrin). Diethylpropion comes in two formulations: a 25-mg tablet and a 75-mg extended-release tablet (Tenuate Dospan). It is usually taken three times a day, 1 hour before meals (regular tablets), or once a day in midmorning (extended-release tablets). The extended-release tablets should be swallowed whole, never crushed, chewed, or cut. The maximum daily dose is 75 mg.

Side effects include dry mouth, unpleasant taste, restlessness, anxiety, dizziness, depression, tremors, upset stomach, vomiting, and increased urination. Side effects that warrant medical attention include tachycardia, palpitations, blurred vision, skin rash, itching, difficulty breathing, chest pain, fainting, swelling of the ankles or feet, fever, sore throat, chills, and painful urination. Diethylpropion was classified as pregnancy Category B in the former FDA classification system and has low abuse potential. It is listed as a Schedule IV drug by the DEA.

Orlistat (Xenical, Alli). Orlistat interferes with the absorption of dietary fats, causing reduced caloric intake. It works by inhibiting gastric and pancreatic lipases, the enzymes that break down triglycerides in the intestine. When lipase activity is blocked, triglycerides from the diet are not hydrolyzed into absorbable free fatty acids and are excreted undigested instead. Only trace amounts of orlistat are absorbed systemically; it is almost entirely eliminated through the feces.

The effectiveness of orlistat in promoting weight loss is definite, though modest. When used as part of a weight loss program, between 30 and 50 percent of patients can expect a 5 percent or more significant decrease in body mass. About 20 percent achieve at least a 10 percent decrease in body mass. After orlistat is stopped, up to a third of people gain the weight they lose.

Among the benefits of orlistat treatment is a decrease in BP and a reduced risk of developing type 2 diabetes.

The most common subjective side effects of orlistat are GI related and include steatorrhea, flatulence, fecal incontinence, and frequent or urgent bowel movements. Patients should avoid foods with high-fat content to

minimize these effects. Also, they should eat a reduced-calorie diet. Because of this side effect, orlistat can be used with high-fat content diets to treat constipation that results from treatment with some psychotropic drugs, such as the TCAs. Side effects are most severe when beginning therapy and may decrease in frequency with time. Hepatic and renal injuries are potentially severe side effects of orlistat use. In 2010, new safety information about rare cases of severe liver injury was added to the product label of orlistat. The rate of acute kidney injury is more common among orlistat users than nonusers. It should be used with caution in patients with impaired liver function and renal function, as well as those with an obstructed bile duct and pancreatic disease. Orlistat is contraindicated in malabsorption syndromes, hypersensitivity to orlistat, reduced gallbladder function, and in pregnancy and breastfeeding. Orlistat was rated pregnancy Category X in the former FDA classification system.

The use of orlistat inhibits the absorption of fat-soluble vitamins and other fat-soluble nutrients. Multivitamin supplements that contain vitamins A, D, E, K, as well as β-carotene, should be taken once a day, preferably at bedtime.

Orlistat can reduce plasma levels of the immunosuppressant cyclosporine (Sandimmune), so the two drugs should, therefore, not be administered concomitantly. Orlistat can also impair the absorption of the antiarrhythmic amiodarone (Nexterone).

At the standard prescription dose of 120 mg three times daily before meals, orlistat prevents approximately 30 percent of dietary fat from being absorbed. Higher doses have not been shown to produce more pronounced effects.

An over-the-counter formulation of orlistat (Alli) is available as 60-mg capsules—half the dosage of prescription orlistat.

Drugs without U.S. Food and Drug Administration Approval for Weight Loss

Topiramate. Topiramate and zonisamide (Zonegran) are discussed more fully among the mood stabilizers earlier in this chapter, but are mentioned here because both agents can have a substantial effect on weight loss.

Topiramate is approved as an antiepileptic drug and for prevention of migraine headaches in adults. The degree of weight loss associated with

topiramate may be comparable to the weight loss that other FDA-approved antiobesity drugs induce. Small studies and extensive anecdotal reports indicate that topiramate can help to offset weight gain associated with SSRIs and SGA drugs. Its impact on body weight may be due to its effects on both appetite suppression and satiety enhancement. These may be the result of a combination of pharmacologic effects including augmenting GABA activity, modulation of voltage-gated ion channels, inhibition of excitatory glutamate receptors, or inhibition of carbonic anhydrase.

The duration and dosage of treatment affect the weight loss benefits of topiramate. Weight loss is higher when the drug is prescribed at doses of 100 to 200 mg/day for more than a month compared with less than a month. In a large study, it was shown that compared to those who took a placebo, topiramate-treated patients were seven times more likely to lose more than 10 percent of their body weight. In clinical practice, many patients experience weight loss at a starting dose of 25 mg/day.

The most common side effects of topiramate are paresthesias, typically around the mouth, impaired taste (taste perversion), and psychomotor disturbances, including slowed cognition and reduced physical movements. Concentration and memory impairment, often characterized by word finding and name recall problems, is often reported. Some patients may experience emotional lability and mood changes. Medical side effects include increased risk of kidney stones and acute-angle closure glaucoma. Patients should report any change in visual acuity. Those with a history of kidney stones should be instructed to drink adequate amounts of fluid.

Topiramate is available as 25-, 50- 100-, and 200-mg tablets and as 15-, 25-, and 50-mg capsules.

Zonisamide. Zonisamide is a sulfonamide-related drug, similar in many ways to topiramate. Its exact mechanism of action is not known. Like topiramate, it can cause cognitive problems, but the incidence is lower than that with topiramate.

Zonisamide was assigned to pregnancy Category C in the former FDA classification system. Animal studies have revealed evidence of teratogenicity. Fetal abnormalities or embryo-fetal deaths have been reported in animal tests at zonisamide dosage and maternal plasma levels similar to, or lower than, human therapeutic levels. Therefore, the use of this drug in

human pregnancy may expose the fetus to significant risk.

The most common side effects include drowsiness, loss of appetite, dizziness, headache, nausea, and agitation or irritability. Zonisamide has also been associated with hypohidrosis. There is a 2 to 4 percent risk of kidney stones. Other drugs known to provoke stones, such as topiramate or acetazolamide (Diamox), should not be combined with zonisamide. Severe, but rare, adverse drug reactions include Stevens–Johnson syndrome, toxic epidermal necrolysis, and metabolic acidosis.

Typical dosing for weight loss has not been established. Generally, zonisamide is started at 100 mg at night for 2 weeks, and increased by 100 mg daily every 2 weeks to a target dose of 200 to 600 mg/day in one or two daily doses.

Metformin (Glucophage). Metformin is a medication for type 2 diabetes mellitus. Its actions include reduction of hepatic glucose production, reduced intestinal glucose absorption, increased insulin sensitivity, and improved peripheral glucose uptake and regulation. It does not increase insulin secretion.

When used as an adjunct to SGAs, it has consistently been shown to reduce body weight and waist circumference. Metformin probably has the best evidence of therapeutic benefit for the treatment of antipsychotic drug-induced metabolic syndrome. In several studies, metformin has been shown to attenuate or reverse some of the weight gain induced by antipsychotics. The degree of effect on body weight compares favorably with the effect of other treatment options that are approved for weight reduction. The weight loss effect of adjunctive metformin appears to be stronger in drug-naive patients treated with SGA medications. This effect is most evident for those being treated with clozapine (Clozaril) and olanzapine (Zyprexa). Based on the existing evidence, if weight gain occurs after SGA initiation, despite lifestyle intervention, metformin should be considered.

Common side effects include nausea, vomiting, abdominal pain, and loss of appetite. GI side effects can be mitigated by dividing the dose, taking the drug after meals, or using delayed-release formulations.

One serious treatment risk is that of lactic acidosis. This side effect is more common in those with reduced renal function than other patients. Although very rare (approximately 9 in 100,000 persons/yr), it has a 50 percent

mortality rate. Alcohol use, along with metformin, can increase the risk of acidosis. Renal function monitoring and alcohol avoidance are essential.

The weight loss effects of metformin are also evident in chronically ill patients with schizophrenia. Long-term use of metformin appears to be safe and effective.

There is no established dose range for metformin when used as an adjunct for weight loss. In most reports, the usual dose ranged from 500 to 2,000 mg/day. The maximum dose used in treating diabetes is 850 mg three times daily. Patients usually start with a low dose to see how the drug affects them.

Metformin is available in 500-, 850-, and 1,000-mg tablets, all now generic. Metformin SR (slow release) or XR (extended-release) is available in 500- and 750-mg strengths. These formulations are intended to reduce GI side effects and to increase patient compliance by reducing the pill burden.

Amphetamine. Amphetamine is a psychostimulant approved for the treatment of ADHD and narcolepsy. It has the effect of reducing appetite and has been used off label for that purpose for many years. Some of the drugs discussed above have amphetamine-like properties, which account for their effectiveness. Amphetamines and other psychostimulants are discussed earlier in the stimulant section of this chapter.

▲ 21.11 Nutritional Supplements and Related

NUTRITIONAL SUPPLEMENTS AND MEDICAL FOODS

Thousands of herbal and dietary supplements are being marketed today. Some are purported to have psychoactive properties. A number have even shown promise in the treatment of specific psychiatric symptoms. Although certain compounds may be beneficial, in many cases, the quantity and quality of data have been insufficient to make definitive conclusions. Nevertheless, some patients prefer to use these substances in place of, or in conjunction with, standard pharmaceutical treatments. If electing to use herbal drugs or nutritional supplements, bear in mind that their use may come at the expense

of proven interventions and that adverse effects are possible. Though more research is needed, information published to date is still of clinical interest in diagnosing and treating patients who may be taking dietary supplements.

Additionally, herbal and nonherbal supplements may augment or antagonize the actions of prescription and nonprescription drugs. Thus, clinicians need to remain informed on the latest research involving these substances. Because of the paucity of clinical trials, the clinician must be extraordinarily alert to the possibility of adverse effects as a result of drug–drug interactions, mainly if psychotropic agents are prescribed, because many phytomedicines have ingredients that produce physiologic changes in the body.

Nutritional Supplements

In the United States, the term *nutritional supplement* is used interchangeably with the term *dietary supplement*. The Dietary Supplement Health and Education Act (DHSEA) of 1994 defined nutritional supplements as items taken by mouth that contain a "dietary ingredient" meant to supplement the diet. These ingredients may include vitamins, minerals, herbs, botanicals, amino acids, and substances such as enzymes, tissues, glandulars, and metabolites. By law, such products must be labeled as supplements and may not be marketed as conventional food.

The DSHEA places dietary supplements in a select category, and therefore the regulations governing them are laxer than those for prescription and over-the-counter drugs. Unlike pharmaceutical drugs, nutritional supplements do not need the approval of the U.S. FDA, and the FDA does not evaluate their effectiveness. Because the FDA does not regulate dietary supplements, the contents and quality on store shelves vary dramatically. Contamination, mislabeling, and misidentification of herbs and supplements are problems. Table 21-62 provides a list of dietary supplements used in psychiatry.

Medical Foods

In recent years the FDA has introduced a new category of nutritional supplement called *medical foods*. According to the FDA, medical food, as defined in the Orphan Drug Act, is "a food which is formulated to be consumed or administered enterally under the supervision of a physician and

which is intended for the specific dietary management of a disease or condition for which distinctive nutritional requirements, based on recognized scientific principles, are established by medical evaluation."

A clear distinction can be made between the regulatory classifications of medical foods and dietary supplements. Medical foods must be shown, by medical evaluation, to meet the distinctive nutritional needs of a specific population of patients with a specific disease being targeted. Dietary supplements, on the other hand, are intended for normal, healthy adults and may not require proof of the efficacy of the finished product. Medical foods are distinguished from the broader category of foods for special dietary use and from foods that make health claims by the requirement that medical foods are to be used under medical supervision.

Medical foods do not have to undergo premarket approval by the FDA. However, medical food firms must comply with other requirements, such as acceptable manufacturing practices and registration of food facilities. Medical foods do have some additional regulations that dietary supplements do not because medical foods are intended to treat illnesses. For example, a compliance program requires annual inspections of all medical food manufacturers.

In summary, to be considered a medical food, a product must, at a minimum, meet the following criteria: (1) The product must be a food for oral or tube feeding; (2) the product must be labeled for the dietary management of a specific medical disorder, disease, or condition for which there are distinctive nutritional requirements; and (3) the product must be intended to be used under medical supervision. The most common medical foods with psychoactive claims are listed in Table 21-63.

Table 21-62
Dietary Supplements Used in Psychiatry

Name	Ingredients/What Is It?	Uses	Adverse Effects	Interactions	Dosage	Comments
Docosahexaenoic acid (DHA)	Omega-3 polyunsaturated fatty acid	ADD, dyslexia, cognitive impairment, dementia	Anticoagulant properties, mild GI distress	Warfarin	Varies with indication	Stop using prior to surgery
Choline	Choline	Fetal brain development, manic conditions, cognitive disorders, tardive dyskinesia, cancers	Restrict in patients with primary genetic trimethyluria, sweating, hypotension, depression	Methotrexate, works with B_6, B_{12}, and folic acid in metabolism of homocysteine	300–1,200 mg, doses >3 g associated with fishy body odor	Needed for structure and function of all cells
L-α-Glyceryl-phosphorylcholine (α-GPC)	Derived from soy lecithin	To increase growth hormone secretion, cognitive disorders	None known	None known	500 mg–1 g daily	Remains poorly understood
Phosphatidylcholine	Phospholipid that is part of cell membranes	Manic conditions, Alzheimer disease, and cognitive disorders, tardive dyskinesia	Diarrhea, steatorrhea in those with malabsorption, avoid with antiphospholipid antibody syndrome	None known	3–9 g/day in divided doses	Soybeans, sunflower, and rapeseed are major sources
Phosphatidylserine	Phospholipid isolated from soya and egg yolks	Cognitive impairment including Alzheimer disease, may reverse memory problems	Avoid with antiphospholipid antibody syndrome, GI side effects	None known	For soya-derived variety, 100 mg tid	Type derived from bovine brain carries hypothetical risk of bovine spongiform encephalopathy
Zinc	Metallic element	Immune impairment, wound healing, cognitive disorders, prevention of neural tube defects	GI distress, high doses can cause copper deficiency, immunosuppression	Bisphosphonates, quinolones, tetracycline, penicillamine, copper, cysteine-containing foods, caffeine, iron	Typical dose 15 mg/day, adverse effects >30 mg	Claims that zinc can prevent and treat the common cold are supported in some studies but not in others; more research needed
Acetyl-L-carnitine	Acetyl ester of L-carnitine	Neuroprotection, Alzheimer disease, Down syndrome, strokes, antiaging, depression in geriatric patients	Mild GI distress, seizures, increased agitation in some with Alzheimer disease	Nucleoside analogs, valproic acid, and pivalic acid–containing antibiotics	500 mg–2 g daily in divided doses	Found in small amounts in milk and meat
Huperzine A	Plant alkaloid derived from Chinese club moss	Alzheimer disease, age-related memory loss, inflammatory disorders	Seizures, arrhythmias, asthma, irritable bowel disease	Acetylcholinesterase inhibitors and cholinergic drugs	60 µg–200 µg/day	*Huperzia serrata* has been used in Chinese folk medicine for the treatment of fevers and inflammation
NADH (nicotinamide adenine dinucleotide)	Dinucleotide located in mitochondria and cytosol of cells	Parkinson disease, Alzheimer disease, chronic fatigue, CV disease	GI distress	None known	5 mg/day or 5 mg bid	Precursor of NADH is nicotinic acid
S-Adenosyl-L-methionine (SAMe)	Metabolite of essential amino acid L-methionine	Mood elevation, osteoarthritis	Hypomania, hyperactive muscle movement, caution in patients with cancer	None known	200–1,600 mg daily in divided doses	Several trials demonstrate some efficacy in the treatment of depression
5-Hydroxytryptophan (5-HTP)	Immediate precursor of serotonin	Depression, obesity, insomnia, fibromyalgia, headaches	Possible risk of serotonin syndrome in those with carcinoid tumors or taking MAOIs	SSRIs, MAOIs, methyldopa, St. John's wort, phenoxybenzamine, 5-HT antagonists, 5-HT receptor agonists	100 mg–2 g daily, safer with carbidopa	5-HTP along with carbidopa is used in Europe for the treatment of depression
Phenylalanine	Essential amino acid	Depression, analgesia, vitiligo	Contraindicated in patients with PKU, may exacerbate tardive dyskinesia or hypertension	MAOIs and neuroleptic drugs	Comes in 2 forms: 500 mg–1.5 g daily for DL-phenylalanine, 375 mg–2.25 g for D-phenylalanine	Found in vegetables, juices, yogurt, and miso
Myoinositol	Major nutritionally active form of inositol	Depression, panic attacks, OCD	Caution in patients with bipolar disorder, GI distress	Possible additive effects with SSRIs and 5-HT receptor agonists (sumatriptan)	12 g in divided doses for depression and panic attacks	Studies have *not* shown effectiveness in treating Alzheimer disease, autism, or schizophrenia
Vinpocetine	Semisynthetic derivative of vincamine (plant derivative)	Cerebral ischemic stroke, dementias	GI distress, dizziness, insomnia, dry mouth, tachycardia, hypotension, flushing	Warfarin	5–10 mg daily with food, no more than 20 mg/day	Used in Europe, Mexico, and Japan as pharmaceutical agent for treatment of cerebrovascular and cognitive disorders
Vitamin E family	Essential fat-soluble vitamin, family made of tocopherols and tocotrienols	Immune-enhancing, antioxidant, some cancers, protection in CV disease, neurologic disorders, diabetes, premenstrual syndrome	May increase bleeding in those with propensity to bleed, possible increased risk of hemorrhagic stroke, thrombophlebitis	Warfarin, antiplatelet drugs, neomycin, may be additive with statins	Depends on form: tocotrienols, 200–300 mg daily with food; tocopherols, 200 mg/day	Stop members of vitamin E family 1 mo prior to surgical procedures
Glycine	Amino acid	Schizophrenia, alleviating spasticity, and seizures	Avoid in those who are anuric or have hepatic failure	Additive with antispasmodics	1 g/day in divided doses for supplement; 40–90 g/day for schizophrenia	
Melatonin	Hormone of pineal gland	Insomnia, sleep disturbances, jet lag, cancer	May inhibit ovulation in 1-g doses, seizures, grogginess, depression, headache, amnesia	Aspirin, NSAIDs, β-blockers, INH, sedating drugs, corticosteroids, valerian, kava kava, 5-HTP, alcohol	0.3–3 mg hs for short periods of time	Melatonin sets the timing of circadian rhythms and regulates seasonal responses
Fish oil	Lipids found in fish	Bipolar disorder, lowering triglycerides, hypertension, decrease blood clotting	Caution in hemophiliacs, mild GI upset, "fishy"-smelling excretions	Coumadin, aspirin, NSAIDs, garlic, ginkgo	Varies depending on form and indication—usually about 3–5 g daily	Stop prior to any surgical procedure

ADD, attention-deficit disorder; CV, cardiovascular; OCD, obsessive-compulsive disorder; GI, gastrointestinal; hs, at night; MAOIs; monamine oxidase inhibitors; PKU, phenylketonuria; SSRIs, serotonin reuptake inhibitors; NSAIDs, nonsteroidal anti-inflammatory drugs; INH, isoniazid; 5-HTP, 5-hydroxytryptophan; tid, three times a day; bid, twice a day.
Table by Mercedes Blackstone, M.D.

Table 21-63

Some Common Medical Foods

Medical Food	Indication	Mechanism of Action
Caprylic-triglyceride (Axona)	Alzheimer disease	Increases plasma concentration of ketones as an alternative energy source in the brain; metabolized in the liver
L-methylfolate (Deplin)	Depression	Regulates synthesis of serotonin, norepinephrine, and dopamine; adjunctive to selective serotonin reuptake inhibitors (SSRIs); 15 mg/day
S-adenosyl-L-methionine (SAMe)	Depression	Naturally occurring molecule involved in synthesis of hormones and neurotransmitters including serotonin and norepinephrine
L-Tryptophan	Sleep disturbance Depression	Essential amino acid; precursor of serotonin; reduces sleep latency; usual dose 4–5 g/day
Omega-3 fatty acid	Depression Cognition	Eicosapentaenoic (EPA) and docosahexaenoic (DHA) acids; direct effect on lipid metabolism; used for augmentation of antidepressant drugs
Theramine (Sentra)	Sleep disturbances Cognitive enhancer	Cholinergic modulator; increases acetylcholine and glutamate
N-Acetylcysteine	Depression Obsessive-	Amino acid that attenuates glutamatergic

	compulsive disorder	neurotransmission; used to augment SSRIs
L-Tyrosine	Depression	Amino acid precursor to biogenic amines epinephrine and norepinephrine
Glycine	Depression	Amino acid that activates *N*-methyl-D-aspartate (NMDA) receptors; may facilitate excitatory transmission in the brain
Citicoline	Alzheimer disease Ischemic brain injury	Choline donor involved in synthesis of brain phosopholipids and acetylcholine; 300–1,000 mg/day; may improve memory
Acetyl L-carnitine (Alcar)	Alzheimer disease Memory loss	Antioxidant that may prevent oxidative damage in the brain

PHYTOMEDICINES

The term *phytomedicines* (from the Greek *phyto*, meaning "plant") refers to herb and plant preparations that are used or have been used for centuries for the treatment of a variety of medical conditions. Phytomedicines are categorized as dietary supplements, not drug products, and are therefore exempt from the regulations that govern prescription and over-the-counter medications. Manufacturers of phytomedicines are not required to provide the FDA with safety information before marketing a product or give the FDA postmarketing safety reports. Thousands of herbal drugs are being marketed today; the most common with psychoactive properties are listed in Table 21-64. Ingredients, when identified, are listed, as are indications, adverse events, dosages, and comments, particularly on interactions with commonly prescribed drugs used in psychiatry. For example, St. John's wort (*wort* is an old English word meaning "root or herb" and a familiar term for home

brewers), which is used to treat depression, decreases the effectiveness of certain psychotropic drugs such as amitriptyline (Elavil), alprazolam (Xanax), paroxetine (Paxil), and sertraline (Zoloft), among others. Kava kava, which is used to treat anxiety states, has been associated with liver toxicity.

Adverse Effects

Adverse effects are possible, and toxic interactions with other drugs may occur with all phytomedicines, dietary supplements, and medicinal foods. Adulteration is possible, especially with phytomedicines. There are few or no consistent standard preparations available for most herbs. The FDA does not test medical foods; however, strict voluntary compliance is required. Safety profiles and knowledge of adverse effects of most of these substances have not been studied rigorously, however. Because of the paucity of clinical trials, all of these agents should be avoided during pregnancy; some herbs may act as abortifacients, for example. Because most of these substances or their metabolites are secreted in breast milk, they are contraindicated during lactation.

Clinicians should always attempt to obtain a history of herbal use or the use of medical foods or nutritional supplements during the psychiatric evaluation.

It is important to be nonjudgmental in dealing with patients who use these substances. Many do so for various reasons: (1) as part of their cultural tradition, (2) because they mistrust physicians or are dissatisfied with conventional medicine, or (3) because they experience relief of symptoms with the particular substance. Because patients will be more cooperative with traditional psychiatric treatments if they are allowed to continue using their preparations, psychiatrists should keep an open mind and not attribute all effects to suggestion. If psychotropic agents are prescribed, the clinician must be extraordinarily alert to the possibility of adverse effects as a result of drug–drug interactions, because many of these compounds have ingredients that produce physiologic changes in the body.

Table 21-64
Phytomedicinals with Psychoactive Effects

Name	Ingredients	Use	Adverse Effects[a]	Interactions	Dosage[a]	Comments
Arctic weed, golden root	MAOI and β endorphin	Anxiolytic, mood enhancer, antidepressant	No side effect yet documented in trials		100 mg bid to 200 mg tid	Use caution with drugs that mimic MAOIs
Areca, areca nut, betel nut, *L. Areca catechu*	Arecoline, guvacoline	For alteration of consciousness to reduce pain and elevate mood	Parasympathomimetic overload: increased salivation, tremors, bradycardia, spasms, GI disturbances, ulcers of the mouth	Avoid with parasympathomimetic drugs; atropine-like compounds reduce effect	Undetermined; 8–10 g is toxic dose for humans	Used by chewing the nut; used in the past as a chewing balm for gum disease and as a vermifuge; long-term use may result in malignant tumors of the oral cavity
Ashwaganda	Also called Indian Winter Cherry or Indian Ginseng, native to India Flavonoids	Anticoxidant, may decrease anxiety levels Improved libido in men and women May lower levels of the stress hormone cortisol	Drowsiness and sleepiness	None	Dosage is 1 tablet twice daily before meals with a gradual increase to 4 tablets per day	None
Belladonna, *L. Atropa belladonna*, deadly nightshade	Atropine, scopolamine, flavonoids[b]	Anxiolytic	Tachycardia, arrhythmias, xerostomia, mydriasis, difficulties with micturition and constipation	Synergistic with anticholinergic drugs; avoid with TCAs, amantadine, and quinidine	0.05–0.10 mg a day; maximum single dose is 0.20 mg	Has a strong smell, tastes sharp and bitter, and is poisonous
Biota, *Platycladus orientalis*	Plant derivative	Used as a sedative. Other uses are to treat heart palpitations, panic, night sweats, and constipation. May be useful in ADHD	No known adverse effects	None	No clear established doses exist	None
Bitter orange flower, *citrus aurantium*	Flavonoids, limonene	Sedative, anxiolytic, hypnotic	Photosensitization	Undetermined	Tincture, 2–3 g/day; drug, 4–6 g/day; extract, 1–2 g/day	Contradictory evidence; some refer to it as a gastric stimulant
Black cohosh, *L. Cimicifuga racemosa*	Triterpenes, isoferulic acid	For PMS, menopausal symptoms, dysmenorrhea	Weight gain, GI disturbances	Possible adverse interaction with male or female hormones	1–2 g/day; over 5 g can cause vomiting, headache, dizziness, cardiovascular collapse	Estrogen-like effects questionable because root may act as an estrogen-receptor blocker
Black haw, cramp bark, *L. Viburnum prunifolium*	Scopoletin, flavonoids, caffeic acids, triterpenes	Sedative, antispasmodic action on uterus; for dysmenorrhea	Undetermined	Anticoagulant-enhanced effects	1–3 g/day	Insufficient data
California poppy, *L. Eschscholtzia californica*	Isoquinoline alkaloids, cyanogenic glycosides	Sedative, hypnotic, anxiolytic; for depression	Lethargy	Combination of California poppy, valerian, St. John's wort, and passion flowers can result in agitation	2 g/day	Clinical or experimental documentation of effects is unavailable
Casein	Casein peptides	Used as antistress agent; May improve sleep	Usually consumed though milk products. May interact with antihypertensive medicine and lower the blood pressure. May cause drowsiness and should be avoided when taking alcohol or benzodiazepines	None	One to two tablets once or twice daily	
Catnip, *L. Nepeta cataria*	Valeric acid	Sedative, antispasmodic; for migraine	Headache, malaise, nausea, hallucinogenic effects	Undetermined	Undetermined	Delirium produced in children
Chamomile, *L. Matricaria chamomilla*	Flavonoids	Sedative, anxiolytic	Allergic reaction	Undetermined	2–4 g/day	May be GABAergic
Coastal water hyssop		Anxiolytic, sedative, epilepsy, asthma	Mild GI discomfort	May stimulate	300–450 mg qid	Insufficient data
Cordyceps sinensis	A genus of fungi that includes about 400 described species, found primarily in the high altitudes of the Tibetan plateau in China; Antioxidant	Has been used for weakness, fatigue, to improve sexual drive in the elderly	GI discomfort, dry mouth, and nausea	None	Dosage in ranges of 3–6 g daily	None
Corydalis, *L. Corydalis cava*	Isoquinoline alkaloids	Sedative, antidepressant; for mild depression	Hallucination, lethargy	Undetermined	Undetermined	Clonic spasms and muscular tremor with overdose
Cyclamen, *L. Cyclamen europaeum*	Triterpene	Anxiolytic; for menstrual complaints	Small doses (e.g., 300 mg) can lead to nausea, vomiting, and diarrhea	Undetermined	Undetermined	High doses can lead to respiratory collapse
Echinacea, *L. Echinacea purpurea*	Flavonoids, polysaccharides, caffeic acid derivatives, alkamides	Stimulates immune system; for lethargy, malaise, respiratory infections and lower UTIs	Allergic reaction, fever, nausea, vomiting	Undetermined	1–3 g/day	Use in HIV and AIDS patients is controversial; may not be effective in coryza
Ephedra, ma-huang *L. Ephedra sinica*	Ephedrine, pseudoephedrine	Stimulant; for lethargy, malaise, diseases of respiratory tract	Sympathomimetic overload: arrhythmias, increased BP, headache, irritability, nausea, vomiting	Synergistic with sympathomimetics, serotonergic agents; avoid with MAOIs	1–2 g/day	Tachyphylaxis and dependence can occur (taken off market)
Ginkgo, *L. Ginkgo biloba*	Flavonoids, ginkgolide A, B	Symptomatic relief of delirium, dementia; improves concentration and memory deficits; possible antidote to SSRI-induced sexual dysfunction	Allergic skin reactions, GI upset, muscle spasms, headache	Anticoagulant: use with caution because of its inhibitory effect on PAF; increased bleeding possible	120–240 mg/day	Studies indicate improved cognition in persons with Alzheimer disease after 4–5 wk of use, possibly because of increased blood flow

Ginseng, *L. Panax ginseng*	Triterpenes, ginsenosides	Stimulant; for fatigue, elevation of mood, immune system	Insomnia, hypertonia, and edema (called ginseng abuse syndrome)	Not to be used with sedatives, hypnotic agents, MAOIs, antidiabetic agents, or steroids	1–2 g/day	Several varieties exist; Korean (most highly valued), Chinese, Japanese, American (*Panax quinquefolius*)
Heather, *L. Calluna vulgaris*	Flavonoids, triterpenes	Anxiolytic, hypnotic	Undetermined	Undetermined	Undetermined	Efficacy for claimed uses is not documented
Holy Basil formula, *Ocimum tenuiflorum*	*Ocimum tenuiflorum*, an aromatic plant native to the tropics, part of the *Lamiaceae* family Flavonoids	Used to combat stress, also used for common colds, headaches, stomach disorders, inflammation, heart disease	No data exist regarding the long-term effects. May prolong clotting time, increase the risk of bleeding during surgery, and lower blood sugar	None	Dosage depends on the formulation type, recommended dose is 2 softgel capsules taken with 8 oz water daily	None
Hops, *L. Humulus lupulus*	Humulone, lupulone, flavonoids	Sedative, anxiolytic, hypnotic; for mood disturbances, restlessness	Contraindicated in patients with estrogen-dependent tumors (breast, uterine, cervical)	Hyperthermia effects with phenothiazine antipsychotics and with CNS depressants	0.5 g/day	May decrease plasma levels of drugs metabolized by CYP450 system
Horehound, *L. Ballota nigra*	Diterpenes, tannins	Sedative	Arrhythmias, diarrhea, hypoglycemia, possible spontaneous abortions	May enhance serotonergic drug effects, may augment hypoglycemic effects of drugs	1–4 g/day	May cause abortion
Jambolan, *L. Syzygium cumini*	Oleic acid, myristic acid, palmitic and linoleic acids, tannins	Anxiolytic, antidepressant	Undetermined	Undetermined	1–2 g/day	In folk medicine, a single dose is 30 seeds (1.9 g) of powder
Kanna, *Sceletium tortuosum*	Alkaloid, mesembrine	Anxiolytic, mood enhancer, empathogen, COPD treatment	Sedation, vivid dreams, headache	Potentiates cannabis, PDE inhibitor	50–100 mg	Insufficient data
Kava kava, *L. Piperis methysticum*	Kava lactones, kava pyrone	Sedative, hypnotic, antispasmodic	Lethargy, impaired cognition, dermatitis with long-term usage, liver toxicity	Synergistic with anxiolytics, alcohol; avoid with levodopa and dopaminergic agents	600–800 mg/day	May be GABAergic; contraindicated in patients with endogenous depression; may increase the danger of suicide
Kratom, *Mitragyna speciosa*	Alkaloid	Stimulant and depressant	Priapism, testicular enlargement, withdrawal, depression, fatigue, insomnia	Structurally similar to yohimbine	Undetermined	Chewed, extracted into water, tar formulations
Lavender, *L. Lavandula angustifolia*	Hydroxycoumarin, tannins, caffeic acid	Sedative, hypnotic	Headache, nausea, confusion	Synergistic with other sedatives	3–5 g/day	May cause death in overdose
Lemon balm, sweet Mary, *L. Melissa officinalis*	Flavonoids, caffeic acid, triterpenes	Hypnotic, anxiolytic, sedative	Undetermined	Potentiates CNS depressant; adverse reaction with thyroid hormone	8–10 g/day	Insufficient data
L-methylfolate	Folate is a B vitamin found in some foods, needed to form healthy cells, especially red blood cells. L-methylfolate and levomefolate are names for the active form of folic acid	Adjunctive L is used for major depression, not an antidepressant when used alone. Folate and L- methylfolate are also used to treat folic acid deficiency in pregnancy, to prevent spinal cord birth defects	GI side effects reported	None	15 mg once a day by mouth with or without food	Considered a "medical food" by the FDA and only available by prescription. Safe to take during pregnancy when used as directed
Mistletoe, *L. Viscum album*	Flavonoids, triterpenes, lectins, polypeptides	Anxiolytic; for mental and physical exhaustion	Berries said to have emetic and laxative effects	Contraindicated in patients with chronic infections (e.g., tuberculosis)	10 per day	Berries have caused death in children
Mugwort, *L. Artemisia vulgaris*	Sesquiterpene lactones, flavonoids	Sedative, antidepressant, anxiolytic	Anaphylaxis, contact dermatitis, may cause hallucinations	Potentiates anticoagulants	5–15 g/day	May stimulate uterine contractions, can induce abortion
N-acetylcysteine (NAC)	Amino acid	Used as an antidote for acetaminophen overdose, treatment of trichotillomania	Rash, cramps, and angioedema may occur	Activated charcoal, ampicillin, carbamazepine, cloxacillin, oxacillin, nitroglycerin, and penicillin G	1,200–2,400 mg/day	Acts as an antioxidant and a glutamate modulating agent. When used as an antidote for acetaminophen overdose, the dose is 20–40 times higher than those used in OCD trials. It has not been shown to be effective in treating schizophrenia
Nux vomica, *L. Strychnos nux vomica*, poison nut	Indole alkaloids: strychnine and brucine, polysaccharides	Antidepressant; for migraine, menopausal symptoms	Convulsions, liver damage, death; severely toxic because of strychnine	Undetermined	0.02–0.05 g/day	Symptoms of poisoning can occur after ingestion of one bean; lethal dose is 1–2 g
Oats, *L. Avena sativa*	Flavonoids, oligo and polysaccharides	Anxiolytic, hypnotic; for stress, insomnia, opium, and tobacco withdrawal	Bowel obstruction or other bowel dysmotility syndromes, flatulence	Undetermined	3 g/day	Oats have sometimes been contaminated with aflatoxin, a fungal toxin linked with some cancers

Omega-3 fatty acid	Comes in three forms, eicosapentaenoic acid (EPA), docosahexaenoic acid (DHA), and alpha-linolenic acid (LNA)	Used as a supplement in the treatment of heart disease, high cholesterol, high blood pressure. May also be helpful in treatment of depression, bipolar disorder, schizophrenia, and ADHD. May reduce the risk of ulcers when used in conjunction with NSAID pain relievers	Can cause gas, bloating, belching, and diarrhea	May increase effectiveness of blood thinners, may increase fasting blood sugar levels when used with diabetes medications such as insulin and metformin	Doses vary from 1 to 4 g/day	Can be contaminated with mercury and PCBs
Passion flower, *L. Passiflora incarnata*	Flavonoids, cyanogenic glycosides	Anxiolytic, sedative, hypnotic	Cognitive impairment	Undetermined	4–8 g/day	Overdose causes depression
Phosphatidylserine and Phosphatidylcholine	Phospholipids	Used for Alzheimer disease, age-related decline in mental function, improving thinking skills in young people, ADHD, depression, preventing exercise-induced stress, and improving athletic performance	Insomnia and stomach upset	None	100 mg three times daily	None
Polygala	Polygala is a genus of about 500 species of flowering plants belonging to the family *Polygalaceae*, commonly known as milkwort or snakeroot	Used for insomnia, forgetfulness, mental confusion, palpitation, seizures, anxiety, and listlessness	Contraindicated in patients who have ulcers or gastritis, should not be used long term	None	Dosage of polygala is 1.5–3 g of dried root, 1.5–3 g of a fluid extract, or 2.5–7.5 g of a tincture. A polygala tea can also be made, with a maximum of three cups per day	None
Rehmannia	Iridoid glycosides	Stimulates the release of cortisol. Used in lupus, rheumatoid arthritis (RA), fibromyalgia, and multiple sclerosis. May improve asthma and urticaria. Used to treat menopause, hair loss, and impotence	Loose bowel movements, bloating, nausea, and abdominal cramps	None	Exact dosage unknown	None
Rhodiola rosea	Potentiator, monoterpene alcohols, flavonoids					
S-adenosyl-L-methionine (SAMe)	S-adenosyl-L-methionine	Used for arthritis and fibromyalgia, may be effective as an augmentation strategy for SSRI in depression	GI symptoms, anxiety, nightmares, insomnia, and worsening of Parkinson symptoms	Use with SSRIs or SNRIs may result in serotonin syndrome. Interacts with levodopa, meperidine, pentazocine, and tramadol	400–1,600 mg/day	A naturally occurring molecule made from the amino acid methionine and ATP, serves as a methyl donor in human cellular metabolism
Scarlet Pimpernel, *L. Anagallis arvensis*	Flavonoids, triterpenes, cucurbitacins, caffeic acids	Antidepressant	Overdose or long-term doses may lead to gastroenteritis and nephritis	Undetermined	1.8 g of powder four times a day	Flowers are poisonous
Skullcap, *L. Scutellaria latwiflora*	Flavonoid, monoterpenes	Amiolytic, sedative, hypnotic	Cognitive impairment, hepatotoxicity	Disulfiram-like reaction may occur if used with alcohol	1–2 g/day	Little information exists to support the use of this herb in humans
St. John's wort, *L. Hypericum perforatum*	Hypericin, flavonoids, xanthones	Antidepressant, sedative, anxiolytic	Headaches, photosensitivity (may be severe), constipation	Report of manic reaction when used with sertraline (Zoloft); do not combine with SSRIs or MAOIs: possible serotonin syndrome; do not use with alcohol, opioids	100–950 mg/day	Mixed results on effectiveness for depression; may act as MAOI or SSRI; 4- to 6-wk trial for mild depressive moods; if no apparent improvement, another therapy should be tried
Strawberry leaf, *L. Fragaria vesca*	Flavonoids, tannins	Anxiolytic	Contraindicated with strawberry allergy	Undetermined	1 g/day	Little information exists to support the use of this herb in humans
Tarragon, *L. Artemisia dracunculus*	Flavonoids, hydroxycoumarins	Hypnotic, appetite stimulant	Undetermined	Undetermined	Undetermined	Little information exists to support the use of this herb in humans
Valerian, *L. Valeriana officinalis*	Valepotriates, valerenic acid, caffeic acid	Sedative, muscle relaxant, hypnotic	Cognitive and motor impairment, GI upset, hepatotoxicity; long-term use: contact allergy, headache, restlessness, insomnia, mydriasis, cardiac dysfunction	Avoid concomitant use with alcohol or CNS depressants	1–2 g/day	May be chemically unstable
Wild lettuce, *Lactuca Virosa*	Flavonoids, coumarins, lactones	Sedative, anesthetic, galactagogue	Tachycardia, tachypnea, visual disturbance, diaphoresis		Undetermined	Bitter taste, added to salad or drinks, active compound closely resembles opium
Winter cherry, *withania somnifera*	Alkaloids, steroidal lactones	Sedative, treatment for arthritis, possible anticarcinogenic	Thyrotoxicosis, unfavorable effects on heart and adrenal gland		Undetermined	Smoke inhaled

ADHD, attention-deficit/hyperactivity disorder; AIDS, acquired immunodeficiency syndrome; ATP, adenosine triphosphate; bid, twice a day; BP, blood pressure; CNS, central nervous system; COPD, chronic obstructive pulmonary disease; FDA, U.S. Food and Drug Administration; GABA, γ-aminobutyric acid; GI, gastrointestinal; MAOI, monoamine oxidase inhibitor; PAF, platelet-activating factor; PCB, polychlorinated biphenyl; PDE, phosphodiesterase; PMS, premenstrual syndrome; NSAID, nonsteroidal anti-inflammatory drug; OCD, obsessive-compulsive disorder; qid, four times a day; SNRI, serotonin and norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant; tid, three times a day; UTI, urinary tract infection.

[a]There are no reliable, consistent, or valid data exist on dosages or adverse effects of most phytomedicinals.

[b]Flavonoids are common to many herbs. They are plant byproducts that act as antioxidants (i.e., agents that prevent the deterioration of material such as deoxyribonucleic acid [DNA] via oxidation).

22 Other Somatic Therapies

ELECTROCONVULSIVE THERAPY

Convulsive therapies for major psychiatric illnesses predate the modern therapeutic era, with the use of camphor reported as early as the 16th century and the existence of several accounts of camphor convulsive therapies from the late 1700s to the mid-1800s.

Unaware of the history of camphor convulsive therapy, the Hungarian neuropsychiatrist Ladislas von Meduna observed that the brains of people with epilepsy had more glial cells than other brains. In contrast, the brains of patients with schizophrenia had fewer glial cells, and von Meduna hypothesized that there might be a biologic antagonism between convulsions and schizophrenia. Following animal experimentation, camphor was (again) selected as the appropriate agent to use for the therapeutic induction of seizures. In 1934, the first catatonic psychotic patient was successfully treated using intramuscular injections of camphor in oil to produce therapeutic seizures. Later, other chemicals were used, including pentylenetetrazol. Insulin coma was also used in the 1940s and 1950s, which also sometimes induced seizures. Lucio Bini and Ugo Cerletti were interested in the use of electricity to induce seizures, and, after a series of animal experiments and observation of the use of electricity commercially, they were able to safely apply current across the heads of animals for this purpose. In 1938, the first electroconvulsive treatment was administered to a delusional and incoherent patient, who improved with one treatment and remitted after 11 treatments. Electrical induction of convulsive therapy could be made more reliable and shorter-acting than chemically induced convulsive therapies, and, by the early 1940s, it had replaced them. In 1940, the first use of electroconvulsive

therapy (ECT) occurred in the United States.

Explorations of nondominant electrode placement and alternative, more efficient waveforms were then undertaken to reduce the retrograde memory problems that persisted for some patients after the initial recovery period post-ECT. The practice of ECT also benefited from the introduction of controlled trials methodology, which demonstrated its safety and efficacy, and from refinements made in diagnostic systems and the process of informed consent. In the 1980s and 1990s, efforts to ensure uniformly high standards of practice were underway with the publication of recommendations for treatment delivery, education, and training by professional organizations in the United States, England, Scandinavia, and Canada, among others.

With the widespread use of pharmacologic agents as first-line treatments for major psychiatric disorders, ECT is now more commonly used for patients with resistance to those treatments, except in the case of life-threatening illness due to inanition, severe suicidal symptoms, or catatonia. Although subconvulsive stimulation was ineffective and a seizure is necessary, it is now known that there is a dose–response relationship with right unilateral ECT and bilateral ECT is likely to be ineffective with ultrabrief pulse widths. Work continues to explore the underlying mechanisms and biologic characteristics of effective ECT treatments, with interest in having the treatment focus on appropriate neural networks with a more efficient stimulus as a method of reducing cognitive side effects. With the growing understanding that depression is a chronic disease for many patients, more emphasis has been placed on continuation and maintenance treatments following an acute course of ECT. Utilization of ECT has diminished since the middle of the 20th century, but because ECT remains the most effective treatment for major depression and is a rapidly effective treatment for life-threatening psychiatric conditions, ECT, unlike its contemporaneous somatic therapies, such as insulin coma, remains in the active treatment portfolio of modern therapeutics. Its use has shifted from public to private institutions, and it is estimated that approximately 100,000 patients have received ECT annually over the past few decades in the United States (Table 22-1).

The Nobel Laureate Paul Greengard has suggested that the term *electrocortical therapy* might be used to replace the current term

electroconvulsive therapy (ECT). Greengard has acknowledged that if the mechanism of action of ECT, as yet unknown, turns out to be subcortical, then the term might have limited use. Until that time, however, the authors of this text think Greengard's suggestion deserves consideration. It would help diminish the fear associated with the word convulsion and help destigmatize a very effective treatment method.

Electrophysiology in Electroconvulsive Therapy

Neurons maintain a resting potential across the plasma membrane and may propagate an action potential, which is a transient reversal of the membrane potential. Regular brain activity is desynchronized; that is, neurons fire action potentials asynchronously. A convulsion, or seizure, occurs when a large percentage of neurons fire in unison. Such rhythmical changes in the extracellular potential entrain neighboring neurons, propagate the seizure activity across the cortex and into deeper structures, and eventually engulf the entire brain in high-voltage synchronous neuronal firing. Cellular mechanisms work to contain the seizure activity and to maintain cellular homeostasis, and the seizure eventually ends. In epilepsy, any of possibly several hundred genetic defects can alter the balance in favor of unrestrained activity. In ECT, seizures are triggered in normal neurons by application through the scalp of pulses of current, under conditions that are carefully controlled to create a seizure of a particular duration over the entire brain.

Ohm's law can describe the qualities of the electricity used in ECT: $E = IR$, or $I = E/R$, in which E is voltage, I is current, and R is resistance. The intensity or dose of electricity in ECT is measured in terms of charge (milliampere-seconds or millicoulombs) or energy (watt-seconds or joules). Resistance is synonymous with impedance, and, in the case of ECT, both the electrode's contact with the body and the nature of the bodily tissues are the significant determinants of resistance. The skull has a high impedance; the brain has a low impedance. Because scalp tissues are much better conductors of electricity than bone, only about 20 percent of the applied charge enters the skull to excite neurons. The ECT machines that are now widely used can be adjusted to administer the electricity under conditions of constant current, voltage, or energy.

Table 22-1
Milestones in the History of Convulsive Therapy

1500s	Paracelsus induces seizures by administering camphor (by mouth) to treat psychiatric illness.
1785	First published report of the use of seizure induction to treat mania, again using camphor.
1934	Ladislas von Meduna begins the modern era of convulsive therapy using intramuscular injection of camphor for catatonic schizophrenia. Camphor is soon replaced with pentylenetetrazol.
1938	Ugo Cerletti and Lucio Bini conduct the first electrical induction of a series of seizures in a catatonic patient and produce a successful treatment response
1940s	ECT is introduced to the United States.
	Curare developed for use as a muscle relaxant at ECT.
1951	Introduction of succinylcholine.
1958	First controlled study of unilateral ECT.
1960	Attenuation of seizure expression with an anticonvulsant agent (lidocaine) reduces the efficacy of ECT. Subconvulsive treatment produces only weak clinical responses; the hypothesis that seizure activity is necessary and sufficient for efficacy is upheld.
1960s	Randomized clinical trials of the efficacy of ECT versus medications in the treatment of depression yield response rates that are significantly higher with ECT.
	Comparisons of neuroleptics and ECT show that neuroleptic medication is superior for acute treatment, although ECT may be more effective in the long term.
1970	The most common electrode positioning for right unilateral

	ECT developed.
1976	A constant current, brief pulse ECT device, the prototype for modern devices, is developed.
1978	The American Psychiatric Association publishes the first Task Force Report on ECT with the aim of establishing standards for consent and the technical and clinical aspects of the conduct of ECT.
Late 1970s–early 1980s	Randomized, controlled trials demonstrate that ECT is more effective than sham treatment for major depression.
1985	The National Institutes of Health and National Institute of Mental Health Consensus Conference on ECT endorse a role for the use of ECT and advocate research and national standards of practice.
1987	The belief that the seizure in itself is sufficient for clinical response is challenged by H. A. Sackheim and collaborators, who report that the combination of dosage just above seizure threshold and right unilateral electrode placement, while producing a seizure of sufficient duration, is ineffective.
1988	Randomized, controlled clinical trials of ECT versus lithium demonstrate them to be equally effective in mania.
2000	In controlled trials, the dose–response relationship for right unilateral ECT is validated; high-dose right unilateral and bilateral ECT show equal response rates in major depression, but right unilateral electrode placement is associated with fewer adverse cognitive effects.
	Convulsive treatment is induced with magnetic stimulation by S. H. Lisanby and colleagues.

2001	The largest modern controlled trial of relapse prevention post-ECT with continuation pharmacotherapy demonstrates a significantly better outcome for combined treatment with a tricyclic antidepressant (nortriptyline) plus lithium compared with nortriptyline alone or placebo during the first 6 months post-ECT.

ECT, electroconvulsive therapy.

Mechanism of Action

The induction of a bilateral generalized seizure is necessary for both the beneficial and adverse effects of ECT. Although a seizure superficially seems as though it is an all-or-none event, some data indicate that not all generalized seizures involve all the neurons in deep brain structures (e.g., the basal ganglia and the thalamus); recruitment of these deep neurons may be necessary for full therapeutic benefit. After the generalized seizure, the electroencephalogram (EEG) shows about 60 to 90 seconds of postictal suppression. This period is followed by high-voltage delta and theta waves, with a return to preseizure activity in about 30 minutes. During a series of ECT treatments, the interictal EEG is generally slower and of greater amplitude than usual, but the EEG returns to pretreatment appearance 1 month to 1 year after the end of the course of treatment.

Positron emission tomography (PET) studies of both cerebral blood flow and glucose use have shown that during seizures, cerebral blood flow, use of glucose and oxygen, and permeability of the blood–brain barrier increase. After the seizure, blood flow and glucose metabolism are decreased, perhaps most markedly in the frontal lobes. Some research indicates that the degree of decrease in cerebral metabolism is correlated with therapeutic response.

Seizure foci in idiopathic epilepsy are hypometabolic during interictal periods; ECT itself acts as an anticonvulsant because its administration is associated with an increase in the seizure threshold as treatment progresses. Recent data suggest that for 1 to 2 months following a session of ECT, EEGs record a massive increase in slow-wave activity located over the prefrontal cortex in patients who responded well to the ECT. High-intensity, bilateral stimulation produced the best response; low-intensity, unilateral stimulation,

the weakest. These data are of unclear significance, however, because the specific EEG correlate disappears 2 months after ECT, whereas the clinical benefit persists.

ECT affects the cellular mechanisms of memory and mood regulation and raises the seizure threshold. The latter effect may be blocked by the opioid antagonist naloxone.

Neurochemical research into the mechanisms of action of ECT has focused on changes in neurotransmitter receptors and, recently, changes in second-messenger systems. Virtually every neurotransmitter system is affected by ECT, but a series of ECT sessions results in the downregulation of postsynaptic β-adrenergic receptors, the same receptor change observed with virtually all antidepressant treatments. The effects of ECT on serotonergic neurons remain controversial. Various research studies have reported an increase in postsynaptic serotonin receptors, no change in serotonin receptors, and a change in the presynaptic regulation of serotonin release. ECT has also been reported to effect changes in the muscarinic, cholinergic, and dopaminergic neuronal systems. In second-messenger systems, ECT has been reported to affect the coupling of G-proteins to receptors, the activity of adenylyl cyclase and phospholipase C, and the regulation of calcium entry into neurons.

Recently, there has been increased interest in structural changes in the brain associated with psychiatric syndromes and response to treatment. This interest has been particularly so for microscopic changes associated with electroconvulsive stimulation, as well as antidepressants and other medications. In animals, mostly rodents, synaptic plasticity in the hippocampus, including mossy fiber sprouting, alterations in cytoskeletal structure, increased connectivity in perforant pathways, promotion of neurogenesis, and suppression of apoptosis have been observed. We also see many of these structural events, although less often, with antidepressant medications such as fluoxetine. These reports have also galvanized controversy over various aspects of the technical validity of the observations. It is unknown whether such changes occur clinically and, if they do, what significance to efficacy and cognitive side effects might be discovered.

Indications

Major Depressive Disorder. The most common indication for ECT is major depressive disorder, for which ECT is the fastest and most effective available therapy. ECT should be considered for use in patients who have failed medication trials, have not tolerated medications, have severe or psychotic symptoms, are acutely suicidal or homicidal, or have marked symptoms of agitation or stupor. Controlled studies have shown that up to 70 percent of patients who fail to respond to antidepressant medications may respond positively to ECT. Table 22-2 presents the indications for the use of ECT.

ECT is effective for depression in both major depressive disorder and bipolar I disorder. Delusional or psychotic depression has long been considered exceptionally responsive to ECT, but recent studies have indicated that major depressive episodes with psychotic features are no more responsive to ECT than nonpsychotic depressive disorders. Nevertheless, because major depressive episodes with psychotic features respond poorly to antidepressant pharmacotherapy alone, ECT should be considered much more often as the first-line treatment for patients with the disorder. Major depressive disorder with melancholic features (e.g., markedly severe symptoms, psychomotor retardation, early morning awakening, diurnal variation, decreased appetite and weight, and agitation) is considered likely to respond to ECT. ECT is particularly indicated for persons who are severely depressed, who have psychotic symptoms, who show suicidal intent, or who refuse to eat. Depressed patients less likely to respond to ECT include those with somatic symptom disorder. Elderly patients tend to respond to ECT more slowly than do young patients. ECT is a treatment for major depressive episode and does not provide prophylaxis unless it is administered on a long-term maintenance basis.

Table 22-2
Indications for the Use of Electroconvulsive Therapy

Major diagnostic indications
Major depressive disorder
Mania, including mixed episodes
Schizophrenia with acute exacerbation or catatonic subtype

Schizoaffective disorder

Other diagnostic indications

Parkinson disease

Neuroleptic malignant disorder

Clinical indications

Primary use

Rapid definitive response required on medical or psychiatric grounds

Risks of alternative treatments outweigh benefits

Past history of poor response to medications or good response to ECT

Patient preference

Secondary use

Failure to respond to pharmacotherapy in the current episode

Intolerance of pharmacotherapy in the current episode

Rapid definitive response necessitated by deterioration of the patient's condition

ECT, electroconvulsive therapy.

Manic Episodes. ECT is at least equal to lithium for the treatment of acute manic episodes. The pharmacologic treatment of manic episodes, however, is so effective in the short term and for prophylaxis that the use of ECT to treat manic episodes is generally limited to situations with specific contraindications to all available pharmacologic approaches. The relative rapidity of the ECT response indicates its usefulness for patients whose manic behavior has produced dangerous levels of exhaustion. ECT should not be used for a patient who is receiving lithium because lithium can lower the seizure threshold and may be more likely to predispose the patient to delirium.

Schizophrenia. Although an effective treatment for the symptoms of acute schizophrenia, ECT is not for those of chronic schizophrenia. Patients with schizophrenia who have marked positive symptoms, catatonia, or affective symptoms are considered most likely to respond to ECT. In such patients, the efficacy of ECT is about equal to that of antipsychotics, but improvement

may occur faster.

Other Indications. Small studies have found ECT effective in the treatment of catatonia, a symptom associated with mood disorders, schizophrenia, and medical and neurologic disorders. ECT is also reportedly useful to treat episodic psychoses, atypical psychoses, obsessive-compulsive disorder (OCD), and delirium and such medical conditions as a neuroleptic malignant syndrome, hypopituitarism, intractable seizure disorders, and the on–off phenomenon of Parkinson disease. ECT may also be the treatment of choice for depressed, suicidal pregnant women who cannot take medication. It also may be the treatment of choice for geriatric and medically ill patients who cannot take antidepressant drugs safely. It may also be appropriate for severely depressed and suicidal children and adolescents who may be less likely to respond to antidepressant drugs compared with adults. ECT is not effective in somatic symptom disorder (unless accompanied by depression), personality disorders, or anxiety disorders.

Clinical Guidelines

Patients and their families are often apprehensive about ECT; therefore, clinicians must explain both beneficial and adverse effects and alternative treatment approaches. The informed-consent process should be documented in the patients' medical records and should include a discussion of the disorder, its natural course, and the option of receiving no treatment. Printed literature and videotapes about ECT may be useful in attempting to obtain genuinely informed consent. The use of involuntary ECT is rare today and should be reserved for patients who urgently need treatment and who have a legally appointed guardian who has agreed to its use. Clinicians must know local, state, and federal laws about the use of ECT.

Pretreatment Evaluation. Pretreatment evaluation should include standard physical, neurologic, and preanesthesia examinations and complete medical history. Laboratory evaluations should include blood and urine chemistries, a chest x-ray, and an electrocardiogram (ECG). A dental examination to assess the state of patients' dentition is advisable for elderly patients and patients who have had inadequate dental care. An x-ray of the spine is needed if other evidence of a spinal disorder is seen. Computed

tomography (CT) or magnetic resonance imaging (MRI) should be performed if a clinician suspects the presence of a seizure disorder or a space-occupying lesion. Practitioners of ECT no longer consider even a space-occupying lesion to be an absolute contraindication to ECT, but with such patients, the procedure should be performed only by experts.

CONCOMITANT MEDICATIONS. Patients' ongoing medications should be assessed for possible interactions with the induction of a seizure, for effects (both positive and negative) on the seizure threshold, and drug interactions with the medications used during ECT. Most antidepressants except bupropion, monoamine oxidase inhibitors, and antipsychotics are generally acceptable. Benzodiazepines should be withdrawn because of their anticonvulsant activity; lithium should be withdrawn because it can result in increased postictal delirium and can prolong seizure activity; clozapine and bupropion should be withdrawn because they are associated with the development of late-appearing seizures. Lidocaine should not be administered during ECT because it markedly increases the seizure threshold; theophylline is contraindicated because it increases the duration of seizures. Reserpine is also contraindicated because it is associated with the further compromise of the respiratory and cardiovascular systems during ECT.

Premedications, Anesthetics, and Muscle Relaxants. Patients should not be given anything orally for 6 hours before treatment. Just before the procedure, the patient's mouth should be checked for dentures and other foreign objects, and an intravenous (IV) line should be established. A bite block is inserted in the mouth just before the treatment is administered to protect the patient's teeth and tongue during the seizure. Except for the brief interval of electrical stimulation, 100 percent oxygen is administered at a rate of 5 L a minute during the procedure until spontaneous respiration returns. Emergency equipment for establishing an airway should be immediately available in case it is needed.

MUSCARINIC ANTICHOLINERGIC DRUGS. Muscarinic anticholinergic drugs are administered before ECT to minimize oral and respiratory secretions and to block bradycardias and asystoles unless the resting heart rate is above 90 beats a minute. Some ECT centers have stopped the routine use of

anticholinergics as premedications, although their use is still indicated for patients taking β-adrenergic receptor antagonists and those with ventricular ectopic beats. The most commonly used drug is atropine, which can be administered 0.3 to 0.6 mg intramuscularly (IM) or subcutaneously (SC) 30 to 60 minutes before the anesthetic or 0.4 to 1.0 mg IV 2 or 3 minutes before the anesthetic. An option is to use glycopyrrolate (0.2 to 0.4 mg IM, IV, or SC), which is less likely to cross the blood–brain barrier and less likely to cause cognitive dysfunction and nausea, although it is thought to have less cardiovascular protective activity than does atropine.

ANESTHESIA. The administration of ECT requires general anesthesia and oxygenation. The depth of anesthesia should be as light as possible, not only to minimize adverse effects but also to avoid elevating the seizure threshold associated with many anesthetics. Methohexital (0.75 to 1.0 mg/kg IV bolus) is the most commonly used anesthetic because of its shorter duration of action and lower association with postictal arrhythmias than thiopental (usual dose 2 to 3 mg/kg IV). However, this difference in cardiac effects is not universally accepted. Four other anesthetic alternatives are etomidate, ketamine, alfentanil, and propofol. Etomidate (0.15 to 0.3 mg/kg IV) is sometimes used because it does not increase the seizure threshold; this effect is particularly useful for elderly patients because the seizure threshold increases with age. Ketamine (6 to 10 mg/kg IM) is sometimes used because it does not increase the seizure threshold, although its use is limited by the association of psychotic symptoms with emergence from anesthesia with this drug. Alfentanil (2 to 9 mg/kg IV) is sometimes coadministered with barbiturates to allow the use of low doses of the barbiturate anesthetics and, thus, reduce the seizure threshold less than usual, although its use can be associated with an increased incidence of nausea. Propofol (0.5 to 3.5 mg/kg IV) has anticonvulsant properties.

MUSCLE RELAXANTS. After the onset of the anesthetic effect, usually within a minute, a muscle relaxant is administered to minimize the risk of bone fractures and other injuries resulting from motor activity during the seizure. The goal is to produce profound relaxation of the muscles, not necessarily to paralyze them, unless the patient has a history of osteoporosis or spinal injury or has a pacemaker and, therefore, is at risk for injury related to motor

activity during the seizure. Succinylcholine, an ultrafast-acting depolarizing blocking agent, has gained virtually universal acceptance for the purpose. Succinylcholine is usually administered in a dose of 0.5 to 1 mg/kg as an IV bolus or drip. Because succinylcholine is a depolarizing agent, its action is marked by the presence of muscle fasciculations, which move in a rostrocaudal progression. The disappearance of these movements in the feet or the absence of muscle contractions after peripheral nerve stimulation indicates maximal muscle relaxation. In some patients, tubocurarine (3 mg IV) is administered to prevent myoclonus and increases in potassium and muscle enzymes; these reactions can be a problem in patients with musculoskeletal or cardiac disease. A blood pressure cuff may be inflated at the ankle to apply pressure over the systolic pressure before infusion of the muscle relaxant to allow observation of relatively innocuous seizure activity in the foot muscles to monitor the duration of the convulsion.

If a patient has a known history of pseudocholinesterase deficiency, atracurium (0.5 to 1 mg/kg IV) or curare can be used instead of succinylcholine. In such a patient, the metabolism of succinylcholine is disrupted, and prolonged apnea may necessitate emergency airway management. In general, however, because of the short half-life of succinylcholine, the duration of apnea after its administration is generally shorter than the delay in regaining consciousness caused by the anesthetic and the postictal state.

ELECTRODE PLACEMENT. Historically, most practitioners have used bifrontotemporal electrode placement because of its reliability in producing efficacy and its ease of use. This electrode placement is also associated with more short- and long-term adverse cognitive effects and is more likely to produce delirium, which may require interrupting a course of ECT and perhaps even terminating it before optimal therapeutic effects have been obtained. Hence, when bifrontotemporal ECT is used, attention should be paid to restricting the dose to a moderately suprathreshold level to attenuate adverse cognitive effects as much as possible. It should be emphasized that the combination of ultrabrief pulse and bifrontotemporal electrode placement has not been demonstrated to be effective. Treatment with bilateral electrode placements, particularly a bifrontal configuration, is more likely to manifest EEG seizure without a motor seizure, and EEG monitoring can be

particularly useful in detecting its occurrence.

Newer electrode placements include bifrontal configuration and asymmetrical placements. There are limitations to these strategies, imposed by the fact that the high impedance of the skull and scalp causes the spreading of the electrical stimulus and restricts possibilities for localization of the stimulus. Bifrontal electrode placement, located sufficiently lateral to minimize interference with impedance relations, has been investigated. There have been several demonstrations that bifrontal electrode placements are equally effective as bifrontotemporal and adequately dosed right unilateral electrode configurations. Evidence of advantages in sparing of cognitive effects is quite preliminary, and adequately powered investigations with more extensive and sensitive cognitive batteries are needed. The seizure threshold is likely to be relatively higher with bifrontal ECT.

The relatively better cognitive side effect profile of right unilateral ECT (also called the d'Elia placement) should encourage wider use now that the efficacy of this electrode placement can be ensured with adequate dosing strategies. In contrast to bilateral ECT, a dose closer to 500 percent above the seizure threshold is more likely to ensure efficacy. ECT devices in the United States are restricted to an output in the range of 504 to 576 mCi. Approximately 90 percent of patients have seizure thresholds that can accommodate optimal dosing with brief pulse right unilateral ECT, and the combination of right unilateral electrode placement with ultrabrief pulse width extends the range of US devices, so that most patients can be treated within these constraints. Individuals with an exceptionally high seizure threshold may require bilateral electrode placements to remain within the device restrictions. Maximizing interelectrode distance by using the d'Elia placement may also be optimal. Many other right unilateral placements have been described, but there is little work to support their use (Fig. 22-1).

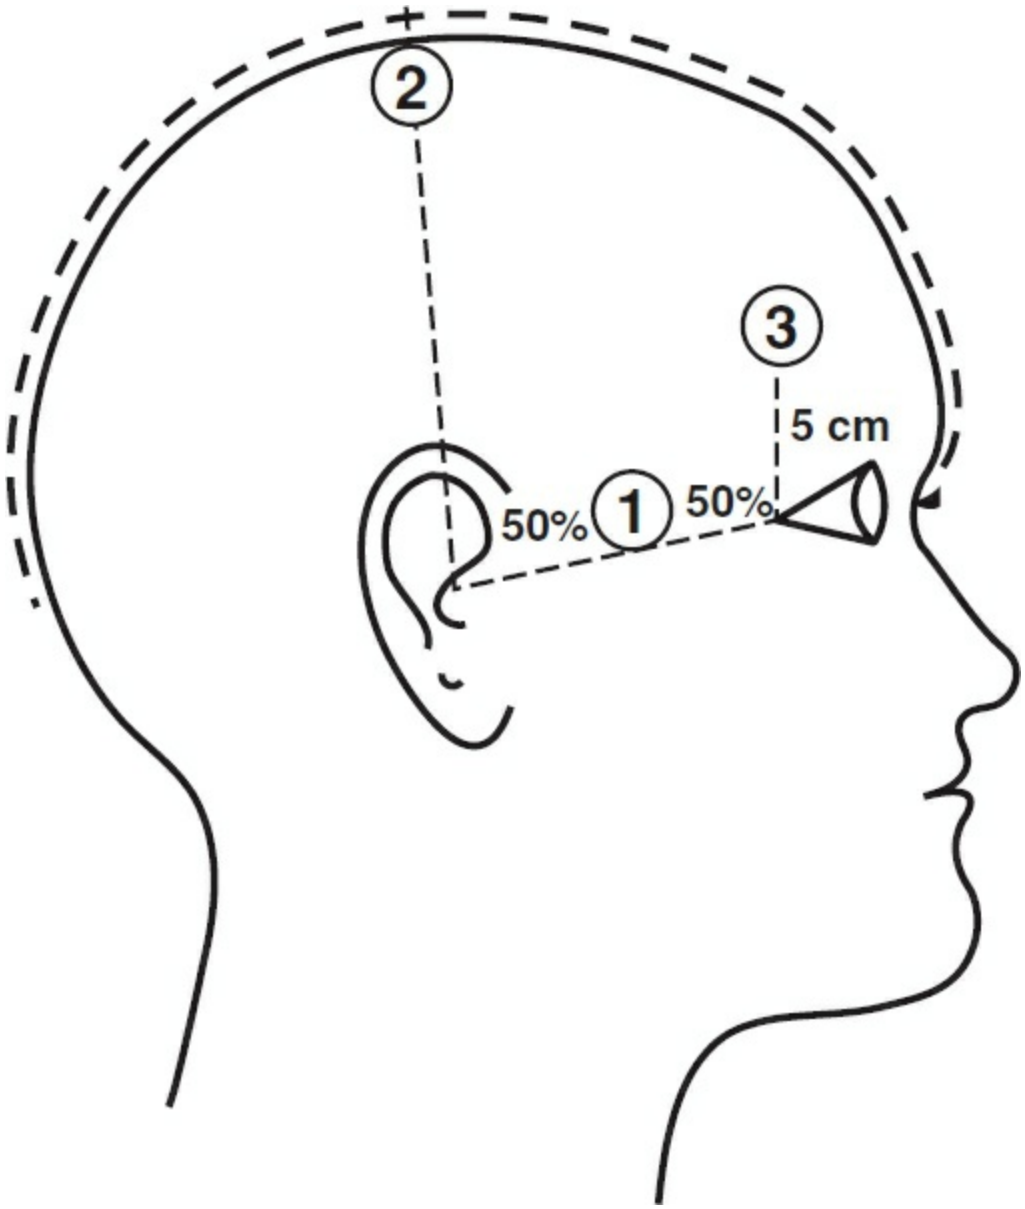

FIGURE 22-1
Electrode placements. Position 1 represents the frontotemporal position, used for both electrodes, one on each side of the head, in conducting bilateral electroconvulsive therapy (ECT). For right unilateral ECT, one electrode is in the right frontotemporal position, and the other is just to the right of the vertex at position 2. (Courtesy of American Psychiatric Association, with permission.)

There has been some concern that left-handed patients may require different electrode placement than right-handed patients, especially if a unilateral placement is desired. Even when handedness is lateralized to the left, the anatomic localization of language function in 70 percent of left-handed individuals is the same as in those who are right-handed.

Furthermore, there is evidence for independent lateralization of affect, with the right hemisphere involved in sustaining depressed mood regardless of handedness. Because of limited indications that affective function and efficacy of ECT are associated with handedness, handedness is not generally used to guide the choice of electrode placement.

Electrical Stimulus. The electrical stimulus must be sufficiently strong to reach the seizure threshold (the level of intensity needed to produce a seizure). The electrical stimulus is given in cycles, and each cycle contains a positive and a negative wave. Old machines use a sine wave; however, this type of machine is now considered obsolete because of the inefficiency of that wave shape. When a sine wave is delivered, the electrical stimulus in the sine wave before the seizure threshold is reached and after the seizure is activated is unnecessary and excessive. Modern ECT machines use a brief pulse waveform that administers the electrical stimulus, usually in 1 to 2 milliseconds, at a rate of 30 to 100 pulses a second. Machines that use an ultrabrief pulse (0.5 milliseconds) are not as effective as brief pulse machines.

Establishing a patient's seizure threshold is not straightforward. A 40 times variability in seizure thresholds occurs among patients. Also, during ECT treatment, a patient's seizure threshold may increase 25 to 200 percent. The seizure threshold is also higher in men than in women and higher in older than in younger adults. A common technique is to initiate treatment at an electrical stimulus that is thought to be below the seizure threshold for a particular patient and then to increase this intensity by 100 percent for unilateral placement and by 50 percent for bilateral placement until the seizure threshold is reached. A debate in the literature concerns whether a minimally suprathreshold dose, a moderately suprathreshold dose (one and a half times the threshold), or a high suprathreshold dose (three times the threshold) is preferable. The debate about stimulus intensity resembles the debate about electrode placement. Essentially, the data support the conclusion that doses of three times the threshold are the most rapidly effective and that minimal suprathreshold doses are associated with the fewest and least severe cognitive adverse effects.

Induced Seizures. A brief muscular contraction, usually strongest in a

patient's jaw and facial muscles, is seen concurrently with the flow of stimulus current, regardless of whether a seizure occurs. The first behavioral sign of the seizure is often a plantar extension, which lasts 10 to 20 seconds and marks the tonic phase. This phase is followed by rhythmic (i.e., clonic) contractions that decrease in frequency and finally disappear. The tonic phase is marked by high-frequency, sharp EEG activity on which a higher-frequency muscle artifact may be superimposed. During the clonic phase, bursts of polyspike activity coincide with the muscular contractions but usually persist for at least a few seconds after the clonic movements stop.

MONITORING SEIZURES. A physician must have an objective measure that a bilateral generalized seizure has occurred after the stimulation. The physician should be able to observe either some evidence of tonic–clonic movements or electrophysiologic evidence of seizure activity from the EEG or electromyogram (EMG). Seizures with unilateral ECT are asymmetrical, with higher ictal EEG amplitudes over the stimulated hemisphere than over the nonstimulated hemisphere. Occasionally, unilateral seizures are induced; for this reason, at least a single pair of EEG electrodes should be placed over the contralateral hemisphere when using unilateral ECT. For a seizure to be effective in the course of ECT, it should last at least 25 seconds.

FAILURE TO INDUCE SEIZURES. If a particular stimulus fails to cause a seizure of sufficient duration, up to four attempts at seizure induction can be tried during a course of treatment. The onset of seizure activity is sometimes delayed as long as 20 to 40 seconds after the stimulus administration. If a stimulus fails to result in a seizure, the contact between the electrodes and the skin should be checked, and the intensity of the stimulus should be increased by 25 to 100 percent. The clinician can also change the anesthetic agent to minimize increases in the seizure threshold caused by the anesthetic. Additional procedures to lower the seizure threshold include hyperventilation and administration of 500 to 2,000 mg IV of caffeine sodium benzoate 5 to 10 minutes before the stimulus.

PROLONGED AND TARDIVE SEIZURES. Prolonged seizures (seizures lasting more than 180 seconds) and status epilepticus can be terminated either with additional doses of the barbiturate anesthetic agent or with IV diazepam (5 to

10 mg). Management of such complications should be accompanied by intubation because the oral airway is insufficient to maintain adequate ventilation over an extended apneic period. Tardive seizures—that is, additional seizures appearing sometime after the ECT treatment—may develop in patients with preexisting seizure disorders. Rarely, ECT precipitates the development of an epileptic disorder in patients. Such situations should be clinically managed as if they were pure epileptic disorders.

Number and Spacing of Treatments. ECT treatments are usually administered two to three times a week; twice-weekly treatments are associated with less memory impairment than thrice-weekly treatments. In general, the course of treatment of major depressive disorder can take 6 to 12 treatments (although up to 20 sessions are possible); the treatment of manic episodes can take 8 to 20 treatments; the treatment of schizophrenia can take more than 15 treatments, and the treatment of catatonia and delirium can take as few as 1 to 4 treatments. Treatment should continue until the patient achieves what is considered the maximal therapeutic response. Further treatment does not yield any therapeutic benefit but increases the severity and duration of the adverse effects. The point of maximal improvement is usually thought to occur when a patient fails to continue to improve after two consecutive treatments. If a patient is not improving after 6 to 10 sessions, bilateral placement and high-density treatment (three times the seizure threshold) should be attempted before ECT is abandoned.

MULTIPLE-MONITORED ELECTROCONVULSIVE THERAPY. Multiple-monitored ECT (MMECT) involves giving multiple ECT stimuli during a single session, most commonly two bilateral stimuli within 2 minutes. This approach may be warranted in severely ill patients and those at exceptionally high risk from the anesthetic procedures. MMECT is associated with the most frequent occurrences of serious cognitive adverse effects.

Maintenance Treatment. A short-term course of ECT induces remission in symptoms but does not, of itself, prevent a relapse. Post-ECT maintenance treatment should always be considered. Maintenance therapy is generally pharmacologic, but maintenance ECT treatments (weekly, biweekly, or

monthly) have been reported to be effective relapse prevention treatments, although data from extensive studies are lacking. Indications for maintenance ECT treatments can include rapid relapse after initial ECT, severe symptoms, psychotic symptoms, and the inability to tolerate medications. If ECT was used because a patient was unresponsive to a specific medication, then, following ECT, the patient should be given a trial of different medications.

Failure of Electroconvulsive Therapy Trial. Patients who fail to improve after a trial of ECT should have another medication trial, even if that agent previously failed. Although the data are primarily anecdotal, many reports indicate that patients who had previously failed to improve while taking an antidepressant drug do improve while taking the same drug after receiving a course of ECT treatments, even if the ECT seemed to be a therapeutic failure. Nonetheless, with the increased availability of drugs that act at diverse receptor sites, it is less often necessary to return to a drug that has failed than it was formerly.

Adverse Effects

Contraindications. ECT has no absolute contraindications, only situations in which a patient is at increased risk and has an increased need for close monitoring. Pregnancy is not a contraindication for ECT, and fetal monitoring is generally considered unnecessary unless the pregnancy is high risk or complicated. Patients with space-occupying central nervous system lesions are at increased risk for edema and brain herniation after ECT. If the lesion is small, however, pretreatment with dexamethasone is given, and hypertension is controlled during the seizure, and the risk of serious complications minimized for these patients. Patients who have increased intracerebral pressure or are at risk for cerebral bleeding (e.g., those with cerebrovascular diseases and aneurysms) are at risk during ECT because of the increased cerebral blood flow during the seizure. This risk can be lessened, although not eliminated, by control of the patient’s blood pressure during the treatment. Patients with recent myocardial infarctions are another high-risk group, although the risk is greatly diminished 2 weeks after the myocardial infarction and is even further reduced 3 months after the infarction. Patients with hypertension should be stabilized on their

antihypertensive medications before ECT is administered. Propranolol and sublingual nitroglycerin can also be used to protect such patients during treatment.

Mortality. The mortality rate with ECT is about 0.002 percent per treatment and 0.01 percent for each patient. These numbers compare favorably with the risks associated with general anesthesia and childbirth. ECT death is usually from cardiovascular complications and is most likely to occur in patients whose cardiac status is already compromised.

Central Nervous System Effects. Common adverse effects associated with ECT are headache, confusion, and delirium shortly after the seizure while the patient is coming out of anesthesia. Marked confusion may occur in up to 10 percent of patients within 30 minutes of the seizure and can be treated with barbiturates and benzodiazepines. Delirium is usually most pronounced after the first few treatments and in patients who receive bilateral ECT or who have coexisting neurologic disorders. The delirium characteristically clears within days or a few weeks at the longest.

MEMORY. The most significant concern about ECT is the association between ECT and memory loss. About 75 percent of all patients given ECT say that memory impairment is the worst adverse effect. Although memory impairment during a course of treatment is almost the rule, follow-up data indicate that almost all patients are back to their cognitive baselines after 6 months. Some patients, however, complain of persistent memory difficulties. For example, a patient may not remember the events leading up to the hospitalization and ECT, and such autobiographical memories may never be recalled. The degree of cognitive impairment during treatment and the time it takes to return to baseline are related, in part, to the amount of electrical stimulation used during treatment. Memory impairment is most often reported by patients who have experienced little improvement with ECT. Despite the memory impairment, which usually resolves, no evidence indicates brain damage caused by ECT. This subject has been the focus of several brain-imaging studies, using a variety of modalities; virtually all concluded that permanent brain damage is not an adverse effect of ECT. Neurologists and epileptologists generally agree that seizures that last less

than 30 minutes do not cause permanent neuronal damage.

Other Adverse Effects of Electroconvulsive Therapy. Fractures often accompanied treatments in the early days of ECT. With routine use of muscle relaxants, fractures of long bones or vertebrae should not occur. Some patients, however, may break teeth or experience back pain because of contractions during the procedure. Muscle soreness can occur in some individuals, but it often results from the effects of muscle depolarization by succinylcholine and is most likely to be particularly troublesome after the first session in a series. This soreness can be treated with mild analgesics, including nonsteroidal anti-inflammatory drugs (NSAIDs). A significant minority of patients experience nausea, vomiting, and headaches following an ECT treatment. Nausea and vomiting can be prevented by treatment with antiemetics at the time of ECT (e.g., metoclopramide, 10 mg IV, or prochlorperazine, 10 mg IV; ondansetron is an acceptable alternative if adverse effects preclude the use of dopamine receptor antagonists).

ECT can be associated with headaches, although this effect is usually readily manageable. Headaches often respond to NSAIDs given in the ECT recovery period. In patients with severe headaches, pretreatment with ketorolac (30 to 60 mg IV), an NSAID approved for brief parenteral use, can be helpful. Acetaminophen, tramadol, and more potent analgesia provided by opioids can be used individually or in various combinations to manage more intractable headache. ECT can induce migrainous headache and related symptoms; sumatriptan (6 mg SC or 25 mg orally) may be a useful addition to the agents described above. Ergot compounds can exacerbate cardiovascular changes observed during ECT and probably should not be a component of ECT pretreatment.

Investigations in Electrical Brain Stimulation Treatment

There is interest in continued refinements of ECT techniques. Common themes in these approaches are focusing the treatment spatially to optimize dosing in brain areas associated with putative neural networks involved in depression and other psychopathologies that are indications for ECT, diminishing dosing in areas associated with adverse cognitive effects, and improving the efficiency of a noninvasive electrical stimulus in direction and

amplitude, even to a subconvulsive level. This research is parallel to investigations in magnetic stimulation (e.g., repetitive transcranial magnetic stimulation [TMS]) and the renaissance of invasive electrical techniques (e.g., vagal nerve stimulation and deep brain stimulation [DBS]).

OTHER BRAIN STIMULATION METHODS

Brain stimulation in psychiatric practice and research uses electrical currents or magnetic fields to alter neuronal firing. There is a growing list of tools capable of eliciting such neuromodulation, each with a different spectrum of action. These tools either apply electrical or magnetic fields transcranially or involve the surgical implantation of electrodes to deliver electrical currents to a cranial nerve or the brain directly. The transcranial techniques include cranial electrical stimulation (CES), ECT, transcranial direct current stimulation (tDCS, also called direct current polarization), TMS, and magnetic seizure therapy (MST). The surgical techniques include cortical brain stimulation (CBS), DBS, and vagus nerve stimulation (VNS).

In 1985, nearly 50 years after the first use of ECT, Anthony Barker and colleagues published on the first use of pulsed magnetic fields to stimulate the brain with a procedure called *transcranial magnetic stimulation.* TMS was initially used in neurology for studies of nerve conduction, but it quickly caught the attention of psychiatrists eager to explore other, less invasive alternatives to ECT. This nonconvulsive stimulation method through TMS is under active study, with some promising results in the treatment of various psychiatric disorders, including depression, anxiety, and schizophrenia. A convulsive treatment derived from the application of more powerful magnetic stimulation has been under investigation in nonhuman primates and human studies in both the United States and Europe. The first MST procedure was performed in an animal in 1998 and a human in 2000. MST is under development as a more focal means of inducing seizures in an attempt to retain the thus-far-unparalleled efficacy of ECT with fewer cognitive side effects.

Two more additions to brain stimulation methods, DBS and VNS, were introduced about a decade following the first trials of TMS. Both were first approved by the U.S. Food and Drug Administration (FDA) in 1997 in the realm of treating sequelae of neurologic syndromes. DBS was initially

approved for the treatment of essential tremor and Parkinson tremors, whereas VNS was approved for the treatment of epilepsy. Five years later, in 2002, indications for DBS were expanded to include treatment of all symptoms of Parkinson disease, including tremor, slowness, and stiffness, as well as involuntary movements induced by medications. TMS, DBS, and VNS originated in the field of neurology. Psychiatrists quickly saw the potential for those tools in the treatment of psychiatric conditions, however, and as a result of clinical trials in depression, VNS subsequently received FDA approval for the long-term adjunctive treatment of chronic or recurrent depression in adults. Also, human studies are underway to validate the efficacy of DBS in the treatment of depression and OCD.

Therapeutic Neuromodulation: Treating Psychiatric Disorders Through Brain Stimulation

Mechanism of Action

ELECTRICAL STIMULATION—COMMON PATHWAY. The brain stimulation modalities just reviewed generate either electrical or magnetic pulses. However, both of these share a common final pathway—they affect the neurons electrically. That electrical effect may either be through the direct application of electricity or the indirect induction of electricity via magnetic stimulation. The direct forms of electrical stimulation are exemplified in either *transcranial* delivery, as with ECT, CES, and tDCS, or *intracerebral* delivery, as in the case of DBS or direct cortical stimulation (epidural or subdural). The indirect forms of electrical stimulation include TMS and MST, which induce electrical fields in the brain through the application of alternating magnetic fields. Of note, both the epidural and intracerebral modalities are more focal than the transcranial application of electricity because electrodes are placed directly in the neuronal tissue, bypassing the impedance of the scalp and skull. The relatively more contemporary magnetic stimulation methods (TMS and MST) also bypass the impedance of the scalp and skull and are thus likewise more focal. However, magnetic stimulation is, in fact, an example of an indirect method of electrical brain stimulation, in that the changing magnetic fields from these devices induce electricity in the brain, the latter acting as a conductor, according to the principle first

described by Michael Faraday in a law that bears his name and later incorporated into James Clerk Maxwell's equations, which unify all of electromagnetism. The magnetic modalities achieve their enhanced focality noninvasively, in contrast to the intracerebral and epidural methods, and are thus at the center of intensive research in that they offer the promise of an unparalleled degree of spatial specificity without the need for surgery.

All but one of the brain stimulation modalities described here act by stimulating neurons. The one exception is tDCS, which does not stimulate but instead polarizes. In this sense, the "S" of tDCS is a misnomer. It is more accurate to conceptualize tDCS as exerting a polarizing effect that may alter the likelihood of neuronal firing.

The action of the subconvulsive modalities of stimulation relies on the effects of the repeated stimulation of the targeted neural circuitry. However, in the case of the convulsive modalities (ECT and MST), the action depends on the seizure induced by the stimulation and the effects of repeated seizure induction on brain processes. This is not to say that the form of stimulation that triggers the seizure does not affect the outcome. Indeed, it is well replicated that electrode placement and electrical stimulus parameters have a profound effect on the efficacy and side effects of ECT. Whether the same will be valid for MST is under active investigation.

ACUTE VERSUS PROLONGED EFFECTS. Brain stimulation can have immediate or lasting effects. A single electrical pulse delivered at sufficient intensity can induce depolarization, trigger an action potential, release neurotransmitters at the synapse, and result in transsynaptic propagation with subsequent activation of a functional circuit. For example, brain stimulation applied to the hand area of the primary motor cortex may activate the corticospinal tract and induce a muscle twitch in the contralateral hand. Such stimulation can result acutely in the induction of either a positive effect, as in the case of a muscle twitch or visualization of phosphenes, or a disruptive effect, as in the case of visual masking.

Repetitive pulses delivered at fixed frequencies can exert even more powerful effects. Epstein and colleagues described in 1999 how repetitive TMS (rTMS) applied to the language-dominant hemisphere induced an arrest of speech. After termination of the stimulation, speech returned to normal.

Some more invasive brain stimulation modalities, such as DBS or VNS,

are programmed to operate chronically, thus extending the acute action for as long as the stimulation is turned on. In the case of DBS, the pulses are typically given continuously at a high frequency, whereas in the case of VNS, the pulses are given in trains lasting up to 30 seconds and typically repeated every 5 minutes. The less invasive modalities, such as rTMS, tDCS, CES, and even ECT, presumably require the induction of some form of neuroplasticity for their effect to become lasting.

Transcranial Magnetic Stimulation

Definition. TMS is the application of a rapidly changing magnetic field to the superficial layers of the cerebral cortex, which locally induces small electric currents, also referred to as *eddy* currents. This induction was initially discovered by Faraday through his experiments in 1831 and later quantified in Maxwell's equations of electromagnetism. Thus, TMS may be referred to as electrical stimulation without an electrode, in that it uses magnetic fields to induce electrical pulses indirectly. TMS devices deliver intense magnetic pulses via a coil that is held on the scalp. Because magnetic fields are unaffected by the electrical impedance of the scalp and skull, this method of stimulation enables the focal stimulation of smaller areas of the brain than is possible with other noninvasive devices that use either alternating (ECT, CES) or direct (tDCS) electrical current for primary stimulation. TMS is an example of noninvasive stimulation of focal regions of the brain and, as such, can be used for research or therapeutically without the need for anesthesia.

Mechanisms of Action. At sufficient intensity, electrical currents will stimulate neuronal depolarization, which can result in an action potential. For example, when the TMS coil is positioned over the hand area of the cerebral cortex's motor strip, the changing magnetic field generated by the repetitive pulses induces local currents immediately below the site of stimulation that cause the neurons in area M1 to fire. In turn, this action potential propagates through the polysynaptic corticospinal tract and results in a twitch in the contralateral hand muscle. In essence, TMS uses magnetic fields to indirectly induce focal electrical currents in the brain, thereby triggering the firing of functional neuronal circuits that can lead to observable behavioral effects. This effect can be easily demonstrated by single TMS pulses that can be used

to map the homunculus by merely moving the TMS coil across the cortical representation of neighboring muscle groups and simultaneously to study the excitability of the corticospinal system.

Single TMS pulses can exert other effects when moved to different cortical areas. When positioned over the primary visual cortex (V1), scotomas, or "blind spots," are often elicited. This illustrates that TMS can transiently disrupt functions.

Activation of motor neurons resulting in a muscle twitch and disruption of visual perception with a single-pulse TMS represent examples of the acute effects of TMS-induced neuronal depolarization, as shown in Table 22-3. The effects of single TMS pulses are believed to be immediate and short-lived. The muscle twitch, as induced by TMS to area M1, is nearly instantaneous, with the hand movement occurring approximately 20 milliseconds after the TMS pulse is applied. The visual masking likewise operates on a similar time scale measured in milliseconds. TMS can, however, exert longer-lasting effects when the pulses are repeated at regular intervals in the process of rTMS. It also occurs when they are paired with other forms of stimulation in which TMS pulses are coupled with electrical stimulation of a peripheral nerve (as in paired associative stimulation [PAS]) or when TMS is paired with audiovisual stimuli, as in the example of classical conditioning of the brain response to TMS. The mechanisms underlying these lasting effects of TMS have been described by various researchers and are thought to be related to neuroplasticity and alterations in synaptic efficacy.

Treatment of psychiatric disorders with rTMS has been informed by attempts to focally alter pathologic cortical excitability, believed to be linked to a specific illness. Reduced activity in the left dorsolateral prefrontal cortex has been implicated in several studies as a physiologic correlate of affective disorders. Numerous studies have applied high frequencies of rTMS, which have been reported to increase excitability to the left dorsolateral prefrontal cortex (DLPFC) in an attempt to normalize activity in this region. In a related approach, some investigators who implicated abnormal interhemispheric balance in activation between the right and left DLPFC applied low-frequency rTMS, which has been reported to be inhibitory, to the right DLPFC in an attempt to normalize this balance.

Table 22-3
Acute and Prolonged Mechanisms of Action

Acute Effects
Phasic activation of neural circuits
Observable motor responses (e.g., twitch)
Temporary disruption (e.g., speech arrest) or facilitation of ongoing processing (e.g., speeds reaction time)
Prolonged Effects
Neuroplasticity
• Change in synaptic efficacy, akin to long-term potentiation or depression
• Alterations in neurotrophic factors
• Modulation of cortical excitability
• Modulation of functional connectivity

Side Effects, Interactions with Medications, and Other Risks. Administration of TMS is a noninvasive, relatively benign procedure when applied by a knowledgeable professional to a subject who has been appropriately evaluated. However, it is not entirely without risk. The most severe known risk of TMS is an unintended seizure. Several factors may contribute to seizure risk. Primarily, these include the form of TMS, with single-pulse stimulation less likely to result in a seizure than rTMS, and, in an equally important manner, the dose, which is the combination of treatment parameters including frequency, power, train duration, and intertrain interval. Also, subject factors can be significant, such as the presence of a neurologic disorder (epilepsy or a focal brain lesion) or the use of seizure-lowering medications.

Single-pulse TMS is generally considered to be of minimal risk when administered to appropriately screened adults without seizure risk factors. On the other hand, rTMS can induce seizures in individuals without predisposing conditions when given at sufficiently high doses.

Patient Selection. Patients who have failed a trial of one or more antidepressant medications or have untoward side effects to medications may

be good candidates for TMS. However, given the lower effect size of TMS, for urgent or severely refractory cases, ECT would remain the gold standard treatment.

Future Directions and Controllable Pulse Shape TMS. TMS and other forms of magnetic stimulation hold a tremendous promise in psychiatric treatment due to their focality and noninvasiveness. However, much research is needed to replicate preliminary findings, improve optimal dosing, establish the patient characteristics that predict response, and examine the influence of concomitant medications on the TMS effect. Posttreatment relapse prevention is one of many areas that have to be adequately explored. Other vigorously pursued directions are attempts to develop stimulation coils that will allow deeper brain penetration and work on pulse shapes that may be more physiologically optimal for human stimulation.

Transcranial Direct Current Stimulation

Definition. tDCS is a noninvasive form of treatment that uses very weak (1 to 3 mA) direct electrical current applied to the scalp. Because direct current (DC) polarizes rather than stimulates with discrete pulses, its action does not appear directly to result in action potential firing in cortical neurons. It is also this DC form of electrical stimulation that distinguishes it from devices that use alternating currents (AC) as found in CES, ECT, VNS, and DBS, which produce discrete pulse stimulation. Also, because tDCS works via polarization and does not affect action potential firing in cortical neurons, the term *transcranial direct current polarization* is favored by some modern investigators, and both terms appear interchangeably in the literature today. The small device is very portable and usually operated by readily available DC batteries.

Side Effects. There are no known severe adverse effects of tDCS. It is well tolerated, with reported common side effects in the literature listing mostly minimal tingling at the site of stimulation, with a few reported cases of skin irritation.

Mechanism of Action. tDCS is believed to act via the alteration of

neuronal membrane polarization, but little is known about the actual mechanism of action of tDCS. Polarization may affect the firing and conductance of neurons by either lowering or raising the threshold of activation. Because tDCS involves the application of low currents to the scalp via cathodal and anodal electrodes, depending on the direction of current flow, polarization can either inhibit (cathodal) or facilitate (anodal) function.

Clinical Studies. Preliminary research suggests that tDCS may enhance certain brain functions independent of mood; however, tDCS technology and its use in psychiatry are in the early stages of exploration. Research is focusing on its potential effectiveness in facilitating recovery from stroke and certain forms of dementia.

Future Directions. Most of the current tDCS devices use large, saline solution–soaked electrodes. Future device development will most likely investigate electrode shape and contact material to optimize the intended clinical effects and further improve ease of use. However, fundamental questions of efficacy, indications, and dose–response relationships, as well as predictors of response, will need to be explored first.

Cranial Electrical Stimulation

Definition. CES, like tDCS, uses a weak (1- to 4-mA) current. However, with CES, the current is alternating. It is traditionally applied via saline-soaked, felt-covered electrodes clipped onto the earlobes. Other placement strategies are also being investigated.

Mechanism of Action. The exact mechanism of action has not been elicited, and there is no agreement among researchers on the predominant mode of action. Previous hypotheses proposed that the stimulation with the alternating microcurrent affects the thalamic and hypothalamic brain tissue and facilitates the release of neurotransmitters. Claims have been made that through interaction with cell membranes, the stimulation produces changes in signal transduction associated with classic second-messenger pathways, including calcium channels and cyclic adenosine monophosphate (AMP). There are summary reports that CES causes increases in plasma serotonin,

norepinephrine, dopamine, and monoamine oxidase type B (MAO_B) in blood platelets and cerebrospinal fluid (CSF), as well as the release of 5-hydroxyindoleacetic acid, dehydroepiandrosterone (DHEA), and enkephalins and reduction of cortisol and tryptophan. However, most of these reports have not been validated through modern research.

Side Effects. It is believed that the CES stimulation is not harmful, primarily due to its low-voltage power supply (9-V battery) and lack of any reported adverse event by the FDA. Local skin effects, as well as a general feeling of dizziness, have been reported, however, and device manufacturers do not advise the use of the device during pregnancy, in those with low blood pressure, or in people who have arrhythmias or pacemakers.

Clinical Studies. In a meta-analysis by the Harvard School of Public Health, 18 human clinical trials were examined that used CES to treat depression, anxiety, drug addiction, insomnia, headache, and pain. The overall pooled result showed CES to be better than sham treatment for anxiety at a statistically significant level.

Current Status in Treatment Algorithms, Patient Selection, and Dosing. The use of CES has not been studied sufficiently in the United States, and it does not have a specific place in any algorithm of standard US psychiatric practice.

Future Directions. As with tDCS, fundamental issues of indications, patient selection, dose–response relationship, and efficacy are under active research and remain to be optimized.

Magnetic Seizure Therapy

Definition. MST is a novel form of convulsive treatment that is under development in several research institutions in the United States and Europe. The treatment uses an alternating magnetic field that crosses the scalp and the calvarium bone unaffected by their high electrical impedance, to in turn induce a more-localized electrical current in the targeted regions of the cerebral cortex than is possible with ECT. The aim is to produce a seizure

whose focus and patterns of spread may be controlled.

MST is a convulsive treatment that is similar to ECT. It is performed under general anesthesia. It requires approximately the same preparation and infrastructure as ECT. However, MST is given using a modified TMS device, one that can administer higher output than the conventional TMS devices and thus relies on magnetic stimulation, unlike electric stimulation in ECT. The MST procedure is performed under general anesthesia with a muscle relaxant. MST is under investigation and is not FDA approved.

Mechanism of Action. Induction of a seizure is hypothesized to be the underlying event responsible for the likely multiple specific mechanisms of action of MST treatment. As in ECT, these are not fully understood. However, due to its focality, MST appears to represent a tool better suited than ECT to study the mechanisms of action of convulsive therapy through its potential of inducing seizures initiated in different regions of the brain.

Side Effects. Adverse effects from MST, like those of ECT, are primarily connected to the risks associated with anesthesia and generalized seizure. Also, the MST magnetic coil produces a clicking noise that may potentially affect hearing. Earplugs should be worn by both the patient and members of the treating team to mitigate that risk and prevent any cumulative damage. Studies suggest that MST results in less retrograde and anterograde amnesia than ECT, although this result should be replicated in a larger trial.

Current Status in Treatment Algorithms. No clinical algorithms exist for MST, given that it is still an investigational protocol, and treatments outside of research are not FDA approved. Assuming the hypothesis that MST can approach the efficacy of ECT (but with fewer side effects) is correct, this magnetically induced convulsive treatment will play an essential role before referral for ECT.

Future Directions. MST is a novel treatment in the early phases of clinical testing. Clinical treatment variables, including dosing, optimal coil placement, patient selection, and mechanisms of action, are the topics of ongoing and future studies.

Vagus Nerve Stimulation

Definition. VNS is the direct, intermittent electrical stimulation of the left cervical vagus nerve via an implanted pulse generator, usually in the left chest wall. The electrode is wrapped around the left vagus nerve in the neck and is connected to the generator subcutaneously.

Mechanisms of Action. The majority of the fibers contained in the left vagus are afferents. It is estimated that as many as 80 percent of these fibers are up-going afferents. Thus chronic stimulation of these nerve fibers predominantly changes activity in the brainstem nuclei such as the nucleus of the tractus solitarius and other neighboring nuclei (e.g., raphe) that alter serotonergic activity in cortical and limbic structures. Also, persistent stimulation of the vagal afferents is anticonvulsant, an effect that appears to depend on the norepinephrine-producing locus ceruleus.

Side Effects and Contraindications. To date, reasonably comprehensive literature confirms that VNS is generally well tolerated. The adverse events that are most frequently reported are voice alteration, dyspnea, and neck pain. Besides of the risk of perioperative infection, the surgical implantation carries a small risk of vocal cord paralysis, bradycardia, or asystole.

Current Status in Treatment Algorithms. The FDA indicated VNS for the long-term adjunctive treatment of chronic or recurrent depression in patients 18 years or older experiencing a major depressive episode in the setting of unipolar or bipolar disease who have not had an adequate response to four or more adequate antidepressant treatments. Consultation with another clinician experienced with treatment-resistant depression and VNS is recommended.

VNS treatment success rates are lower than those with ECT. Its onset of action is also comparatively slow—typically, an approximately 30 percent response rate is observed after 1 year. VNS may be worth considering, therefore, when patients have failed to respond to less invasive treatments, ECT was ineffective, or post-ECT relapse cannot be prevented with less invasive means. VNS might be helpful with longer-term relapse prevention,

but results of controlled trials would be useful to guide practice.

Patient Selection. VNS is approved as a long-term adjunctive treatment for chronic or recurrent depressive episodes in adults with a major depressive episode who have not had a satisfactory response to four or more adequate antidepressant trials. The efficacy of VNS in other disorders is unknown.

ECT can be safely used in patients with an implant as long as the VNS generator is turned off during the convulsive treatment. This precaution is needed because of the anticonvulsant effects of VNS. It remains to be studied whether VNS could be useful in relapse prevention post-ECT.

Dosing. The optimal dosing for psychiatric applications of VNS is still mostly an area of investigation. The published studies do not identify optimal dosing parameters like time on, time off, frequency, current, or pulse width. However, the epilepsy literature suggests that there is a threshold current for efficacy. Given current knowledge of VNS dosing, electrical current is typically increased up to greater than 1 mA, and clinical benefit is assessed over several months. Because the adverse effects of VNS are known to be dose-dependent, treatment parameters are often chosen to mitigate specific side effects. For example, lowering the pulse width reduces neck pain, allowing patients to tolerate higher currents.

Future Directions. More research is required to establish dose–response relationships for VNS. Future studies may explore optimal medication strategies to augment responses, test the potential role of VNS for long-term relapse prevention (e.g., after ECT), and study its mechanism of action.

Implanted Cortical Stimulation

Definition. CBS is a novel neurosurgical approach in which electrodes are implanted over the surface of the cortex to provide electrical brain stimulation in a targeted superficial region. This approach is being studied for the treatment of conditions like stroke, tinnitus, and treatment-resistant depression.

NEUROSURGICAL TREATMENTS AND DEEP BRAIN

STIMULATION

After a long and checkered history, neurosurgical treatments for psychiatric illness have reemerged as a focus of great interest. Many still associate psychiatric neurosurgery with the bygone era of crude freehand "psychosurgery" when prefrontal lobotomy saw broad and indiscriminate use. Those primitive operations, which predated modern psychopharmacology, yielded modest reductions in symptoms but were accompanied by unacceptable adverse effects. Over nearly five decades, techniques, and significantly, procedures and practices have evolved tremendously. First, ablative lesions are now accurately, precisely, and reproducibly placed in specific brain targets stereotactically guided by MRI and specialized software. Alternative methods include radiosurgery, which allows stereotactic lesion placement without craniotomy. DBS, while requiring craniotomy to implant stimulating electrodes in specific brain targets, is intentionally nonablative and allows flexible and reversible modulation of brain function. Second, strict criteria for patient selection are observed, and the process of determining appropriate candidacy has been formalized.

Currently, surgical intervention is predominantly reserved for patients with severe, incapacitating major depression or OCD who have failed an exhaustive array of standard treatments. Surgery is not approved unless a multidisciplinary committee reaches consensus regarding its appropriateness for a given candidate, and the patient renders informed consent. Although a large body of clinical data has already been collected that indicates the effectiveness and safety of modern neurosurgical interventions, major centers providing these treatments continue to gather information prospectively, and controlled trials are underway or planned. With these advances in neurosurgical techniques and better-established selection criteria and long-term follow-up procedures, available data suggest that psychiatric neurosurgery yields a substantial improvement in symptoms and functioning in approximately 40 to 70 percent of cases, with morbidity and mortality drastically lower than for earlier procedures.

Although lesion procedures have been influenced by theories implicating corticolimbic systems in disordered behavior, they were initially mainly developed empirically. Although psychiatric neurosurgery is sometimes

criticized for this reason, as for any clinical therapy, the relevant issues are safety and efficacy, not a correction of pathophysiologic processes that are not yet fully understood. However, psychiatric neurosurgery is now developing in a scientific context where the translation of data between clinical results to cross-species anatomical, neuroimaging, and physiologic studies of neural networks involved a promise to illuminate mechanisms of therapeutic action.

History

Trephination performed by ancient civilizations probably represents the earliest form of surgical intervention for psychopathology. In 1891, the first formal report of neurosurgical treatment in psychiatry was published, describing bilateral cortical excisions in demented and depressed patients, which yielded mixed results. After four decades in which little progress was made, in 1935, John Fulton and Charles Jacobsen presented their research on primate behavior following frontal cortical ablation. They observed that lobectomized chimpanzees showed a reduction in “experimental neurosis” and were less fearful while retaining an ability to perform complex tasks. António Egaz Moniz, a renowned Portuguese neurologist, pioneered prefrontal leukotomy in collaboration with his neurosurgical colleague, Almeida Lima. First, by using absolute alcohol injections and subsequently by mechanical means with a leucotome, Moniz and Lima performed “psychosurgery” on 20 severely ill institutionalized patients; 14 were said to have exhibited worthwhile improvement. In an era of overflowing asylums and few effective treatments for chronic debilitating psychiatric illness, this mode of therapy was initially enthusiastically embraced, and Moniz won the 1949 Nobel Prize in Physiology or Medicine for this contribution.

From the mid-1930s until the emergence of the phenothiazines in the mid-1950s, these techniques proliferated globally. Walter Freeman, a neuropsychiatrist, was perhaps the most zealous promoter of psychosurgery in the United States. Pioneering a series of freehand procedures to achieve prefrontal lobotomy (i.e., severing the white matter connections between the prefrontal cortex and the rest of the brain), Freeman, together with neurosurgeon James Watts, reported on their first 200 cases by 1942. Although the benefits of the surgery were highlighted, others acknowledged a

significant complication rate, including frontal lobe syndrome, seizures, and even deaths. At its peak, lobotomy was being performed on approximately 5,000 patients per year in the United States alone. A review of the results of 10,365 prefrontal lobotomies performed from 1942 to 1954 in Britain concluded that, while 70 percent showed an improvement, adverse effects included 6 percent mortality, seizures in 1 percent, and disinhibition syndromes in 1.5 percent. There were widespread reports of blunted personality and socially inappropriate behavior. In the late 1940s and early 1950s, recognition of these risks prompted attempts to develop modified stereotactic surgical procedures that might yield better results. For example, Ernest Spiegel and Henry Wycis, who began stereotactic neurosurgery in humans, reported in the 1940s that dorsomedial thalamotomies improved obsessive-compulsive symptoms. However, with the introduction of chlorpromazine in 1954, medical management of psychiatric illness became possible. Following this, psychiatric neurosurgery was all but abandoned in favor of nonsurgical therapies.

Patient Selection: Indications and Contraindications

Although limited reports have suggested efficacy across a broad range of psychiatric conditions and research is expanding rapidly, as of this writing, the best-established indications for psychiatric neurosurgery remain major depression and OCD. In evaluating candidates, several factors are considered:

1. *Primary diagnosis:* The patient must meet clinical criteria for the diagnostic indication, and this disorder should be a primary cause of the patient's debility and suffering.
2. *Severity:* The patient must have a chronic, severe, and debilitating illness; the duration of the primary illness must exceed 1 year and typically exceeds 5 years. Severity is gauged on standardized instruments (e.g., patients with OCD typically have Yale-Brown Obsessive-Compulsive Scale scores of 25 to 30; patients with major depression typically have Beck Depression Inventory scores of 30 or higher), while a low level of functioning should indicate debility (e.g., a Global Assessment of Functioning score of 50 or less) and a low quality of life.
3. *Adequacy of previous treatment:* Patients must have already undergone

an exhaustive array of other available established treatments, which are documented in detail.

4. *Psychiatric comorbidity:* Appropriate treatment must have been rendered for any comorbid psychiatric disorder; the presence of psychoactive substance use or severe personality disorders are considered strong relative contraindications.
5. *Medical comorbidity and surgical fitness:* Structural brain lesions or significant central nervous system injuries are strong contraindications. Medical conditions that increase neurosurgical risks (e.g., cardiopulmonary disease) and age greater than 65 years are relative contraindications for lesion procedures, while for DBS, the relative age restriction might be older. A history of past seizures is a risk factor for perioperative seizures after lesion procedures and must be weighed in the overall risk–benefit assessment (again, data are currently less clear in this regard for psychiatric DBS).
6. *Access to postoperative care:* The psychiatric neurosurgery procedures themselves represent the beginning of a new episode of care. Patients must have access to adequate postoperative treatment, including a psychiatrist (typically the referring physician) who will accept responsibility for managing the case after discharge. Arrangements for postoperative care (e.g., intensive behavior therapy) should be confirmed ahead of time. Notably, after lesion procedures, care can generally be delivered in standard treatment settings without the need for highly specialized psychiatric neurosurgery teams. For DBS, access to such teams is essential over the long term. Once implanted, patients require clinical monitoring and device adjustment, which can be intensive and time-consuming, especially early in treatment. Device monitoring and replacements may need to occur on a relatively urgent basis. The continuing costs incurred can be substantial, and adequacy of third-party reimbursement needs to be ensured in advance to the extent possible. After either lesion procedures or DBS, family or significant others may be needed to support and accompany patients to follow-up care, similar to the level of support that is usually necessary during the intensive evaluation process.
7. *Informed consent:* Under no circumstances should psychiatric neurosurgery be performed on patients against their will. The patient must be able and willing to render informed consent. Formal consent

monitoring may be used to ensure that the consent process is adequate. In rare instances, these procedures are performed with the assent of the patient and formal consent from a legal guardian. In this context, age less than 18 years also represents a relative contraindication.

Postoperative Care

Immediate postoperative care includes the standard medical and surgical considerations following any stereotactic neurosurgical procedure. Special attention is paid to signs or symptoms of potential surgical complications, including infection, hemorrhage, seizures, or altered mental status. A postoperative MRI should be obtained to document the placement and extent of lesions. Intensive postoperative psychiatric treatment is recommended since the efficacy of the surgery may rely on some synergy between the neurosurgical intervention itself and enhanced response to pharmacologic or behavioral therapies. Although dosages of psychotropic medications may be reduced during the immediate perioperative period, the medication regimen should be readjusted as tolerated postoperatively. Moreover, in the case of OCD, intensive behavior therapy should be initiated as soon as possible, preferably within the first month postoperatively.

For DBS, electrode implantation is usually followed by a several-week delay to enable resolution of local edema and stabilization of other factors that might influence the response to stimulation. Then, systematic outpatient adjustment of stimulation parameters is performed before initial settings are determined. This adjustment is often a time-consuming process, lasting hours over one or more days. Ongoing protocols for DBS entail frequent follow-up, especially during the approximate 6 months after implantation, to enable optimization of stimulation parameters, monitoring of the patient, and coordination of other pharmacologic and behavioral therapies.

Lesion Procedures

Although numerous approaches have been tried, four lesion procedures have evolved as the safest and most effective for treating psychiatric disorders. All four entail bilateral lesions and are performed using modern stereotactic methods.

Subcaudate Tractotomy. Subcaudate tractotomy was introduced by Geoffrey Knight in Great Britain in 1964 as one of the first attempts to limit adverse effects by restricting lesion size. By targeting the substantia innominata (just inferior to the head of the caudate nucleus), the goal was to interrupt white matter tracts connecting the orbitofrontal cortex and subcortical structures. The surgery involved the placement of radioactive yttrium-90 seeds at the desired centroid, yielding lesion volumes of approximately 2 cc on each side. Indications for subcaudate tractotomy are major depression, OCD, and other severe anxiety disorders.

Anterior Cingulotomy. Anterior cingulotomy remains the most commonly employed neurosurgical treatment for psychiatric disease in North America. The surgery is conducted under local anesthesia, and two or three approximately 1-cc lesions are made on each side by thermocoagulation through bilateral burr holes. The target is within the anterior cingulate cortex (Brodmann areas 24 and 32), at the margin of the white matter bundle known as the cingulum. Initially, the placement of lesions was determined by ventriculography; however, since 1991, anterior cingulotomy has been conducted via MRI guidance. Approximately 40 percent of patients return several months following the first operation for a second procedure to extend the first set of lesions. The indications for anterior cingulotomy include major depression and OCD.

Limbic Leukotomy. Desmond Kelly and colleagues introduced limbic leukotomy in England in 1973. The procedure combines the targets of subcaudate tractotomy and anterior cingulotomy. The lesions have typically been made via thermocoagulation or with a cryoprobe. Historically, the precise placement of the lesions was guided by intraoperative stimulation; pronounced autonomic responses were believed to designate the optimal lesion site. The indications for limbic leukotomy include major depression, OCD, and other severe anxiety disorders. More recently, there is also some evidence that this procedure might be beneficial for repetitive self-injurious behaviors or in the context of severe tic disorders.

Anterior Capsulotomy. Anterior capsulotomy or its newer variant, Gamma Knife (Elekta, Stockholm) capsulotomy, are used in Scandinavia, the

United States, Belgium, Brazil, and elsewhere. The procedure places lesions within the anterior limb of the internal capsule, which impinges on the adjacent ventral striatum, thereby interrupting fibers of passage between the prefrontal cortex and subcortical nuclei, including the dorsomedial thalamus. Although the original anterior capsulotomy procedure is performed using thermocoagulation via burr holes in the skull, for the past 15 years, capsulotomy has used the Gamma Knife as an alternative. This radiosurgical instrument makes craniotomy unnecessary. Typically, gamma capsulotomy lesions are smaller than those induced by thermocapsulotomy, remaining within the ventral portion of the anterior capsule. Hence, the term *gamma ventral capsulotomy* is coming into use to describe this procedure.

In contrast to thermocapsulotomy, gamma ventral capsulotomy may be performed as an outpatient procedure, and at most, the patient might require one night of hospitalization. The relative advantages and disadvantages of this radiosurgical approach are the focus of ongoing research. Some data suggest, unsurprisingly, that the rates of neuropsychiatric adverse effects may be considerably lower for gamma ventral capsulotomy than for earlier procedures in which much larger tissue volumes were lesioned. Indications for anterior capsulotomy include major depression, OCD, and other severe anxiety disorders.

Deep Brain Stimulation

DBS for psychiatric illness is not a new idea, although the devices, surgical techniques, and theoretical models of relevant neurocircuitry have all advanced. The procedure involves the placement of small-diameter brain “leads” (e.g., approximately 1.3 mm) with multiple electrode contacts into subcortical nuclei or specific white matter tracts. The surgeon drills burr holes in skull bone under local anesthesia and then places the leads, guided by multimodal imaging and precise stereotactic landmarking. Usually, this is done bilaterally. The patient is typically sedated but awake during surgery. Later, the “pacemaker” (also known as an implantable neurostimulator or pulse generator) is implanted subdermally (e.g., in the upper chest wall) and connects via extension wires tunneled under the skin to the brain leads. The goals of DBS are to achieve improved efficacy and more favorable adverse effect profiles in comparison with ablation. Because various combinations of

electrodes can be activated, at adjustable polarity, intensity, and frequency, DBS allows more flexible modulation of brain function, referred to as *neuromodulation.* Thus, parameters can be optimized for individual patients, but the process, typically performed by a specially trained psychiatrist in the outpatient setting, can be quite time-consuming and requires attentive long-term follow-up. In cases where no beneficial settings can be identified despite extensive efforts, the electrodes can be inactivated, and devices may be removed. In that event, devices are usually only partly explanted, with the brain electrodes left in place given the small risk of hemorrhage upon removal. The relative advantages and disadvantages of DBS are the focus of very active research.

Treatment Outcome

For all four contemporary ablative procedures, outcomes cannot be fairly assessed for a considerable period postoperatively, which could extend from 6 months to 2 years. In the first two or three decades of this work, clinical reports usually employed measures of global improvements, such as the Pippard Postoperative Rating Scale, which rates outcomes as follows: (1) symptom-free, (2) much improved, (3) slightly improved, (4) unchanged, and (5) worse. Most studies have operationalized significant improvement as categories 1 and 2. Also, many of the reports employ a measure of symptom severity that is specific to the indication for the procedure (e.g., the Yale-Brown Obsessive-Compulsive Scale for OCD and the Beck Depression Inventory for major depression). Most studies focus on one or another of the procedures and are best reviewed according to the surgical approach.

Outcome with Subcaudate Tractotomy. Significant improvement was seen in 68 percent of patients with major depression, 50 percent of patients with OCD, and 62.5 percent of patients with other anxiety disorders. Patients with schizophrenia, substance abuse, or personality disorders did poorly. Short-term side effects include transient headache and confusion or somnolence, which typically resolve in less than 1 week. Patients are usually ambulatory by the third postoperative day. Transient disinhibition syndromes were common. In 1994, a large-scale review of 1,300 cases was conducted and concluded that the procedure enables 40 to 60 percent of patients to lead

normal or near-normal lives, with a reduction in suicide rate to 1 percent versus 15 percent in a similarly affected control group with major affective disorders.

Outcome with Anterior Cingulotomy. Significant improvement occurred in 62 percent of patients with affective disorders, 56 percent with OCD, and 79 percent with other anxiety disorders. Among patients with unipolar depression, 60 percent responded favorably; among patients with bipolar disorder, 40 percent responded favorably; and among patients with OCD, 27 percent were classified as responders with another 27 percent categorized as possible responders. Short-term side effects include headache, nausea, or difficulty with urination; however, these typically resolve within a few days. Patients are usually ambulatory within 12 hours following the operation and discharged on the third to fifth postoperative day. Over the past 10 years, the practice of treating patients who experience perioperative seizures with chronic anticonvulsant therapy has been discontinued, and no cases of new-onset recurrent seizures have been seen. Although patients have occasionally (5 percent or less) noted transient problems with memory, an independent analysis of 34 patients was performed. It demonstrated no significant intellectual or behavioral impairments attributable to anterior cingulotomy; a subsequent study of 57 patients likewise found no evidence for lasting neurologic or behavioral adverse effects.

Outcome with Limbic Leukotomy. Significant improvement occurred in 89 percent of patients with OCD, 78 percent with major depression, and 66 percent with other anxiety conditions. Short-term side effects include headache, lethargy or apathy, confusion, and lack of sphincter control, which may last from a few days to a few weeks. In particular, it is common for postoperative confusion to last at least several days, and patients are often not discharged in less than 1 week. There were no seizures and no deaths; however, one patient suffered severe memory loss due to improper lesion placement, and enduring lethargy was present in 12 percent of cases.

Outcome with Anterior Capsulotomy

THERMOCAPSULOTOMY. A favorable response occurred in 50 percent of those

with OCD and 48 percent of those with major depression. Short-term side effects can include transient headache or incontinence. Postoperative confusion often lasts for up to 1 week. Recovery from gamma capsulotomy is swifter and characterized by less discomfort and virtually no confusion, but side effects from radiation exposure, principally cerebral edema, may be delayed for up to 8 to 12 months. For the open capsulotomy, patients are typically ambulatory in a matter of hours to days following the operation, although the duration of confusion may influence the length of hospital stay. Weight gain has been noted to be a common enduring side effect with a mean increase in the mass of 10 percent.

GAMMA VENTRAL CAPSULOTOMY. Gamma capsulotomy was generally well tolerated and effective for patients with otherwise intractable OCD. Adverse events included cerebral edema and headache, small asymptomatic caudate infarctions, and possible exacerbation of preexisting bipolar mania. A therapeutic response, defined conservatively, was seen in 60 percent of over 50 patients receiving a gamma capsulotomy procedure, in which pairs of lesions in the ventral capsule are made bilaterally, impinging on the ventral striatum. The therapeutic benefit was achieved over 1 to 2 years and was essentially stable by 3 years. Adverse effects of gamma ventral capsulotomy include significant radiation-induced edema, appearing months after the procedure, apparently due to differential sensitivity to radiation that remains poorly understood. Long-term follow-up will be necessary to clarify the risks and benefits of gamma ventral capsulotomy. The same applies to any neurosurgery, including lesion procedures and DBS.

Outcomes with DBS

OBSESSIVE-COMPULSIVE DISORDER. Long-term outcomes of open stimulation in 26 patients showed clinically significant symptom reductions and functional improvement in about two-thirds of patients overall. Conservatively defined responses (35 percent or more significant reductions on the Yale-Brown Obsessive-Compulsive Scale) were seen in one-third of patients in the initial group, irrespective of the study center, while the response rate was over 70 percent in the second and third patient cohorts treated. The development of psychiatric DBS is following the path of

stimulation for movement disorders, where several targets have been pursued with therapeutic benefit. As in movement disorders, overlapping or converging effects of DBS at different anatomical sites on the neurocircuitry involved are likely and are a focus of active research. The same reasoning applies to DBS for depression.

MAJOR DEPRESSION. A body of functional neuroimaging research implicates the subgenual cingulate cortex as a node in circuits involved in the normal experience of sadness, symptoms of depressive illness, and responses to depression treatments. Chronic DBS for up to 6 months was associated with sustained remission of depression in four of the six patients studied. Another line of research on DBS for depression was prompted by the OCD research discussed above and also by the reported antidepressant effects of anterior capsulotomy on which the VC/VS (ventral capsule/ventral striatum) stimulation target was initially based. The OCD patients, who had very high rates of comorbid depression, characteristically responded to stimulation onset with mood enhancement and reductions in nonspecific as well as OCD-related anxiety. Such effects were accompanied, or even preceded by, improvements in social interaction and daily functioning. Worsening in these same clinical domains was noted in some patients with the cessation of VC/VS stimulation. Moreover, DBS-induced changes in mood and nonspecific anxiety often seemed to precede reductions in core OCD symptoms.

Outcome Across Contemporary Neurosurgical Procedures. Although the field is developing rapidly, the conclusion reached is that 40 to 70 percent of carefully selected psychiatric patients should meaningfully benefit from contemporary neurosurgical treatment. Twenty-five percent or more might be expected to show outstanding improvement. Responses to ablative procedures have appeared marginally superior for major depression than for OCD generally. The adverse effect profiles of this group of procedures are influenced by lesion size, the surgical approach, and whether radiosurgical methods (in which the tempo of lesion development is very slow vs. thermocoagulation) are used. However, adverse effects are greatly minimized in comparison with the procedures of the past. Although minor short-term side effects may be expected after some modern ablative

procedures, severe or enduring adverse consequences are relatively rare. These can include seizures in about 1 to 5 percent of cases. Although frontal syndromes, confusion, or subtle cognitive deficits can still be seen, overall cognitive function, as indicated by the standard intelligence quotient, is generally enhanced, a finding that has been attributed to the overriding beneficial effects of symptomatic improvement. Psychiatric neurosurgery likely reduces mortality, as evidenced by data on comparative suicide rates. Nonetheless, patients who undergo and fail to benefit from these procedures are at exceptionally high risk for completed suicide. Therefore, as with any therapy, the potential risks and benefits of psychiatric neurosurgery must be weighed against the potential risks and benefits of undergoing this brand of treatment.

The advent of DBS in psychiatry has created tremendous interest and considerable research activity. This therapy is intentionally nonablative, can be optimized for individual patients, is reversible, and is based on devices that are (to varying degrees) removable. DBS may therefore be accepted by patients who would not choose to undergo lesion procedures (although the reverse is also true). With all of its advantages, DBS requires that patients be treated by highly specialized teams willing and able to provide long-term care. The logistics and expenses involved can represent significant barriers.

In contrast, psychiatric care can be delivered in standard treatment settings after lesion procedures. However, although the relative risks of enduring adverse effects after psychiatric DBS remain to be established, at this stage, ablative methods appear to carry a more significant risk. Because rates of adverse outcomes are low when modern lesion procedures are performed at highly experienced centers, there may be a particularly strong rationale for referral of appropriate patients to such expert centers.

23 Psychotherapy

This chapter provides an overview of common psychotherapeutic approaches, covering a broad spectrum of therapy modalities.

PSYCHOANALYSIS AND PSYCHOANALYTIC PSYCHOTHERAPY

As broadly practiced today, psychoanalytic treatment encompasses a wide range of uncovering strategies used in varying degrees and blends. Despite the inevitable blurring of boundaries in actual application, we describe the original modality of classic psychoanalysis and major modes of psychoanalytic psychotherapy (expressive and supportive) separately here (Table 23-1). Analytical practice, in all its complexity, resides on a continuum. The individual technique is always a matter of emphasis, as the therapist titrates the treatment according to the needs and capacities of the patient at every moment.

Psychoanalysis is virtually synonymous with the renowned name of its founding father, Sigmund Freud. It is also referred to as “classic” or “orthodox” psychoanalysis to distinguish it from more recent variations known as *psychoanalytic psychotherapy*.

Psychoanalysis is based on the theory of sexual repression and traces the unfulfilled infantile libidinal wishes in the individual’s unconscious memories. It remains unsurpassed as a method to discover the meaning and motivation of behavior, especially the unconscious elements that inform thoughts and feelings.

Psychoanalysis

Psychoanalytic Process. The psychoanalytic process involves bringing to the surface repressed memories and feelings through a scrupulous unraveling of hidden meanings of verbalized material and of the unwitting ways in which the patient wards off underlying conflicts through defensive forgetting and repetition of the past.

The overall process of analysis is one in which unconscious neurotic conflicts are recovered from memory and verbally expressed, reexperienced in the transference, reconstructed by the analyst, and, ultimately, resolved through understanding. Freud referred to these processes as *recollection, repetition,* and *working through,* which make up the totality of remembering, reliving, and gaining insight. *Recollection* entails the extension of memory back to early childhood events, a time in the distant past when the core of neurosis developed. The actual reconstruction of these events comes through reminiscence, associations, and autobiographical linking of developmental events. *Repetition* involves more than mere mental recall; it is an emotional replay of former interactions with significant individuals in the patient's life. The replay occurs within the unique context of the analyst as a projected parent, a fantasized object from the patient's past with whom the latter unwittingly reproduces forgotten, unresolved feelings and experiences from childhood. Finally, *working through* is both an affective and cognitive integration of previously repressed memories that are brought into consciousness and through which the patient is gradually set free (cured of neurosis). The analytical course includes three major stages (Table 23-2).

Indications and Contraindications. In general, all of the so-called *psychoneuroses* are suitable for psychoanalysis. These include anxiety disorders, obsessional thinking, compulsive behavior, conversion disorder, sexual dysfunction, depressive states, and many other nonpsychotic conditions, such as personality disorders. Significant suffering must be present so that patients are motivated to make the sacrifices of time and financial resources required for psychoanalysis. Patients who enter analysis must have a genuine wish to understand themselves, not a desperate hunger for symptomatic relief. They must be able to withstand frustration, anxiety, and other strong affects that emerge in the analysis without fleeing or acting out their feelings in a self-destructive manner. They must also have a reasonable, mature superego that allows them to be honest with the analyst.

Intelligence must be at least average, and above all, they must be psychologically minded in the sense that they can think abstractly and symbolically about the unconscious meanings of their behavior.

Many contraindications for psychoanalysis are the flip side of the indications. The absence of suffering, poor impulse control, inability to tolerate frustration and anxiety, and low motivation to understand are all contraindications. The presence of extreme dishonesty or antisocial personality disorder contraindicates analytic treatment. Concrete thinking or the absence of psychological mindedness is another contraindication. Some patients who might ordinarily be psychologically minded are not suitable for analysis because they are in the midst of a major upheaval or life crisis, such as a job loss or a divorce. Serious physical illness can also interfere with a person's ability to invest in a long-term treatment process. Patients of low intelligence generally do not understand the procedure or cooperate in the process. An age older than 40 years was once considered a contraindication, but today analysts recognize that patients are malleable and analyzable in their 60s or 70s. One final contraindication is a close relationship with the analyst. Analysts should avoid analyzing friends, relatives, or persons with whom they have other involvements.

Patient Requisites. Table 23-3 lists the most important patient requisites for psychoanalysis.

Table 23-1
Scope of Psychoanalytic Practice: A Clinical Continuum

Features	"Classic" Analytic	Expressive Mode (Exploratory)	Support Mode
Frequency	Regular 4–5 times/wk; "50-minute hour"	Regular 1–3 times/wk; 1/2 to full hour	Flexible or less needed full ho
Duration	Long term; usually 3–5+ yr; maybe considerably	Short or long term; several sessions to months or	Short or interm long te

	longer	years	single to lifet
Setting	Patient primarily on couch with analyst out of view	Patient and therapist face to face; occasional use of couch	Patient a therap to-face contra
Modus operandi	Systematic analysis of all positive and negative transference and resistance; primary focus on analyst and intrasession events; transference neurosis facilitated; regression encouraged	Partial analysis of dynamics and defenses; focus on current interpersonal events and transference to others outside of sessions; analysis of negative transference; positive transference left unexplored unless it impedes progress; limited regression encouraged	Formatic therap allianc real ob relatio analys transfe contra with ra excep focus consci extern regres discou
Analyst/therapist role	Absolute neutrality; frustration of patient; reflector/mirror role	Modified neutrality; implicit gratification of patient and greater activity of therapist	Neutralit suspe limited gratific directi disclos
Mutative change agents	Insight predominates within relatively	Insight within more empathic environment;	Auxiliary surrog as a te

	deprived environment	identification with benevolent object	substit holdin enviro insight degree
Patient population	Neuroses; mild character psychopathology	Neuroses; mild to moderate character psychopathology, especially narcissistic and borderline disorders	Severe d disord latent manife psych acute physic
Patient requisites	High motivation, psychological mindedness, good previous object relationships, ability to maintain transference neuroses, good frustration tolerance	High moderate motivation and psychological-mindedness, ability to form therapeutic alliance, some frustration tolerance	Some de motiva ability therap allianc
Basic goals	Structural reorganization of personality; resolution of unconscious conflicts; insight into intrapsychic events; symptom relief	Partial reorganization of personality and defenses; resolution of preconscious and conscious derivatives of conflicts; insight	Reintegr self ar to cop stabiliz restora preexi equilib streng of defe

	an indirect result	into current interpersonal events; improved object relations; symptom relief a goal or prelude to further exploration	better adjust accep pathol sympt and enviro restruc primar
Major techniques	Free association method predominates; full dynamic interpretation (including confrontation, clarification, and working through), with emphasis on genetic reconstruction	Limited free association; confrontation, clarification, and partial interpretation predominate, with emphasis on here-and-now interpretation and limited genetic interpretation	Free ass metho contra sugge (advic predor abreac useful confro clarific and interpr the he now a secon geneti interpr contra
Adjunct treatment	Primarily avoided; if applied, all negative and positive meanings and implications thoroughly analyzed more	May be necessary, e.g., psychotropic drugs as temporary measure; if applied, negative implications are	Often ne e.g., psych drugs, rehabi therap hospit if appl

	recently, medication adjunct	explored and diffused	positiv implica empha

This division is not categorical; all practice resides on a clinical continuum.

Ms. M, a 29-year-old unmarried woman who worked in a low-level capacity for a magazine, presented for consultation with the chief complaints of considerable sadness and distress over her parent's reaction when they found that she had had a homosexual relationship. She also realized that she had been working far below her potential. She had never sought any treatment before. She was clearly intelligent, sensitive, self-reflective, and insightful. When she learned about the possibility of psychoanalysis as a treatment option, she worried that meant she was "sicker." Ms. M, however, began reading Freud, realized that analysis was actually recommended for those who are higher functioning, and became intrigued by the idea. She agreed to come 4 days a week for 50-minute sessions.

She was the oldest of three children and the only girl. Ms. M's father, a successful professional, was described as very demanding and intrusive; someone who never thought anything was good enough. He had always expected his children to do the "extra credit" assignments as part of their regular work. Ms. M, however, was very proud of her father's accomplishments. She spoke of her mother in conflicting terms as well: she was a homemaker, weak, and sometimes acquiescent to the powerful father but also an individual in her own right who was involved in community volunteer work and could be a powerful public speaker.

Just before beginning her analysis, Ms. M had had her wallet stolen. In her first analytic session, she spoke of losing all of her identification cards, and to her, it seemed as if she were starting analysis "with a completely new identity." Initially, she was somewhat hesitant to use the couch because she wanted to see her analyst's reactions, but Ms. M quickly appreciated that she could associate more easily without seeing the analyst.

As her analysis proceeded, through dreams and free associations, Ms. M became quite focused on the analyst. She became extremely curious

about the analyst's life. What emerged from her associations to seeing the analyst's appointment book on the desk was that she felt "slotted in." Whenever Ms. M saw other patients, she felt the office was "like an assembly line." Further associations led to her feeling slotted in by her parents as they ran from one activity to another. Her resistance manifested itself in Ms. M, often coming as much or more than 15 minutes late to her sessions. Her associations led to her admitting that she did not want her analyst to think that she was "too eager." Ms. M was able to see that she needed to devalue her analyst and her importance to Ms. M as a defense against an overwhelmingly positive and even erotic transference toward her.

For example, Ms. M wanted to improve her appearance so that the therapist, whom she called a "role model," would find her more attractive. Her negative transference, however, was never far from the surface, and she denigrated the analyst by wondering if the analyst were a "clotheshorse" who was financing her wardrobe with the patient's payments.

Her conflicts about her sexual orientation were a central preoccupation in the course of her analysis, particularly because her father was homophobic. Early on, Ms. M felt awkward and uncomfortable when she went to a lesbian bar, and when asked if she qualified for the "lesbian discount," she said she did not. At one point, she began seeing several men, including a male psychologist. The analyst made the transference interpretation, which Ms. M accepted, that a date with this man seemed as if it were a date with the analyst, and sleeping with him would be equivalent to sleeping with the analyst. Ms. M was also able to see that her transient choice of dating a male therapist was a defensive compromise. Although her homosexual object choice was multidetermined, Ms. M came to appreciate, through her work in analysis, that at least a part of her conflicts about homosexuality stemmed from her relationship with her father. It was a means of securing his attention as well as infuriating him.

Over 4 years, Ms. M performed considerably better at work and earned a promotion to a job commensurate with her potential. She was also able to deal better with both her parents and particularly her father, regarding her sexual orientation. She became much more comfortable with her

"new identity" and became involved in a relationship with a professional woman. At the end of therapy, Ms. M and this woman were committed to each other and considering adopting a child. (Courtesy of T. Byram Karasu, M.D. and S. R. Karasu, M.D.)

Goals. In developmental terms, psychoanalysis aims at the gradual removal of amnesias rooted in early childhood based on the assumption that filling all gaps in memory will lead to cessation of the morbid condition because the patient no longer needs to repeat or remain fixated to the past. The patient should be better able to relinquish former regressive patterns and to develop new, more adaptive ones, particularly as he or she learns the reasons for his or her behavior. A related goal of psychoanalysis is for the patient to achieve some measure of self-understanding or insight.

Table 23-2
Stages of Psychoanalysis

Stage one: Patient becomes familiar with the methods, routines, and requirements of analysis, and a realistic therapeutic alliance is formed between patient and analyst. Basic rules are established; the patient describes his or her problems; there is some review of history, and the patient gains initial relief through catharsis and a sense of security before delving more deeply into the source of the illness. The patient is primarily motivated by the wish to get well.

Stage two: Transference neurosis emerges that substitutes for the actual neurosis of the patient and in which the wish for health comes into direct conflict with the simultaneous wish to receive emotional gratification from the analyst. There is a gradual surfacing of unconscious conflicts; an increased irrational attachment to the analyst, with regressive and dependent concomitants of that bond; a developmental return to earlier forms of relating (sometimes compared with that of mother and infant); and a repetition of childhood patterns and recall of traumatic memories through transfer to the analyst of unresolved libidinal wishes.

Stage three: The termination phase is marked by the dissolution of the analytical bond as the patient prepares for leave-taking. The irrational attachment to the analyst in the transference neurosis has subsided because it has been worked through, and more rational aspects of the psyche preside, providing greater mastery and more mature adaptation to the patient's problems. Termination is not a hard-and-fast event, and the patient invariably has to continue to work through any problems outside of the therapy situation without the analyst or may need intermittent assistance after analysis has technically terminated.

Courtesy of T. Byram Karasu, M.D.

Table 23-3
Patient Prerequisites for Psychoanalysis

High motivation. The patient needs a strong motivation to persevere, in light of the rigors of intense and lengthy treatment. The desire for health and self-understanding must surpass the neurotic need for unhappiness. The patient must be willing to face issues of time and money and to endure the pain and frustration associated with sacrificing rapid relief in favor of future cure and with foregoing the secondary gains of illness.

Ability to form a relationship. The capacity to form and maintain, as well as to detach from, a trusting object relationship is essential. The patient also has to withstand a frustrating and regressive transference without decompensating or becoming excessively attached. Patients with a history of impaired or transient interpersonal relations who cannot establish a viable connection to another human make poor candidates for psychoanalysis.

Psychological mindedness and capacity for insight. As an introspective process, psychoanalysis requires curiosity about oneself and the capacity for self-scrutiny. Those who are unable to articulate and comprehend their inner thoughts and feelings cannot negotiate with the fundamental analytical coin words and their meanings. The inability to examine one's own motivations and

behaviors precludes benefits from the analytical method.

Ego strength. Ego strength is the integrative capacity to oscillate appropriately between two antithetical types of ego functioning: On the one hand, the patient must be able to reflect temporarily, to relinquish reality for fantasy, and to be dependent and passive. On the other hand, the patient has to be able to accept analytical rules, to integrate interpretations, to defer important decisions, to shift perspectives to become an observer of his or her intrapsychic processes, and to function in a sustained interpersonal relationship as a responsible adult.

Courtesy of T. Byram Karasu, M.D.

Psychoanalytic goals often seem formidable (e.g., a total personality change), involving the radical reorganization of old developmental patterns based on earlier affects and the entrenched defenses built up against them. Goals may also be elusive, framed as they are in theoretical intrapsychic terms (e.g., greater ego strength) or conceptually ambiguous ones (resolution of the transference neurosis). Criteria for successful psychoanalysis may be largely intangible and subjective, and it is best to view them as conceptual endpoints of treatment that the therapist must translate into more realistic and practical terms.

In practice, the goals of psychoanalysis for any patient naturally vary, as do the many manifestations of neuroses. The form that the neurosis takes—unsatisfactory sexual or object relationships, inability to enjoy life, underachievement, and fear of work or academic success, or excessive anxiety, guilt, or depressive ideation—determines the focus of attention and the general direction of treatment, as well as the specific goals. Such goals may change at any time during analysis, especially as many years of treatment may be involved.

Major Approach and Techniques. Structurally, *psychoanalysis* usually refers to individual (dyadic) treatment that is frequent (four or five times per week) and long term (several years). All three features take their precedent from Freud himself.

The dyadic arrangement is a direct function of the Freudian theory of neurosis as an intrapsychic phenomenon, which takes place within the person

as instinctual impulses continually seek discharge. Because it is crucial to resolve dynamic conflicts internally if structural personality reorganization is to take place, the individual's memory and perceptions of the repressed past are pivotal.

Freud initially saw patients 6 days a week for 1 hour each day, a routine now reduced to four or five sessions per week of the classic 50-minute hour, which leaves time for the analyst to take notes and organize relevant thoughts before the next patient. Therapists should avoid long intervals between sessions so that the momentum gained in uncovering conflictual material is not lost, and confronted defenses do not have time to restrengthen.

Freud's belief that successful psychoanalysis always takes a long time because profound changes in the mind occur slowly still holds. The process is similar to the fluid sense of time that is characteristic of our unconscious processes. Moreover, because psychoanalysis involves a detailed recapitulation of present and past events, any compromise in time presents the risk of losing pace with the patient's mental life.

PSYCHOANALYTIC SETTING. As with other forms of psychotherapy, psychoanalysis takes place in a professional setting, apart from the realities of everyday life, in which the therapist offers the patient a temporary sanctuary in which to ease psychic pain and reveal intimate thoughts to an accepting expert. The design of the psychoanalytic environment promotes relaxation and regression. The setting is usually spartan and sensorially neutral and minimizes external stimuli.

Use of the Couch. The couch has several clinical advantages that are both real and symbolic: (1) the reclining position is relaxing because it is associated with sleep and so eases the patient's conscious control of thoughts; (2) it minimizes the intrusive influence of the analyst, thus curbing unnecessary cues; (3) it permits the analyst to make observations of the patient without interruption; and (4) it holds a symbolic value for both parties, a tangible reminder of the Freudian legacy that gives credibility to the analyst's professional identity, allegiance, and expertise. The reclining position of the patient with analyst nearby can also generate threat and discomfort, however, as it recalls anxieties derived from the earlier parent–child configuration that it physically resembles. It may also have personal meanings—for some, a

portent of dangerous impulses or submission to an authority figure; for others, relief from confrontation by the analyst (e.g., fear of the use of the couch and over-eagerness to lie down may reflect resistance and, thus, need to be analyzed). Although the use of the couch is requisite to the analytical technique, it is not applied automatically; the therapist introduces it gradually and may suspend its use whenever additional regression is unnecessary or countertherapeutic.

Fundamental Rule. The fundamental rule of free association requires patients to tell the analyst everything that comes into their heads—however disagreeable, unimportant, or nonsensical—and to let themselves go as they would in a conversation that leads from "cabbages to kings." It differs decidedly from ordinary conversation—instead of connecting personal remarks with a rational thread, the therapist asks the patient to reveal those very thoughts and events that are objectionable precisely because of being averse to doing so.

This directive represents an ideal because free association does not arise freely but is guided and inhibited by a variety of conscious and unconscious forces. The analyst must not only encourage free association through the physical setting and a nonjudgmental attitude toward the patient's verbalizations but also examine those very instances when the flow of associations is diminished or comes to a halt—they are as important analytically as the content of the associations. The analyst should also be alert to how individual patients use or misuse the fundamental rule.

Aside from its primary purpose of eliciting recall of deeply hidden early memories, the fundamental rule reflects the analytical priority placed on verbalization, which translates the patient's thoughts into words, so the patient does not channel them physically or behaviorally. As a direct concomitant of the fundamental rule, which prohibits action in favor of verbal expression, patients should postpone making significant alterations in their lives, such as marrying or changing careers, until they discuss and analyze them within the context of treatment.

Principle of Evenly Suspended Attention. As a reciprocal corollary to the rule that patients communicate everything that occurs to them without criticism or selection, the principle of evenly suspended attention requires the analyst to

suspend judgment and to give impartial attention to every detail equally. The method consists simply of making no effort to concentrate on anything specific while maintaining a neutral, quiet attentiveness to all that the patient says.

Analyst as Mirror. A second principle is the recommendation that the analyst is impenetrable to the patient and, like a mirror, only reflect what the patient shows. Analysts should be neutral blank screens and not bring their personalities into treatment. They are not to bring their values or attitudes into the discussion or to share personal reactions or mutual conflicts with their patients, although they may sometimes feel the temptation to do so. The bringing in of reality and external influences can interrupt or bias the patient's unconscious projections. Neutrality also allows the analyst to accept without censure all forbidden or objectionable responses.

Rule of Abstinence. The fundamental rule of abstinence does not mean corporal or sexual abstinence but refers to the frustration of emotional needs and wishes that the patient may have toward the analyst or part of the transference. It allows the patient's longings to persist and serve as driving forces for analytical work and motivation to change. Freud advised that the analyst proceeds through the analytical treatment in a state of renunciation. The analyst must deny the patient who is longing for love the satisfaction he or she craves.

LIMITATIONS. At present, the predominant treatment constraints are often economic, relating to the high cost in time and money, both for patients and in the training of future practitioners. In addition, because clinical requirements emphasize such requisites as psychological mindedness, verbal and cognitive ability, and stable life situation, psychoanalysis may be unduly restricted to a diagnostically, socioeconomically, or intellectually advantaged patient population. Other intrinsic issues pertain to the use and misuse of its stringent rules, whereby overemphasis on technique may interfere with an authentic human encounter between analyst and patient, and to the major long-term risk of interminability, in which protracted treatment may become a substitute for life. The reification of the classic analytical tradition may interfere with a more open and flexible application of its tenets to meet

changing needs. It may also obstruct a comprehensive view of patient care that includes a greater appreciation of other treatment modalities in conjunction with or as an alternative to psychoanalysis.

Ms. A, a 25-year-old articulate and introspective medical student began analysis complaining of mild, chronic anxiety, dysphoria, and a sense of inadequacy, despite above-average intelligence and performance. She also expressed difficulty in long-term relationships with her male peers.

Ms. A began the initial phase of analysis with enthusiastic self-disclosure, frequent reports of dreams and fantasies, and over idealization of the analyst; she tried to please him by being a compliant, good patient, just as she had been a good daughter to her father (a professor of medicine) by going to medical school.

Over the next several months, Ms. A gradually developed a strong attachment to the analyst and settled into a phase of excessive preoccupation with him. Simultaneously, however, she began dating an older psychiatrist and proceeded to complain about the analyst's coldness and unresponsiveness, even considering dropping out of the analysis because he did not meet her demands.

In the course of analysis, through dreams and associations, Ms. A recalled early memories of her ongoing competition with her mother for her father's attention and realized that failing to obtain his exclusive love, she had tried to become like him. She was also able to see how her increasing interest in becoming a psychiatrist (rather than following her original plan to be a pediatrician), as well as her recent choice of a man to date, were recapitulations of the past vis-à-vis the analyst. As this repeated pattern was recognized, the patient began to relinquish her intense erotic and dependent tie to the analyst, viewing him more realistically and beginning to appreciate how his quiet presence reminded her of her mother. She also became less disturbed by the similarities she shared with her mother and was able to disengage from her father more comfortably. By the fifth year of analysis, she was happily married to a former classmate, was pregnant, and was a pediatric chief resident. Her anxiety had attenuated and become situation-specific (i.e., she was concerned about motherhood and the termination of analysis). (Courtesy

of T. Byram Karasu, M.D.)

Psychoanalytic Psychotherapy

Psychoanalytic psychotherapy, based on fundamental dynamic formulations and techniques that derive from psychoanalysis, is designed to broaden its scope. Psychoanalytic psychotherapy, in its narrowest sense, is the use of insight-oriented methods only. As generically applied today to an ever-larger clinical spectrum, it incorporates a blend of uncovering and suppressive measures.

The strategies of psychoanalytic psychotherapy currently range from expressive (insight-oriented, uncovering, evocative, or interpretive) techniques to supportive (relationship-oriented, suggestive, suppressive, or repressive) techniques. Although those two methods may seem antithetical, their precise definitions and the distinctions between them are by no means absolute.

The duration of psychoanalytic psychotherapy is generally shorter and more variable than in psychoanalysis. Treatment may be brief, even with an initially agreed-upon or fixed time limit, or may extend to a less definite number of months or years. Brief treatment is chiefly used for selected problems or highly focused conflict, whereas more prolonged treatment may be applied for more chronic conditions or for intermittent episodes that require ongoing attention to deal with pervasive conflict or recurrent decompensation. Unlike psychoanalysis, psychoanalytic psychotherapy rarely uses the couch; instead, the patient and therapist sit face to face. This posture helps to prevent regression because it encourages the patient to look at the therapist as a real person from whom to receive direct cues, even though transference and fantasy will continue. The couch is unnecessary because the free-association method is rarely used, except when the therapist wishes to gain access to fantasy material or dreams to enlighten a particular issue.

Expressive Psychotherapy

INDICATIONS AND CONTRAINDICATIONS. Diagnostically, psychoanalytic psychotherapy in its expressive mode is suited to a range of psychopathology with mild to moderate ego weakening, including neurotic conflicts, symptom

complexes, reactive conditions, and the whole realm of nonpsychotic character disorders, including those disorders of the self that are among the more transient and less profound on the severity-of-illness spectrum, such as narcissistic personality disorders. It is also one of the treatments recommended for patients with borderline personality disorders (BPDs), although special variations may be required to deal with the associated turbulent personality characteristics, primitive defense mechanisms, tendencies toward regressive episodes, and irrational attachments to the analyst.

Ms. B, an intelligent and verbal 34-year-old divorced woman, presented with complaints of being unappreciated at work. Always angry and irritable, she considered quitting her job and even leaving the city. Her social life was also being negatively affected; her boyfriend had threatened to leave her because of her extremely hostile, clinging behavior (the same reason her ex-husband had given when he left her 9 years earlier after only 16 months of marriage). Her past included promiscuity and experimentation with various drugs, and, currently, she indulged in heavy drinking on weekends and occasionally smoked marijuana. She had held many jobs and had lived in various cities.

The eldest of three children of a middle-class family, she came from an unhappy and unstable home: her brother had been in and out of psychiatric hospitals; her sister had left home at the age of 16 after becoming pregnant and being forced to marry; and her overly controlling parents had subjected their children to psychological (and occasionally physical) abuse, alternating between heated arguments and passionate reconciliations.

Initially, Ms. B attempted to contain her rage in treatment, but it frequently surfaced and alternated with child-like helplessness; she interrogated the psychiatrist regarding his credentials, ridiculed psychodynamic concepts, constantly challenged statements, and would demand practical advice but then denigrate or fail to follow the guidance given. The psychiatrist remained unprovoked by her aggression and explored with her the need to engage him negatively. Her response was to question and test his continued concern.

When her boyfriend left her, she attempted suicide (she cut her wrists superficially), was briefly hospitalized, and, on discharge, was placed on a selective serotonin reuptake inhibitor (SSRI) for 6 months for her minor, but protracted, depression. The psychiatrist maintained their regular frequency of sessions despite her greater demands. Although she was puzzled by the steadiness of his interest, she gradually felt safe enough to express her vulnerabilities. As they explored her lack of full commitment to work, friends, and therapy, she began to understand the meaning of her anger in terms of the early abusive relationship with her parents and her tendency to bring it into contemporary relationships. With the psychiatrist's encouragement, she also began to seek work and make small strides in relationship-oriented efforts. By the end of her second year of treatment, she decided to remain in the city, to stay at her place of employment, and to continue therapy. She needed to experience and practice her somewhat fragile new self, which included greater intimacy in relationships, additional mastery of work skills, and a more cohesive sense of self. (Courtesy of T. Byram Karasu, M.D.)

The persons best suited for the expressive psychotherapy approach have reasonably well-integrated egos and the capacity to both sustain and detach from a bond of dependency and trust. They are, to some degree, psychologically minded and self-motivated, and they are generally able, at least temporarily, to tolerate doses of frustration without decompensating. They must also have the ability to manage the rearousal of painful feelings outside the therapy hour without additional contact. Patients must have some capacity for introspection and impulse control, and they should be able to recognize the cognitive distinction between fantasy and reality.

GOALS. The overall goals of expressive psychotherapy are to increase the patient's self-awareness and to improve object relations through the exploration of current interpersonal events and perceptions. In contrast to psychoanalysis, expressive psychotherapy modifies major structural changes in ego function and defenses in light of patient limitations. The aim is to achieve a more limited and, thus, select and focused understanding of one's problems. Rather than uncovering deeply hidden and past motives and tracing

them back to their origins in infancy, the major thrust is to deal with preconscious or conscious derivatives of conflicts as they became manifest in present interactions. Although the therapy seeks insight, it is less extensive; instead of delving to a genetic level, greater emphasis is on clarifying recent dynamic patterns and maladaptive behaviors in the present.

MAJOR APPROACH AND TECHNIQUES. The primary modus operandi involves the establishment of a therapeutic alliance and early recognition and interpretation of negative transference. Only limited or controlled regression is encouraged, and positive transference manifestations are generally left unexplored unless they are impeding therapeutic progress; even here, the emphasis is on shedding light on current dynamic patterns and defenses.

LIMITATIONS. A general limitation of expressive psychotherapy, as of psychoanalysis, is the problem of emotional integration of cognitive awareness. The primary danger for patients who are at the more disorganized end of the diagnostic spectrum, however, may have less to do with the over intellectualization that is sometimes seen in neurotic patients than with the threat of decompensation from or acting out of, deep or frequent interpretations that the patient is unable to integrate properly.

Some therapists fail to accept the limitations of a modified insight-oriented approach and so apply it inappropriately to modulate the techniques and goals of psychoanalysis. Overemphasis on dreams and fantasies, zealous efforts to use the couch, indiscriminate deep interpretations, and continual focus on the analysis of transference may have less to do with the patient's needs than with those of a therapist who is unwilling or unable to be flexible.

Ms. S was an attractive 30-year-old unmarried woman working as a secretary when she presented for consultation. Her chief complaints at the time were feeling "only anger and tension" and an inability to apply herself to studying voice, "which is one of the most important things to me."

In obtaining a history, the therapist noted that Ms. S had never completed anything: she had dropped out of college, never pursued a music degree, and switched from job to job, and even city to city. What

initially seemed like a woman with diverse interests (e.g., jobs as a research assistant; freelance copyeditor; part-time radio announcer; manager of data entry for a software company; and, most recently, secretary) actually reflected a woman with a chaotic lifestyle and serious difficulties committing to anyone or anything. Although obviously intelligent, Ms. S presented with unrealistic expectations regarding her consultation. For example, after the first consultative session, Ms. S said she felt good afterward but felt there were "no revelations yet." Because of Ms. S's inability to commit and her somewhat disorganized life, the therapist recommended a course of psychotherapy, beginning twice a week, rather than something more intense like psychoanalysis. The therapist also realized throughout the consultation that Ms. S would have difficulty with free association without getting disorganized. The therapist also thought that Ms. S might regress unproductively on the couch without visual contact with the therapist.

Ms. S was the second oldest of four children—two brothers and a younger sister, with whom she was most competitive and who seemed the mother's favorite. She described her mother as a successful professor who was demanding and critical as if she had a "raised eyebrow" in disapproval. For example, much to her mother's chagrin, Ms. S had once wanted a sandwich "with everything on it." Ms. S was also disappointed when she received one piece of luggage rather than a complete set for a Christmas gift. She was able to accept the therapist's interpretation that she felt "part of a set" by being one of four siblings. Ms. S initially idealized her father, who was active in the family church, but eventually saw him as disappointing and rejecting.

Ms. S's ideal therapist would be "flexible," by which she meant a therapist who might do hypnosis one session, psychotherapy the next, and, maybe, analysis another session. In fact, within the first week of beginning therapy, Ms. S had simultaneously consulted a hypnotherapist, which she mentioned in passing only weeks later, for her neck pain and tension. Although she did not pursue hypnosis, she did maintain a chiropractor for most of her therapy, also something she mentioned many months after beginning therapy. She did speak of wanting to be "on best behavior" and "follow the rules." Her tremendous sense of entitlement, however, was evident: she expected "cut-rate prices" on everything from

haircuts and car repairs to doctors' visits. Her initial fee was a much reduced one, which she paid late and begrudgingly.

Although she had therapy only twice a week, Ms. S developed intense feelings for her therapist. Mostly she experienced rage when she saw evidence of the therapist's other patients, such as footprints on the waiting room floor after a snowstorm or a coat hanger turned around. She expressed the wish to keep some of her things, like bobby pins and hairspray, in the therapist's bathroom. She vacillated between feelings she wanted to move in and feelings that the therapist did not exist. For example, before she took a plane flight, she wondered who would tell her therapist if something happened to her. She had never given the therapist's name to anyone, nor did she have her name in her weekly appointment book. The therapist interpreted that she had a simultaneous wish to devalue her and not to share her with anyone else. Associations to a dream with an image of a string of baroque pearls led to thoughts that these pearls—irregular and imperfect—defective and even lopsided, represented how she viewed herself.

Over the next few years, Ms. S was able to commit to regularly coming to therapy, although the course was somewhat tumultuous, with many threats of quitting and much withholding of information. At one point, she even tried to provoke the therapist by seeking a consultation with another therapist in order to "tattle" on her, just as she had tattled on her siblings. Her therapist remained unprovoked and continued to provide a safe environment for Ms. S to explore her ambivalence to the therapist and the therapeutic situation. The therapist was also able to contain Ms. S's tendency to regress, particularly with separations, by providing her with the therapist's telephone number.

She had actually entered therapy with an unconscious wish to become a world-famous singer who would win her mother's approval and praise. Her narcissism and sense of entitlement made it difficult for her to give up on that fantasy despite repeated evidence that she did not have sufficient talent. She was finally able to settle on a compromise: she began to work diligently and closely as a research assistant to her mother, who was writing a book, and as Ms. S became more focused and organized over time, she even thought she might write a book about the church. (Courtesy of T. Byram Karasu, M.D. and S. R. Karasu, M.D.)

Supportive Psychotherapy. Supportive psychotherapy aims at the creation of a therapeutic relationship as a temporary buttress or bridge for the deficient patient. It has roots in virtually every therapy that recognizes the ameliorative effects of emotional support and a stable, caring atmosphere in the management of patients. As a nonspecific attitude toward mental illness, it predates scientific psychiatry, with foundations in 18th-century moral treatment, whereby for the first time, patients received understanding and kindness in a humane, interpersonal treatment environment free from mechanical restraints.

Supportive psychotherapy has been the primary form used in the general practice of medicine and rehabilitation, frequently to augment other measures, such as prescriptions of medication to suppress symptoms, rest to remove the patient from excessive stimulation, or hospitalization to provide a structured therapeutic environment, protection, and control of the patient. It can serve as primary or ancillary treatment. The global perspective of supportive psychotherapy (often part of a combined treatment approach) places major etiologic emphasis on external rather than intrapsychic events, particularly on stressful environmental and interpersonal influences on a severely damaged self.

INDICATIONS AND CONTRAINDICATIONS. Supportive psychotherapy is generally indicated for those patients for whom classic psychoanalysis or insight-oriented psychoanalytic psychotherapy is typically contraindicated—those who have poor ego strength and whose potential for decompensation is high. Amenable patients fall into the following major areas: (1) individuals in acute crisis or a temporary state of disorganization and inability to cope (including those who might otherwise be well functioning) whose intolerable life circumstances have produced extreme anxiety or sudden turmoil (e.g., individuals going through grief reactions, illness, divorce, job loss, or who were victims of crime, abuse, natural disaster, or accident); (2) patients with chronic severe pathology with fragile or deficient ego functioning (e.g., those with latent psychosis, impulse disorder, or severe character disturbance); (3) patients whose cognitive deficits and physical symptoms make them particularly vulnerable and, thus, unsuitable for an insight-oriented approach

(e.g., certain psychosomatic or medically ill persons); and (4) individuals who are psychologically unmotivated, although not necessarily characterologically resistant to a depth approach (e.g., patients who come to treatment in response to family or agency pressure and are interested only in immediate relief or those who need assistance in very specific problem areas of social adjustment as a possible prelude to more exploratory work).

Mr. C, a 50-year-old married man with two sons, the owner of a small construction company, was referred by his internist after recovery from bypass surgery because of frequent, unfounded physical complaints. He was taking minor tranquilizers in increasing doses, not adhering to his daily regimen, avoiding sexual contact with his wife, and had dropped out of group therapy for postsurgical patients after one session.

He came to his first appointment 20 minutes late, after having "forgotten" two previous appointments. He was extremely anxious, often lost in his train of thought, and was semi-delusional about his wife and sons, suggesting that they might want to have him locked up. He briefly told his life history, which included his coming from a strict and hard-working but caring middle-class family and the death of his mother when he was only 11 years old. He had joined his father's business (taking over after his father's death 2 years earlier), with both of his sons as associates. Describing himself as successful in work and marriage, he claimed that "the only test I ever failed was the stress test."

Mr. C explained his lack of adherence to dietary restrictions as a lack of will and his constant contact with the internist as his having real physical problems not yet diagnosed; he rejected the idea of addiction to tranquilizers, insisting that he could quit any time. He had no fantasy life, remembered no dreams, made it clear that he had entered treatment on his internist's instruction only, and started each session by stating that he had nothing to discuss.

After suggesting that Mr. C was coming to sessions just to pass the "sanity test" and that there was no reason to have him locked up, the psychiatrist encouraged the patient to join him in figuring out the real reasons for his anxiety. Initial sessions were devoted to discussing the patient's medical condition and providing factual information about heart

and bypass surgery. The therapist likened the patient's condition to that of an older house getting new plumbing, trying to allay his unrealistic fears of impending death. As Mr. C's anxiety declined, he became less defensive and more psychologically accessible. As the therapist began to explore his difficulty in accepting help, Mr. C was able to talk about his inability to admit problems (i.e., weaknesses). The therapist's explicit recognition of the patient's strength in admitting his weaknesses encouraged the patient to reveal more about himself—how he had welcomed his father's death and his belief that perhaps his illness was punishment. The psychiatrist also encouraged him to speak about his unrealistic guilt and, at the same time, helped him recognize his suspicion of his sons as the reflection of his own wishes concerning his father and his lack of commitment to his medical regimen as a wish to die to expiate guilt. After steady urging by the therapist, Mr. C returned to work. He agreed to meet monthly with the psychiatrist and to taper off his use of tranquilizers. He even agreed that he might see the psychiatrist for "deep analysis" in the future because his wife now jokingly complained of his obsessive dieting, his uncompromising exercise regimens, and his regularly scheduled sexual activities. (Courtesy of T. Byram Karasu, M.D.)

Because support forms a tacit part of every therapeutic modality, it is rarely contraindicated as such. The typical attitude regards better-functioning patients as unsuitable not because a supportive approach will harm them, but because they will not be sufficiently benefited by it. In aiming to maximize the patient's potential for further growth and change, supportive therapy is relatively restricted and superficial and, thus, is not recommended as the treatment of choice if the patient is available for, and capable of, a more in-depth approach.

GOALS. The general aim of supportive treatment is the amelioration or relief of symptoms through behavioral or environmental restructuring within the existing psychic framework. Supportive therapy helps the patient to adapt better to problems and to live more comfortably with his or her psychopathology. To restore the disorganized, fragile, or decompensated

patient to a state of relative equilibrium, the therapist's primary goal is to suppress or control symptomatology and to stabilize the patient in a protective and reassuring benign atmosphere that militates against overwhelming external and internal pressures. The ultimate goal is to maximize the integrative or adaptive capacities so that the patient increases the ability to cope while decreasing vulnerability by reinforcing assets and strengthening defenses.

MAJOR APPROACH AND TECHNIQUES. Supportive therapy uses several methods, either singly or in combination, including warm, friendly, strong leadership; partial gratification of dependency needs; support in the ultimate development of legitimate independence; help in developing pleasurable activities (e.g., hobbies); adequate rest and diversion; removal of excessive strain, when possible; hospitalization, when indicated; medication to alleviate symptoms; and guidance and advice in dealing with current issues. This therapy uses techniques to help patients feel secure, accepted, protected, encouraged, safe, and not anxious.

LIMITATIONS. To the extent that much supportive therapy is spent on practical, everyday realities and on dealing with the external environment of the patient, it may be viewed as more mundane and superficial than depth approaches. Because those patients attend therapy sessions intermittently and less frequently, the interpersonal commitment may not be as compelling on the part of either the patient or the therapist. Greater severity of illness (and possible psychoses) also makes such treatment potentially more erratic, demanding, and frustrating. The need for the therapist to deal with other family members, caretakers, or agencies (auxiliary treatment, hospitalization) can become an additional complication because the therapist comes to serve as an ombudsman to negotiate with the outside world of the patient and with other professional peers. Finally, the supportive therapist must be able to accept personal limitations and the patient's limited psychological resources and to tolerate the often unrewarded efforts until the patient makes small gains.

Mr. W was a 42-year-old widowed businessman who was referred by his

internist because of the sudden death of his wife, who had had an intracranial hemorrhage, about 2 months earlier. Mr. W had two children, a boy and a girl, ages 10 and 8 years, respectively.

Mr. W had never been to a psychiatrist before, and when he arrived, he admitted he was not sure what a psychiatrist could do for him. He just had to get over his wife's death. He was not sure how talking about anything could help. He had been married for 15 years. He admitted to having difficulty sleeping, particularly awakening in the middle of the night with considerable anxiety about the future. One of his relatives had given him some of her clonazepam for his anxiety, which helped tremendously, but he feared getting dependent on it. He was also drinking more than he thought he should. He was most concerned about raising his children alone and felt somewhat overwhelmed by the responsibility. He was beginning to appreciate just how wonderful a mother his wife had been and now saw how critical he had been of her for spending so much time with the children. "It really does take a lot of effort," he said.

Mr. W did admit to feelings of guilt. For one thing, he admitted to some sense that he could now start over. He had been somewhat restless in the marriage recently before his wife's death and had been unfaithful for a brief period early in the marriage. He also felt some guilt that had he been awake the night of his wife's hemorrhage, and maybe he could have saved his wife. In reality, there was nothing he could have done.

Mr. W agreed to come for a few sessions to talk about his wife. At this point, only 2 months after her death, he seemed to have an uncomplicated mourning reaction. Although he talked easily in session, he was clearly worried that he might like "being here too much." The therapist chose not to interpret his dependency conflicts. Mr. W seemed to have good coping skills and used humor as a high-functioning defense. For example, in giving a eulogy for his wife (who had been a very popular member of their congregation), he looked around at the enormous crowd of people at the church service and said he had never seen so many people attending church before, adding, "Sorry, Reverend."

After about four sessions, Mr. W said that he felt better and no longer saw the need for further sessions. He was sleeping better and had stopped drinking excessively. The therapist suggested that he might want to continue to talk more about his guilt and his life as he went forward

without his wife. The therapist was also reassuring that there seemed to be nothing else Mr. W could have done to save his wife. He also encouraged the patient to begin dating when he felt ready, something that Mr. W's in-laws were not encouraging. For now, however, Mr. W was not interested in any further therapy. He was appreciative of the therapist and felt that talking about his wife's death had been helpful. The therapist accepted his wish to discontinue their sessions but encouraged Mr. W to keep in touch to let him know how he was doing. (Courtesy of T. Byram Karasu, M.D. and S. R. Karasu, M.D.)

CORRECTIVE EMOTIONAL EXPERIENCE. The relationship between therapist and patient allows a therapist to display behavior different from the destructive or unproductive behavior of a patient's parent. At times, such experiences seem to neutralize or reverse some effects of the parents' mistakes. If the patient had overly authoritarian parents, the therapist's friendly, flexible, nonjudgmental, nonauthoritarian—but at times firm and limit setting—attitude allows the patient to adjust to, be led by, and identify with a new parent figure. Franz Alexander described this process as a corrective emotional experience. It draws on elements of both psychoanalysis and psychoanalytic psychotherapy.

BRIEF PSYCHODYNAMIC PSYCHOTHERAPY

Brief psychodynamic psychotherapy has gained widespread popularity, partly because of the great pressure on health care professionals to contain treatment costs. It is also easier to evaluate treatment efficacy by comparing groups of persons who have had short-term therapy for mental illness with control groups than it is to measure the results of long-term psychotherapy. Thus, short-term therapies have been the subject of much research, especially on outcome measures, which have found them to be effective. Other short-term methods include interpersonal therapy and cognitive-behavioral therapy (CBT, discussed later in this chapter).

Brief psychodynamic psychotherapy is a time-limited treatment (10 to 12 sessions) based on psychoanalysis and psychodynamic theory. It is useful in helping persons with depression, anxiety, and posttraumatic stress disorder

(PTSD), among others. There are several methods, each having its own treatment technique and specific criteria for selecting patients; however, they are more similar than different.

In 1946, Franz Alexander and Thomas French identified the basic characteristics of brief psychodynamic psychotherapy. They described a therapeutic experience designed to put patients at ease, to manipulate the transference, and to use trial interpretations flexibly. Alexander and French conceived psychotherapy as a corrective emotional experience capable of repairing traumatic events of the past and convincing patients that new ways of thinking, feeling, and behaving are possible. At about the same time, Eric Lindemann established a consultation service at Massachusetts General Hospital in Boston for persons experiencing a crisis. He developed new treatment methods to deal with these situations and eventually applied these techniques to persons who were not in crisis, but who were experiencing various kinds of emotional distress. Since then, the field has been influenced by many workers such as David Malan in England, Peter Sifneos in the United States, and Habib Davanloo in Canada.

Types

Brief Focal Psychotherapy (Tavistock–Malan). Brief focal psychotherapy was originally developed in the 1950s by the Balint team at the Tavistock Clinic in London. Malan, a member of the team, reported the results of the therapy. Malan's selection criteria for treatment included eliminating absolute contraindications, rejecting patients for whom certain dangers seemed inevitable, clearly assessing patients' psychopathology, and determining patients' capacities to consider problems in emotional terms, face disturbing material, respond to interpretations, and endure the stress of the treatment. Malan found that high motivation invariably correlated with a successful outcome. Contraindications to treatment were serious suicide attempts, substance dependence, chronic alcohol abuse, incapacitating chronic obsessional symptoms, incapacitating chronic phobic symptoms, and gross destructive or self-destructive acting out.

REQUIREMENTS AND TECHNIQUES. In Malan's routine, therapists should identify the transference early and interpret it and the negative transference.

They should then link the transferences to patients' relationships with their parents. Both patients and therapists should be willing to become deeply involved and to bear the ensuing tension. Therapists should formulate a circumscribed focus and set a termination date in advance, and patients should work through grief and anger about termination. An experienced therapist should allow about 20 sessions as an average length for the therapy; a trainee should allow about 30 sessions. Malan himself did not exceed 40 interviews with his patients.

Time-Limited Psychotherapy (Boston University–Mann). A psychotherapeutic model of exactly 12 interviews focusing on a specified central issue was developed at Boston University by James Mann and his colleagues in the early 1970s. In contrast with Malan's emphasis on clear-cut selection and rejection criteria, Mann was not as explicit about the appropriate candidates for time-limited psychotherapy. Mann considered the major emphases of his theory to be determining a patient's central conflict reasonably correctly and exploring young persons' maturational crises with many psychological and somatic complaints. Mann's exceptions, similar to his rejection criteria, include persons with major depressive disorder that interferes with the treatment agreement, those with acute psychotic states, and desperate patients who need, but cannot tolerate, object relations.

REQUIREMENTS AND TECHNIQUES. Mann's technical requirements included strict limitation to 12 sessions, positive transference predominating early, specification and strict adherence to a central issue involving transference, positive identification, making separation a maturational event for patients, absolute prospect of termination to avoid development of dependence, clarification of present and past experiences and resistances, active therapists who support and encourage patients, and education of patients through direct information, reeducation, and manipulation. The conflicts likely to be encountered included independence versus dependence, activity versus passivity, unresolved or delayed grief, and adequate versus inadequate self-esteem.

Short-Term Dynamic Psychotherapy (McGill University–Davanloo). As conducted by Davanloo at McGill University, short-term

dynamic psychotherapy encompasses nearly all varieties of brief psychotherapy and crisis intervention. Davanloo's series classified patients treated as those whose psychological conflicts are predominantly oedipal, those whose conflicts are not oedipal, and those whose conflicts have more than one focus. Davanloo also devised a specific psychotherapeutic technique for patients with severe, long-standing neurotic problems, specifically those with incapacitating obsessive-compulsive disorders (OCDs) and phobias.

Davanloo's selection criteria emphasize evaluating those ego functions of primary importance to psychotherapeutic work: the establishment of a psychotherapeutic focus; the psychodynamic formulation of the patient's psychological problems; the ability to interact emotionally with evaluators; a history of give-and-take relationships with a significant person in the patient's life; the patient's ability to experience and tolerate anxiety, guilt, and depression; the patient's motivations for change, psychological mindedness, and an ability to respond to interpretation and to link evaluators with persons in the present and past. Both Malan and Davanloo emphasized a patient's responses to interpretation as an essential selection and prognostic criterion.

REQUIREMENTS AND TECHNIQUES. The highlights of Davanloo's psychotherapeutic approach are flexibility (therapists should adapt the technique to the patient's needs), control, the patient's regressive tendencies, active intervention to avoid having the patient develop overdependence on a therapist, and the patient's intellectual insight and emotional experiences in the transference. These emotional experiences become corrective as a result of the interpretation.

Ana, a divorced 60-year-old woman, sought psychiatric help following a severe depressive episode lasting several months. This episode, which was one of many in her life, was especially severe in terms of loss of energy, interest, motivation, and the intensity of her sadness and wish to die. Only her profound religious convictions protected her from acting on these wishes. Ana had lost much weight, had trouble sleeping, experienced many nightmares, and had difficulty with concentration. Pervasive feelings of hatred for her mother plagued Ana; her mother was

very old, ill, and dependent on Ana, who was unable to forgive her for abandoning her in an orphanage when she was 5 or 6 years of age.

After an extensive assessment, the dynamic formulation of Ana's problem was:

1. *Life problems:* Recurrent depressive episodes plagued by feelings of guilt and self-reproach; problems with men involving choosing partners who are commonly cold, distant, or otherwise unavailable; involuntary and painful emotional distance from her children, friends, and other close relationships; and unproductive and unrewarding work life, despite considerable intellectual gifts.
2. *Dynamics:* Ambivalent relationship with her mother, whom she blames for most of the tragedies of her life; guilt and need for punishment concerning her unrelenting hatred for her mother; and pathologic grief reaction for the loss of an idealized and more optimal relationship with her mother, the one she remembers she had before her orphanage placement. From this focus, there flows a melancholic conviction of the inevitable failure of human relationships.
3. *Pathogenic foci:* Grief and inability to mourn the loss of her mother after going to live in the orphanage, with attendant rage and guilt; pathologic grief for the loss of her father, who, because of severe alcoholism, abandoned the family first, a move that caused the mother to place her children in an orphanage in order to be able to work and ultimately recover their care. Unconsciously, she blamed her mother for the family catastrophe, thus "protecting" an idealized view of her father, to whom she was profoundly attached.

For Ana, the initial phase of treatment focused on the clarification and the experience of her destructive impulses toward her mother, which, as they were worked through, made possible the appearance of a modicum of empathy with her mother's painful life situation around the time she placed Ana and her sisters in the orphanage. Next, the therapy focused on Ana's father. She experienced deep feelings of idealization, disappointment, anger, and grief with increasing clarity and intensity, frequently via displaced feelings in the transference and after overcoming considerable resistance. The last phase of treatment permitted the

development of realistic feelings of empathy and appreciation for her mother, now without anger or emotional distancing, and the reawakening within Ana of feelings of joy and hope, as well as professional ambition. (Courtesy of M. Trujillo, M.D.)

Short-Term Anxiety-Provoking Psychotherapy (Harvard University–Sifneos). Sifneos developed short-term anxiety-provoking psychotherapy at the Massachusetts General Hospital in Boston during the 1950s. He used the following criteria for selection: a circumscribed chief complaint (implying a patient's ability to select one of a variety of problems to be given top priority and the patient's desire to resolve the problem in treatment), one meaningful or give-and-take relationship during early childhood, the ability to interact flexibly with an evaluator and to express feelings appropriately, above-average psychological sophistication (implying not only above-average intelligence but also an ability to respond to interpretations), a specific psychodynamic formulation (usually a set of psychological conflicts underlying a patient's difficulties and centering on an oedipal focus), a contract between therapist and patient to work on the specified focus and the formulation of minimal expectations of outcome, and good to excellent motivation for change, not just for symptom relief.

Chris, a 31-year-old single man, sought help for a moderate depressive episode precipitated by the loss of his relationship with his girlfriend, Joanna. She had broken off the relationship after approximately 1 year, tired of Chris's erratic work ethic and emotional instability and discouraged by his fear of commitment to the future of their relationship. This cycle of infatuation, increasing fear of commitment, and relationship loss had become a pattern in Chris's interpersonal life. His work life experienced similar problems. He frequently lost jobs because of serious conflict and threatening confrontations with his superiors. As conflicts arose at both work and home, Chris typically suffered increasing anxiety and episodic panic attacks. After the loss of each relationship, Chris usually confronted moderate depressive feelings, at times accompanied by suicidal ideation.

After an assessment, the dynamic hologram for Chris was:

1. *Life problems:* Recurrent episodes of anxiety and depression; work problems; unstable interpersonal relationships; conflict with authority figures; antagonism toward, and emotional distance from, his father, brother, and male friends; and fears of heterosexual intimacy and commitment.
2. *Dynamic forces:* Ongoing hostility and envy toward males, authority figures, and successful people, and compulsive and possessive seeking of female love objects with a serious inability to consider, fulfill, or tolerate their independent needs.
3. *Genetic pathogenic foci:* Unconscious loss of maternal objects precipitated by birth of a brother when Chris was age 2 years; uncontrolled grief for that loss with a compulsive drive to experience child-like possession of love objects; and compulsive hostility toward others perceived as rivals.

The therapist's active inquiry yielded additional confirmation of the persistence of repressed sexual feelings toward his mother and the presence of hostile feelings toward all rivals for his mother's affection. A memory suffused with very visceral feelings emerged in this phase as a result of the therapist's active inquiry. In this memory, Chris saw himself in his mother's arms in a dark room. He remembered the intense pleasure of contact with his mother's warm skin, the texture of her clothes, and the smell of her perfume vividly. While narrating this memory to the therapist, Chris became so absorbed in the experience that he blushed intensely. He also described the painful termination of this moment of pleasure by his father's sudden and disruptive opening of the door and the flood of light that disturbed his pleasurable absorption. This sequence gave way to experiencing grief at the loss of the intense and exclusive bond with his mother after his brother's birth and a reexperiencing of anger, impotence, and loneliness. These feelings were all too familiar in his present life when his romantic attachments would be threatened or lost. The affective link between this childhood experience and his intimacy problems in the present became very obvious to Chris, and the acceptance of this link enhanced his capacity to work through this essential component of his pathology. A parallel conflict appeared in the

transference as the patient resented the “intrusion” of the inquiring therapist into the zealously guarded privacy of this primal fantasy of material possession. (Courtesy of M. Trujillo, M.D.)

REQUIREMENTS AND TECHNIQUES. Treatment includes four major phases: patient–therapist encounter, early therapy, height of treatment, and evidence of change and termination. Therapists use the following techniques during the four phases.

Patient–Therapist Encounter. A therapist establishes a working alliance by using the patient’s quick rapport with, and positive feelings for, the therapist that appear in this phase. The judicious use of open-ended and forced-choice questions enables the therapist to outline and concentrate on a therapeutic focus. The therapist specifies the minimal expectations of outcome to be achieved by the therapy.

Early Therapy. Transference involves clarifying feelings for the therapist as soon as they appear, a technique that establishes a true therapeutic alliance.

Height of the Treatment. Height of treatment emphasizes active concentration on the oedipal conflicts that have been chosen as the therapeutic focus; repeated use of anxiety-provoking questions and confrontations; avoidance of pregenital characterologic issues, which the patient uses defensively to avoid dealing with the therapist’s anxiety-provoking techniques; avoidance at all costs of a transference neurosis; repetitive demonstration of the patient’s neurotic ways or maladaptive patterns of behavior; concentration on the anxiety-laden material, even before the defense mechanisms have been clarified; repeated demonstrations of parent-transference links by the use of properly timed interpretations based on material given by the patient; establishment of a corrective emotional experience; encouragement and support of the patient, who becomes anxious while struggling to understand the conflicts; new learning and problem-solving patterns; and repeated presentations and recapitulations of the patient’s psychodynamics until the defense mechanisms used in dealing with oedipal conflicts are understood.

Evidence of Change and Termination of Psychotherapy. The final phase of

therapy emphasizes the tangible demonstration of change in the patient's behavior outside therapy, evidence that the patient is using adaptive patterns of behavior, and initiation of talk about terminating the treatment.

Overview and Results

The shared techniques of all the brief psychotherapies described above outdistance their differences. They share the therapeutic alliance or dynamic interaction between therapist and patient, the use of transference, the active interpretation of a therapeutic focus or central issue, the repetitive links between parental and transference issues, and the early termination of therapy.

The outcomes of these brief treatments have undergone extensive investigation. Contrary to prevailing ideas that the therapeutic factors in psychotherapy are nonspecific, controlled studies and other assessment methods (e.g., interviews with unbiased evaluators, patients' self-evaluations) point to the importance of the specific techniques used. The capacity for genuine recovery in certain patients is far greater than was thought. A certain type of patient receiving brief psychotherapy can benefit greatly from a practical working through of his or her nuclear conflict in the transference. Such patients can be recognized in advance through a process of dynamic interaction because they are responsive, motivated, and able to face disturbing feelings and because they have a circumscribed focus formulated for them. The more radical the technique in terms of transference, depth of interpretation, and the link to childhood, the more radical the therapeutic effects will be. For some disturbed patients, a carefully chosen partial focus can be therapeutically effective.

GROUP PSYCHOTHERAPY, COMBINED INDIVIDUAL AND GROUP PSYCHOTHERAPY, AND PSYCHODRAMA

Group psychotherapy is a modality that employs a professionally trained leader who selects, composes, organizes, and leads a collection of members to work together toward the maximal attainment of the goals for each individual in the group and for the group itself. Certain properties present in groups, such as mutual support, can be harnessed in the service of providing relief from psychological suffering and supply peer support to counter

isolation experienced by many who seek psychiatric help. Similarly, homogeneously composed small groups are ideal settings for the dissemination of accurate information about a condition shared by group members. Medical illness, substance use disorders, and chronic and persistent severe psychiatric conditions, including schizophrenia and major affective disorders, are cases in point.

A widely accepted psychiatric treatment modality, group psychotherapy uses therapeutic forces within the group, constructive interactions among members, and interventions of a trained leader to change the maladaptive behaviors, thoughts, and feelings of emotionally distressed individuals. Group therapy applies to inpatient and outpatient settings, institutional work, partial hospitalization units, halfway houses, community settings, and private practice. Group psychotherapy is also widely used by those who are not mental health professionals in the adjuvant treatment of physical disorders. Application of group psychotherapy principles has also found success in the business and education fields in the form of training, sensitivity, and role-playing.

Group psychotherapy is a treatment in which carefully selected persons who are emotionally ill meet in a group guided by a trained therapist and help one another effect personality change. By using a variety of technical maneuvers and theoretical constructs, the leader directs group members' interactions to bring about changes.

Classification

Group therapy, at present, has many approaches. Many individually derived forms of psychotherapy have their group counterparts. A representative sample of major theoretical orientations toward group therapy can be broadly subsumed under the psychodynamic, interpersonal, and cognitive-behavioral schools of thought. Table 23-4 illustrates some of the similarities and differences among representative group formats.

Patient Selection

To determine a patient's suitability for group psychotherapy, a therapist needs to gather a great deal of information in a screening interview. The psychiatrist should take a psychiatric history and perform a mental status

examination to obtain certain dynamic, behavioral, and diagnostic information.

Robert entered therapy seeking to understand why he was unable to maintain close or lasting relationships. A handsome and successful businessman, he had made a painful and courageous transition away from self-centered, dysfunctional parents early in his life. Although Robert made good initial impressions in his jobs, he was always puzzled and disappointed when his superiors gradually lost interest in him, and his colleagues avoided him. In one-on-one therapy, he was charming and entertaining, but perceived narcissistic slights caused him to become angry and attack. His therapist recommended group psychotherapy when the patient's transference feelings remained intense, and therapy was at a seeming impasse. Initially, Robert charmed the group and strove to be the center of attention. Visibly annoyed whenever he felt the group leader was paying more attention to other members, Robert was especially critical and hostile toward older people in the group and displayed little empathy for others. After repeated and forceful confrontations from the group about his antagonistic behavior, he gradually realized that he was repeating childhood patterns in his family of desperately seeking the attention of unloving parents and then entering violent rages when they lost interest. (Courtesy of Normund Wong, M.D.)

Diagnosis. The diagnosis of patients' disorders is essential in determining the best therapeutic approach and in evaluating patients' motivations for treatment, capacities for change, and personality structure strengths and weaknesses. Few contraindications exist for group therapy. Antisocial patients generally do poorly in a heterogeneous group setting because they cannot adhere to group standards, but if the group is composed of other antisocial patients, they may respond better to peers than to perceived authority figures. Depressed patients profit from group therapy after they have established a trusting relationship with the therapist. Patients who are actively suicidal or severely depressed should not be treated solely in a group setting. Patients who are manic are disruptive but, once under pharmacologic control, do well in the group setting. Therapists should exclude patients who

are delusional and who may incorporate the group into their delusional system, as well as patients who pose a physical threat to other members because of uncontrollable aggressive outbursts.

Table 23-4
Comparison of Major Group Therapy Orientations

	Supportive	Psychodynamic	Self-Help	Cognitive/Behavioral
	Group therapy	Group therapy	Groups	Group therapy
Frequency	1–5 times/wk	1–2 times/wk	7 days/wk	1–3 times/wk
Individual screening	Usually	Always	None	Always
Group size	8–15 members	5–9 members	No size limits	5–10 members
Goals	Better adaptation for daily living	Reconstruction of personality dynamics	Social support	Relief of specific symptoms
Indications	Crisis situations; severe emotional	Neuroses; mild personality disorders	Shared life experiences	Phobias; anxiety disorders
Group composition	Homogeneous for level of psychopathology	Balance of similarities and differences	Homogeneous	Homogeneous for similar symptoms
Group focus	"Here and now"; family, vocational, environmental factors	Past and present; intragroup and extragroup dynamics	Education; emotional "sharing"	Training in methods that control symptoms
Use of confrontation	No	Yes	No	Rarely
Therapist activity	Actively structures and leads the group	Active around interpretation	No formal group leader	Very active in teaching skills to patient
Extragroup contacts	Encouraged	Prohibited or discouraged	Encouraged; formal peer sponsorship	Discouraged
Transference	Not analyzed	Utilized extensively	Not analyzed	Not relevant to the group work
Therapeutic factors	Cohesion; universality; reality testing instillation of hope imparting information	Cohesion; catharsis; family replay; interpersonal learning	Cohesion; universality; education; peer support	Cohesion; universality; education; reinforcement

Preparation

Patients prepared by a therapist for a group experience tend to continue in treatment longer and report less initial anxiety than those who are not prepared. The preparation consists of having a therapist explain the procedure in as much detail as possible and answer the patient's questions before the first session.

Size. Group therapy has been successful with as few as 3 members and as many as 15, but most therapists consider 8 to 10 members the optimal size. Interaction may be insufficient with fewer members unless they are especially verbal, and with more than 10 members, the interaction may be too great for the members or the therapist to follow.

Frequency and Length of Sessions. Most group psychotherapists conduct group sessions once a week. Maintaining continuity in sessions is essential. When there are alternate sessions, the group meets twice a week, once with and once without the therapist. Group sessions generally last anywhere from 1 to 2 hours, but the time limit should be constant.

Marathon groups were most popular in the 1970s but are much less common today. In time-extended therapy (marathon group therapy), the group meets continuously for 12 to 72 hours. Enforced interactional proximity and, during the most prolonged time-extended sessions, sleep deprivation break down certain ego defenses, release affective processes, and theoretically promote open communication. Time-extended sessions, however, can be dangerous for patients with weak ego structures, such as persons with schizophrenia or BPD.

Homogeneous versus Heterogeneous Groups. Most therapists believe that groups should be as heterogeneous as possible to ensure maximal interaction. Members with different diagnostic categories and varied behavioral patterns, from all races, social levels, and educational backgrounds, and of varying ages and both sexes, should be brought together. Patients between the ages of 20 and 65 years can be included effectively in the same group. Age differences help in developing parent–child and brother–sister models, and patients have the opportunity to relive and rectify interpersonal difficulties that may have appeared insurmountable.

Both children and adolescents benefit the most in groups comprising mostly persons in their age groups. Some adolescent patients are capable of assimilating the material of an adult group, regardless of content, but they may benefit significantly from a constructive peer experience that they might otherwise not have.

Open versus Closed Groups. Closed groups have a set number and composition of patients. If members leave, no new members are accepted. In open groups, membership is more fluid, and new members join whenever old members leave.

Mechanisms

Group Formation. Each patient approaches group therapy differently, and, in this sense, groups are microcosms. Patients use typical adaptive abilities, defense mechanisms, and ways of relating, and when these tactics are ultimately reflected back to them by the group, they learn to be introspective about their personality functioning. A process inherent in group formation requires that patients suspend their previous ways of coping. In entering the group, they allow their executive ego functions—reality testing, adaptation to and mastery of the environment, and perception—to be assumed, to some degree, by the collective assessment provided by the total membership, including the leader.

Therapeutic Factors. Table 23-5 outlines 20 significant therapeutic factors that account for change in group psychotherapy.

Table 23-5
Therapeutic Factors

Factor	Definition
Abreaction	A process by which repressed material, particularly a painful experience or conflict, is brought back to consciousness. During the process, the person not only recalls, but also relives the material, which is accompanied by the appropriate emotional response; insight usually results from the experience.
Acceptance	The feeling of being accepted by other members of the group; differences are tolerated, and there is an absence of censure.
Altruism	The act of one member's being of help to another; putting another person's need before one's own and learning that there is value in giving to others. The term was originated by Auguste Comte (1798–1857), and Freud believed it was a major factor in establishing group cohesion and

	community feeling.
Catharsis	The expression of ideas, thoughts, and suppressed material that is accompanied by an emotional response that produces a state of relief in the patient.
Cohesion	The sense that the group is working together toward a common goal; also referred to as a sense of we-ness; believed to be the most important factor related to positive therapeutic effects.
Consensual validation	Confirmation of reality by comparing one's own conceptualizations with those of other group members; interpersonal distortions are thereby corrected. The term was introduced by Harry Stack Sullivan. Trigant Burrow had used the phrase consensual observation to refer to the same phenomenon.
Contagion	The process in which the expression of emotion by one member stimulates the awareness of a similar emotion in another member.
Corrective familial experience	The group recreates the family of origin for some members who can work through conflicts psychologically through group interaction (e.g., sibling rivalry, anger toward parents).
Empathy	A capacity of a group member to put himself or herself into the psychological frame of reference of another group member and, thereby, understand his or her thinking, feeling, or behavior.
Identification	An unconscious defense mechanism in which the person incorporates the characteristics and qualities of another person or object into his or her ego system.

Imitation	The conscious emulation or modeling of one's behavior after that of another (also called role modeling); also known as "spectator therapy," as one patient learns from another.
Insight	Conscious awareness and understanding of one's own psychodynamics and symptoms of maladaptive behavior. Most therapists distinguish two types: (1) intellectual insight—knowledge and awareness without any changes in maladaptive behavior and (2) emotional insight—awareness and understanding leading to positive changes in personality and behavior.
Inspiration	The process of imparting a sense of optimism to group members; the ability to recognize that one has the capacity to overcome problems; also known as installation of hope.
Interaction	The free and open exchange of ideas and feelings among group members; effective interaction is emotionally charged.
Interpretation	The process during which the group leader formulates the meaning or significance of a patient's resistance, defenses, and symbols; the result is that the patient develops a cognitive framework within which to understand his or her behavior.
Learning	Patients acquire knowledge about new areas, such as social skills and sexual behavior; they receive advice, obtain guidance, and attempt to influence and are influenced by other group members.
Reality testing	Ability of the person to evaluate objectively the world outside the self; includes the capacity to perceive oneself and other group members accurately.

Transference	Projection of feelings, thoughts, and wishes onto the therapist, who has come to represent an object from the patient's past. Such reactions, although perhaps appropriate for the condition prevailing in the patient's earlier life, are inappropriate and anachronistic when applied to the therapist in the present. Patients in group therapy may also direct such feelings toward one another, a process called multiple transferences.
Universalization	The awareness of the patient that he or she is not alone in having problems; others share similar complaints or difficulties in learning; the patient is not unique.
Ventilation	The expression of suppressed feelings, ideas, or events to other group members; the sharing of personal secrets that ameliorates a sense of sin or guilt (also referred to as self-disclosure).

Role of the Therapist

Although opinions differ about how active or passive a group therapist should be, the consensus is that the therapist's role is primarily facilitative. Ideally, the group members themselves are the primary source of cure and change. The climate produced by the therapist's personality is a potent agent of change. The therapist is more than an expert applying techniques; he or she exerts a personal influence that taps such variables as empathy, warmth, and respect.

Inpatient Group Psychotherapy

Group therapy is an integral part of hospitalized patients' therapeutic experiences. Group organization can take many forms on a ward. In a community meeting, an entire inpatient unit meets with all the staff members (e.g., psychiatrists, psychologists, and nurses). In team meetings, 15 to 20

patients and staff members meet; a regular or small group comprising 8 to 10 patients may meet with 1 or 2 therapists, as in traditional group therapy. Although the goals of each group vary, they all have common purposes: to increase patients' awareness of themselves through their interactions with the other group members, who provide feedback about their behavior; to provide patients with improved interpersonal and social skills; to help the members adapt to an inpatient setting; and, to improve communication between patients and staff. In addition, one type of group meeting is attended only by inpatient hospital staff in order to improve communication among the staff members and to provide mutual support and encouragement in their day-to-day work with patients. Community meetings and team meetings are more helpful for dealing with patient treatment problems than they are for providing insight-oriented therapy, which is the province of the small-group therapy meeting.

Group Composition. Two critical factors of inpatient groups common to all short-term therapies are the heterogeneity of the members and the rapid turnover of patients. Outside the hospital, therapists have large caseloads from which to select patients for group therapy. On the ward, therapists have a limited number of patients to choose from and have restrictions in terms of those patients who are both willing to participate and suitable for a small-group experience. In certain settings, group participation may be mandatory (e.g., in substance use disorder units), but mandatory attendance does not usually apply in a general psychiatry unit. Most group experiences are more productive when the patients themselves choose to enter them.

More sessions are preferable to fewer. During patients' hospital stays, groups may meet daily to allow interactional continuity and the carryover of themes from one session to the next. A new group member can be brought up to date quickly, either by the therapist in an orientation meeting or by another group member. A newly admitted patient has often learned many details about the small-group program from another patient before actually attending the first session. The less frequently the group sessions are held, the greater the need for a therapist to structure the group and be active in it.

Inpatient versus Outpatient Groups. Although the therapeutic factors that account for change in small inpatient groups are similar to those in the

outpatient settings, there are qualitative differences. For example, the relatively high turnover of patients in inpatient groups complicates the process of cohesion. However, the fact that all the group members are together in the hospital aids cohesion, as do the therapists' efforts to foster the process. Sharing of information, universalization, and catharsis are the main therapeutic factors at work in inpatient groups. Although insight more likely occurs in outpatient groups because of their long-term nature, some patients can obtain a new understanding of their psychological makeup within the confines of a single group session. A unique quality of inpatient groups is the patients' extra-group contacts, which are extensive because they live together on the same ward. Verbalizing their thoughts and feelings about such contacts in the therapy sessions encourages interpersonal learning. In addition, conflicts between patients or between patients and staff members can be anticipated and resolved.

Twelve former psychiatric inpatients who attended the monthly medication clinic would meet for 1 hour before their individual appointments with the psychiatrist to review their current social situation and medications. All received treatment from the same ward doctor and had known one another while on the inpatient service. The psychiatrist who performed the medication reviews also served as the group leader. Periodically, a staff member who was also familiar with the patients assisted with the group. Coffee was available, and the patients often brought pastries from home. The patients socialized with one another during the hour and frequently exchanged helpful ideas and tips about job opportunities. Those without cars shared rides with other members. The group was open-ended and well attended. Most of the patients were single and had a long history of psychotic illness. For most, this meeting was their only opportunity to socialize and be among peers. Frequently, when a member entered the hospital again, many in the group would visit their colleague on the ward. (Courtesy of Normund Wong, M.D.)

Self-Help Groups

Leaderless or self-help group experiences, usually homogeneously composed

of participants with a common issue, represent an additional use of the group setting as a vehicle for change. Although these groups are not strictly considered a form of psychotherapy, they do share several parameters and can have therapeutic benefits for participants. Perhaps the best-known examples are the Twelve Step groups of Alcoholics Anonymous (AA), Al-Anon, Adult Children of Alcoholics (ACoA), and other substance use disorder centered groups. In addition, many self-help groups develop around health and illness, loss, or shared life experience. Cancer support groups, groups for widows or widowers, parents without partners, and bipolar support groups are but a few well-known self-help groups.

Combined Individual and Group Psychotherapy

In combined individual and group psychotherapy, patients see a therapist individually and also take part in group sessions. The therapist for the group and individual sessions is usually the same person. Groups can vary in size from 3 to 15 members, but the most helpful size is 8 to 10. Patients must attend all group sessions. Attendance at individual sessions is also essential, and the therapeutic process should examine failure to attend either group or individual sessions.

Combined therapy is a particular treatment modality, not a system by which to augment individual therapy by an occasional group session or a group therapy in which a participant meets alone with a therapist from time to time. Instead, it is an ongoing plan in which meaningful integration of the group experience with the individual sessions yields reciprocal feedback to help form an integrated therapeutic experience. Although the one-to-one doctor–patient relationship makes an in-depth examination of the transference reaction possible for some patients, it may not provide other patients with the corrective emotional experiences necessary for therapeutic change. The group gives patients a variety of persons with whom they can have transferential reactions. In the microcosm of the group, patients can relive and work through familial and other important influences.

Techniques. The combined therapy format may include different techniques based on varying theoretical frameworks. Some clinicians increase the frequency of individual sessions to encourage the emergence of

the transference neurosis. In the behavioral model, individual sessions occur regularly, but they tend to be less frequent than in other approaches. Whether patients use a couch or a chair during individual sessions depends on a therapist's orientation. Other techniques include alternate meetings or "after-sessions" without the therapist present. A combined therapy approach called *structured interactional group psychotherapy* has a different group member as the focus of each weekly group session who is discussed in depth by the other members.

Results. Most workers in the field believe that combined therapy has the advantages of both dyadic and group settings, without sacrificing the qualities of either. Generally, the dropout rate in combined therapy is lower than that in group therapy alone. In many cases, combined therapy appears to bring problems to the surface and to resolve them more quickly than might be possible with either method alone.

Psychodrama

Psychodrama is a method of group psychotherapy originated by the Viennese-born psychiatrist Jacob Moreno that explores personality makeup, interpersonal relationships, conflicts, and emotional problems through special dramatic methods. Therapeutic dramatization of emotional problems includes the protagonist or patient, the person who acts out problems with the help of auxiliary egos, persons who enact varying aspects of the patient, and the director, psychodramatist, or therapist, the person who guides those in the drama toward the acquisition of insight.

Roles

DIRECTOR. The director is the leader or therapist and so must be an active participant. He or she has a catalytic function by encouraging the members of the group to be spontaneous. The director must also be available to meet the group's needs without superimposing his or her values. Of all the group psychotherapies, psychodrama requires the most participation from the therapist.

PROTAGONIST. The protagonist is the patient in conflict. The patient chooses

the situation to portray in the dramatic scene, or the therapist chooses it if the patient so desires.

AUXILIARY EGO. An auxiliary ego is another group member who represents something or someone in the protagonist's experience. The auxiliary egos help account for the great range of therapeutic effects available in psychodrama.

GROUP. The members of the psychodrama and the audience make up the group. Some are participants, and others are observers, but all benefit from the experience to the extent that they can identify with the ongoing events. The concept of spontaneity in psychodrama refers to the ability of each group member, especially the protagonist, to experience the thoughts and feelings of the moment and to communicate emotion as authentically as possible.

Techniques. The psychodrama can focus on any particular area of functioning (a dream, a family, or a community situation), a symbolic role, an unconscious attitude, or an imagined future situation. The group can also act out such symptoms as delusions and hallucinations. Techniques to advance the therapeutic process and to increase productivity and creativity include the soliloquy (a recital of overt and hidden thoughts and feelings), role reversal (the exchange of the patient's role for the role of a significant person), the double (an auxiliary ego acting as the patient), the multiple double (several egos acting as the patient did on varying occasions), and the mirror technique (an ego imitating the patient and speaking for him or her). Other techniques include the use of hypnosis and psychoactive drugs to modify the acting behavior in various ways.

Ethical and Legal Issues

Confidentiality. Except where the law requires disclosure, the group therapist legally and ethically gives information about the group members to others only after obtaining appropriate patient consent. The therapist is obligated to take appropriate steps to be responsible to society, as well as to patients, when patients pose a danger to themselves or others. The guidelines for ethics of the American Group Psychotherapy Association state that

therapists must obtain specific permission to confer with the referring therapist or with the individual therapist when the patient is in conjoint therapy.

Although the group members, as well as the therapist, should protect the identity of the members and maintain confidentiality, the group members are not legally bound to do so. During the preparation of patients for group psychotherapy, therapists should routinely instruct the prospective members to keep all material discussed in the group confidential. Theoretically, in a legal case, one member of a group can be asked to testify against another, but such a situation is likely to be rare.

A therapist must exercise clinical judgment and caution in placing a patient in a group if he or she thinks that the burdens of maintaining secrets will be too great for some potential members or if a prospective group patient harbors a secret of such magnitude or notoriety that membership in a group would not be wise.

Violence and Aggression. Although reports of violence and aggression are rare, the potential exists that a group member may physically attack another patient or a therapist. The attack may occur within the group or outside the group. Careful selection of group members can diminish the likelihood of such an event. Patients with a demonstrated history of assaultive behavior and psychotic patients who pose a potential for violence should not participate in a group. In institutional settings, in which group therapy is common, sufficient safeguards must be in place to discourage any physical danger to others—for example, guards or attendants can act as observers.

Sexual Behavior. For therapists, sexual intercourse with a patient or a former patient is unethical; in many states, such behavior is considered a criminal act. The issue is complicated in group psychotherapy, however, because members may engage in sexual activities with one another. The issues of pregnancy, rape, and sexually transmitted infections by group members are open questions. If an injury results from sexual activity by group members, the therapist could be held accountable for not preventing such behavior. The therapist should advise prospective group members that each patient is responsible for reporting any sexual contact between members. The therapist cannot anticipate every group sexual encounter or

prevent sexual relationships from developing, but he or she is obligated to provide patients with guidelines of acceptable behavior. The therapist should identify sexual, vulnerable, or exploitive patients in the selection and preparation of patients for the group. Explicitly inform sociopathic patients who sexually exploit others that such behavior is not acceptable in the group and should be verbalized rather than acted out. The therapist must not encourage or tacitly allow sexual activity in the conduct of the group. Patients with AIDS are encouraged to reveal that they harbor the virus.

FAMILY THERAPY AND COUPLES THERAPY

Family Therapy

The family is the foundation of most societies. The study of families in different cultures has been a subject of fascination and scientific interest from viewpoints as diverse as sociology, group dynamics, anthropology, ethnicity, race, evolutionary biology, and, of course, the mental health field. The confluence of information gleaned from family studies has set the backdrop against which the contemporary practice of family therapy has evolved.

Family therapy is any psychotherapeutic endeavor that explicitly focuses on altering the interactions between or among family members and seeks to improve the functioning of the family as a unit. Both family therapy and couple therapy aim at some change in relational functioning. In most cases, they also aim at some other change, typically in the functioning of specific individuals in the family. Family therapy meant to heal a rift between parents and their adult children is an example of the use of family therapy centered on relationship goals. Family therapy aimed at increasing the family's coping with schizophrenia and at reducing the family's expressed emotion is an example of family therapy aimed at individual goals (in this case, the functioning of the person with schizophrenia), as well as family goals. In the early years of family therapy, experts viewed change in the family system as sufficient to produce individual change. More recent treatments aimed at change in individuals, as well as in the family system, tend to supplement the interventions that focus on interpersonal relationships with specific strategies that focus on individual behavior.

Indications. The presence of a relational difficulty is a clear indication for family and couple therapy. Couples and family therapies are the only treatments with evidence to support their use for such problems as marital maladjustment, and other methods, such as individual therapy, often have deleterious effects in these situations. Couples and family therapy also have a clear and important role in the treatment of numerous specific psychiatric disorders, often as a component within a multimethod treatment.

Of course, as with any therapy, the indications for family and couple therapy are broad and vary from case to case. Family therapy is a therapeutic collage of ideas regarding the underpinnings of family and individual stability and change, psychopathology, and problems in living, as well as relational ethics. Family therapy might better be called *systemically sensitive therapy*, and, in this sense, reflects a basic worldview as much as a clinical treatment methodology. For therapists thus inclined, then, all clinical problems involve salient interactional components; thus, some kind of family (or other functionally significant other's) involvement in therapy is always indicated, even in treatment that emphasizes individual problems.

An impressive array now exists of common clinical disorders and problems, including child, adolescent, and adult disorders, for which research has demonstrated family or couple treatment methods to be effective. In a few instances, couple and family interventions are probably even the treatment of choice, and for several disorders, the research argues for family intervention to be an essential part of treatment.

Techniques

INITIAL CONSULTATION. Family therapy is familiar enough to the general public for families with a high level of conflict to request it specifically. When the initial complaint is about an individual family member, however, pretreatment work may be needed. Underlying resistance to a family approach typically includes fears by parents that the therapist will blame them for their child's difficulties, that the entire family will be pronounced sick, that a spouse will object, and that open discussion of one child's misbehavior will have a negative influence on siblings. Refusal by an adolescent or young adult patient to participate in family therapy is frequently a disguised collusion with the fears of one or both parents.

INTERVIEW TECHNIQUE. The unique quality of a family interview springs from two important facts. A family comes to treatment with its history and dynamics firmly in place. To a family therapist, the established nature of the group, more than the symptoms, constitutes the clinical problem. Family members usually live together and, at some level, depend on one another for their physical and emotional well-being. Whatever transpires in the therapy session is known to all. Central principles of technique also derive from these facts. For example, the therapist must carefully channel the catharsis of anger by one family member toward another. The person who is the object of the anger will react to the attack, and the anger may escalate into violence and fracture relationships, with one member or more withdrawing from therapy. For another example, free association is inappropriate in family therapy because it can encourage one person to dominate a session. Thus, therapists must always control and direct the family interview.

FREQUENCY AND LENGTH OF TREATMENT. Unless an emergency arises, sessions occur no more than once a week. Each session, however, may require as much as 2 hours. Extended sessions can include an intermission to give the therapist time to organize the material and plan a response. A flexible schedule is necessary when geography or personal circumstances make it physically difficult for the family to get together. The length of treatment depends both on the nature of the problem and on the therapeutic model. Therapists who use problem-solving models exclusively may accomplish their goals in a few sessions, whereas therapists using growth-oriented models may work with a family for years and may schedule sessions at long intervals.

Schools of Family Therapy. Many schools of family therapy exist, none of which is superior to the others. The particular model used depends on the training received, the context in which therapy occurs, and the personality of the therapist. Table 23-6 outlines the major schools of family therapy, the influential practitioners of each method, and the focus of each technique.

Table 23-6
Schools of Family and Couple Therapy

Therapeutic Approach (Examples)	Core Concepts	Typical Goals	Common Strategies and Techniques	Comments
Behavioral/cognitive-behavioral (James Alexander, Neil Jacobson, Donald Baucom, Gerald Patterson)	Functional analysis Social learning theory Communication and problem solving Attributional style	Resolution of presenting problem Enhanced communication and problem-solving skills Balance between change and acceptance	Communication and problem-solving training Acceptance training/ reattribution techniques Parent management, emphasis on behavior/ consequences Therapist as educator	Functional analysis, not treatment techniques, is defining characteristic Arguably the most empirically supported of all family and couple methods
Bowen family systems (Murray Bowen, Philip Guerin, Michael Kerr, Monica McGoldrick)	Differentiation of self Triangulation Emotional cutoffs Family emotional system Sibling position	Increased differentiation Detriangulation Cutoffs resolved Improved ability to manage anxiety	Use of genogram Therapist as "coach" Education about multigenerational family processes	Often conducted with only a single patient Influence continues but has waned since Bowen's death
Experiential–humanistic (Susan Johnson and Leslie Greenberg, Virginia Satir, Carl Whitaker)	Communication styles (e.g., placater–blamer) Psychotherapy of the absurd Attachment theory	Fostering creativity (comfort with "craziness") Increased family cohesion Personal growth, self-esteem Tolerance for conflict	Resolving the battle for structure and the battle for initiative Frequent use of cotherapists Family sculpture Use of self Family reconstruction	Since Whitaker's death, symbolic–experiential approach receding in visibility Emotionally focused therapy one of few nonbehavioral or psychodynamic couple methods increasing in influence
Integrative (Alan Gurman, William Pinsof, Douglas Snyder, Froma Walsh)	Importance of and relationships among multiple levels of experience Theoretical and technical eclecticism	Improved communication and problem solving Enhanced interactional insight Presenting problems	Combinations of cognitive-behavioral and psychodynamic methods, in general systems context	Along with behavioral and psychoeducational methods, the most sensitive to research findings Attempts to match interventions to problem and family
Mental Research Institute brief therapy (Don Jackson, John Weakland, Paul Watzlawick)	Distinction between "difficulties" and "problems" Communication processes Symptom as communication First- and second-order change	Resolution of presenting problem Second-order change	Reframing Therapist maneuverability	Historically overlaps strategic, but with important differences (e.g., "function" of symptoms)
Feminist (Virginia Goldner, Rachel Hare-Mustin, Betty Carter)	Raising gender consciousness Underlying effect of gender	Gender equality Recognizing gender inequities	Raising consciousness Identifying and challenging culturally constructed narratives	Not so much a way of intervening as a set of issues to address; has had a pervasive effect on family and couple therapy
Narrative (David Epston, Michael White, Harlene Anderson)	Constructivism "Languaging" "Stories" socially created Problem-saturated descriptions	Resolution of presenting problem Enhancing undiscovered parts of self	Externalization of problems Focusing on "unique outcomes" Creation of new meaning via "restorying" Therapeutic letters	Currently very popular but rarely acknowledges overlaps with cognitive and behavioral theory
Psychodynamic–psychoanalytic (Nathan Ackerman, Henry Dicks, Clifford Sager, Jill Scharff and David Scharff)	Object relations Projective identification Splitting Scapegoating	Improved insight Genetic (historical) awareness Enhanced empathy De-emphasize presenting problem Disentangle interlocking pathologies	Transference, resistance, and countertransference analysis Creation of holding environment Interpretation Emphasis on therapeutic alliance	Probably influences family therapists' clinical work more than is usually acknowledged

Psychoeducational (Carol Anderson, Ian Falloon, William McFarlane, David Miklowitz)	Biopsychosocial theory Stress-diathesis Expressed emotion	Enhanced family coping skills Improved communication and problem-solving skills Relapse prevention	Survival skills workshops Family management Family information and education Concurrent use of psychopharmacology	Without doubt, the most effective family-based approach for families with a member with major psychiatric disorder
Solution focused (Steve de Shazer and Insoo Berg, William O'Hanlon, Michele Weiner-Davis)	Focus on solutions, not problems Unimportance of problem etiology Disbelief in resistance	Resolution of presenting problem Creation of solutions	Scaling questions Miracle questions Exception questions Client empowerment Coping questions Inquire about changes made since deciding to take action ("pre-session changes")	Grows out of basic Mental Research Institute philosophy, emphasizing solutions more than problems. Has made extraordinary claims of effectiveness
Strategic (Milton Erickson, Jay Haley, Cloe Madanes, James Keim)	Power and control Family life cycle Symptom-maintaining sequences Function of problems	Resolve presenting problem Disruption of problem-maintaining sequences	Persuasion Paradoxical injections Insight downplayed Pretend and ordeal techniques	Unfortunate de-emphasis on biology, psychiatric diagnosis, and personality theory
Structural (Harry Aponte, Salvador Minuchin, Jose Szapocznik)	Boundaries Hierarchies Coalitions and alliances Complementarity Engagement–enmeshment	Increased flexibility Adaptability to developmental change Balance between connectedness and differentiation Subsystem functioning	Unbalancing Enactment Joining	Arguably the most influential family therapy approach
Transgenerational (Ivan Boszormenyi-Nagy, James Framo, Laura Roberto-Forman)	Invisible loyalties Ledgers and debts Family mourning Personal authority	More universal than family-specific goals Increased trust Repair ruptured relationships	Multidirected partiality Family-of-origin sessions Use of cotherapy	Almost all multi-/transgenerational methods have significant psychodynamic underpinnings

Modifications of Techniques

FAMILY GROUP THERAPY. Family group therapy combines several families into a single group. Families share mutual problems and compare their interactions with those of the other families in the group. Treatment of families impacted by schizophrenia has been effective in multiple family groups. Parents of disturbed children may also meet together to share their situations.

SOCIAL NETWORK THERAPY. In social network therapy, the social community or network of a disturbed patient meets in group sessions with the patient. The network includes those with whom the patient comes into contact in daily life, not only the immediate family but also relatives, friends, tradespersons, teachers, and coworkers.

PARADOXICAL THERAPY. With the paradoxical therapy approach, which evolved from the work of Gregory Bateson, a therapist suggests that the patient intentionally engage in the unwanted behavior (called the paradoxical

injunction) and, for example, avoid a phobic object or perform a compulsive ritual. Although paradoxical therapy and the use of paradoxical injunctions seem to be counterintuitive, the therapy can create new insights for some patients. It is used in individual therapy as well as in family therapy.

REFRAMING. Reframing, also known as *positive connotation,* is a relabeling of all negatively expressed feelings or behavior as positive. When the therapist attempts to get family members to view behavior from a new frame of reference, "This child is impossible," becomes "This child is desperately trying to distract and protect you from what he or she perceives as an unhappy marriage." Reframing is an important process that allows family members to view themselves in new ways that can produce change.

Goals. Family therapy has several goals: to resolve or reduce pathogenic conflict and anxiety within the matrix of interpersonal relationships; to enhance the perception and fulfillment by family members of one another's emotional needs; to promote appropriate role relationships between the sexes and generations; to strengthen the capacity of individual members and the family as a whole to cope with destructive forces inside and outside the surrounding environment; to influence family identity and values to orient members toward health and growth. The therapy ultimately aims to integrate families into the large systems of society, extended family, and community groups and social systems, such as schools, medical facilities, and social, recreational, and welfare agencies.

Couples (Marital) Therapy

Couples or marital therapy is a form of psychotherapy designed to psychologically modify the interaction of two persons in conflict with each other over one parameter or a variety of parameters—social, emotional, sexual, or economic. In couples therapy, a trained person establishes a therapeutic contract with a patient-couple and, through definite types of communication, attempts to alleviate the disturbance, to reverse or change maladaptive patterns of behavior, and to encourage personality growth and development.

Marriage counseling may be considered more limited in scope than marriage therapy: the focus is only surrounding a particular familial conflict,

and the counseling is primarily task-oriented, geared to solving a specific problem, such as child-rearing. Marriage therapy, by contrast, emphasizes restructuring a couple's interaction and sometimes explores the psychodynamics of each partner. Both therapy and counseling emphasize helping marital partners cope effectively with their problems. Most important is the definition of appropriate and realistic goals, which may involve extensive reconstruction of the union or problem-solving approaches or a combination of both.

Types of Therapies

INDIVIDUAL THERAPY. In individual therapy, the partners may consult different therapists, who do not necessarily communicate with each other and indeed may not even know each other. The goal of treatment is to strengthen each partner's adaptive capacities. At times, only one of the partners is in treatment, and, in such cases, it is often helpful for the person who is not in treatment to visit the therapist. Not only can the visiting partner provide data about the patient that the therapist might otherwise overlook, but the therapist can identify and deal with overt or covert anxiety in the visiting partner resulting from change in the patient, correct irrational beliefs about treatment events, and examine conscious or unconscious attempts by the partner to sabotage the patient's treatment.

INDIVIDUAL COUPLES THERAPY. In individual couples therapy, each partner is in therapy, which is either concurrent, with the same therapist, or collaborative, with each partner seeing a different therapist.

CONJOINT THERAPY. In conjoint therapy, the most common treatment method in couples therapy, either one or two therapists treat the partners in joint sessions. Cotherapy with therapists of both sexes prevents a particular patient from feeling ganged up on when confronted by two members of the opposite sex.

FOUR-WAY SESSION. In a four-way session, each partner is seen by a different therapist, with regular joint sessions in which all four persons participate. A variation of the four-way session is the roundtable interview, developed by

William Masters and Virginia Johnson for the rapid treatment of sexually dysfunctional couples. Two patients and two opposite-sex therapists meet regularly.

GROUP PSYCHOTHERAPY. Group therapy for couples allows a variety of group dynamics to affect the participants. Groups usually consist of three to four couples and one or two therapists. The couples identify with one another and recognize that others have similar problems; each gains support and empathy from fellow group members of the same or opposite sex. They explore sexual attitudes and have an opportunity to gain new information from their peer groups, and each receives specific feedback about his or her behavior, either negative or positive, which may have more meaning and be better assimilated coming from a neutral, nonspouse member, for example, than from the spouse or the therapist.

During the middle phase of a couples group comprising four couples, the theme of whether to have children arose. One couple had just come from a visit to the gynecologist, who informed them that they were running out of time because of the wife's age. The woman in the couple did not want to have children, but her husband did. His complaint about the marriage was that his wife never was demonstrative in showing her loving feelings for him. He felt her to be detached, distant, and sexually inhibited.

The prevailing sentiment among the other couples who had children was that children only added additional stress to an already stressed relationship. One other couple, however, voiced their different view by describing how their children had enriched their lives.

As the talk about going forward and getting pregnant progressed, the group leader noted the nonverbal communication between the ambivalent couple. Whenever the tone of the group leaned toward having children, the wife would reach out and grasp the hand of her husband tenderly. This action invariably had the effect of stopping him from pursuing the topic for fear of the withdrawal of her affection. All this occurred without words. Once identified, this repetitive nonverbal pattern was available for examination in the group, and the supportive elements provided by other members and the leader encouraged a frank, direct, and open

conversation between the partners, who eventually chose to go forward and attempt to have a child. (Courtesy of H. I. Spitz, M.D. and S. Spitz, ACSW.)

COMBINED THERAPY. Combined therapy refers to all or any of the preceding techniques used concurrently or in combination. Thus, a particular patient-couple may begin treatment with one or both partners in individual psychotherapy, continue in conjoint therapy with the partner, and terminate therapy after a course of treatment in a married couples' group. The rationale for combined therapy is that there is no evidence to support that a single approach to marital problems is superior to another. Familiarity with a variety of approaches thus allows therapists flexibility that provides maximal benefit for couples in distress.

Indications. Whatever the specific therapeutic technique, initiation of couples therapy is appropriate when individual therapy has failed to resolve the relationship difficulties, when the onset of distress in one or both partners is clearly a relational problem, and when a couple in conflict requests couples therapy. Problems in communication between partners are a prime indication for couples therapy. In such instances, one spouse may be intimidated by the other, may become anxious when attempting to tell the other about thoughts or feelings, or may project unconscious expectations onto the other. The therapy works toward enabling each partner to see the other realistically.

Conflicts in one or several areas, such as the partners' sexual life, are also indications for treatment. Similarly, difficulty in establishing satisfactory social, economic, parental, or emotional roles implies that a couple needs help. Clinicians should evaluate all aspects of the marital relationship before attempting to treat only one problem, which could be a symptom of a pervasive marital disorder.

Contraindications. Contraindications for couples therapy include patients with severe forms of psychosis, particularly patients with paranoid elements and those in whom the marriage's homeostatic mechanism is a protection against psychosis, marriages in which one or both partners really want to divorce, marriages in which one spouse refuses to participate because of

anxiety or fear, and when there is a threat of domestic violence.

Goals. Nathan Ackerman defined the aims of couples therapy as follows: the goals of therapy for partner relational problems are to alleviate emotional distress and disability and to promote the levels of well-being of both partners together and of each as an individual. Ideally, therapists move toward these goals by strengthening the shared resources for problem-solving, by encouraging the substitution of adequate controls and defenses for pathogenic ones, by enhancing both the immunity against the disintegrative effects of emotional upset and the complementarity of the relationship, and by promoting the growth of the relationship and of each partner.

Part of a therapist's task is to persuade each partner in the relationship to take responsibility for understanding the psychodynamic makeup of personality. The emphasis is on each person's accountability for the effects of behavior on his or her own life, the life of the partner, and the lives of others in the environment. The result is often a deep understanding of the problems that created marital discord.

Couples therapy does not ensure the maintenance of any marriage or relationship. Indeed, in certain instances, it may show the partners that they are in a nonviable union and should consider dissolution. In these cases, couples may continue to meet with therapists to work through the difficulties of separating and obtaining a divorce, a process referred to as *divorce therapy*.

DIALECTICAL BEHAVIOR THERAPY

Dialectical behavior therapy (DBT) is the psychosocial treatment that has received the most empirical support for patients with BPD. Put simply, the overarching goal of DBT is to help create a life worth living for patients who often suffer tremendously from chronic and pervasive problems across many areas of their lives. DBT is a type of psychotherapy initially developed for chronically self-injurious patients with BPD and parasuicidal behavior. In recent years, its use has extended to other forms of mental illness. The method is eclectic, drawing on concepts derived from supportive, cognitive, and behavioral therapies. Some elements trace back to Franz Alexander's view of therapy as a corrective emotional experience and other elements from

certain Eastern philosophical schools (e.g., Zen).

Weekly visits aim to improve interpersonal skills and decrease self-destructive behavior using techniques involving advice, metaphor, storytelling, and confrontation, among others. Patients with BPD especially are helped to deal with the ambivalent feelings that are characteristic of the disorder. Marsha Linehan, Ph.D., developed the treatment method based on her theory that such patients cannot identify emotional experiences and cannot tolerate frustration or rejection. As with other behavioral approaches, DBT assumes all behavior (including thoughts and feelings) is learned and that patients with BPD behave in ways that reinforce or even reward their behavior, regardless of how maladaptive it is.

Functions of DBT

As described by its originator, there are five essential "functions" in treatment: (1) to enhance and expand the patient's repertoire of skillful behavioral patterns; (2) to improve patient motivation to change by reducing reinforcement of maladaptive behavior, including dysfunctional cognition and emotion; (3) to ensure that new behavioral patterns generalize from the therapeutic to the natural environment; (4) to structure the environment so that effective behaviors, rather than dysfunctional behaviors, are reinforced; and (5) to enhance the motivation and capabilities of the therapist so that the treatment rendered is effective. Figure 23-1 illustrates how DBT breaks the cycle of problem behavior being used to avoid emotional distress.

The four modes of treatment in DBT are as follows: (1) group skills training, (2) individual therapy, (3) phone consultations, and (4) consultation team. Descriptions of these modes of treatment are below. Other ancillary treatments used are pharmacotherapy and hospitalization when needed.

Group Skills Training. In group format, patients learn specific behavioral, emotional, cognitive, and interpersonal skills. Unlike traditional group therapy, observations about others in the group are discouraged. Instead, DBT takes a didactic approach, using specific exercises from a skills training manual, many of which emphasize control of emotional dysregulation and impulsive behavior.

Individual Therapy. Sessions in DBT occur weekly, generally for 50 to 60

minutes, in which review of skills learned during group training takes place, along with examination of life events from the previous week. Therapists note episodes of pathologic behavioral patterns that could have been corrected if learned skills had been put into effect. Patients are encouraged to record their thoughts, feelings, and behaviors on diary cards, which therapists analyze in the session.

Telephone Consultation. Therapists are available for phone consultation 24 hours per day. Patients are encouraged to call when they feel themselves heading toward some crisis that might lead to injurious behavior to themselves or others. Calls are intended to be brief and usually last about 10 minutes.

Consultation Team. Therapists meet in weekly meetings to review their work with their patients. By doing so, they provide support for one another and maintain motivation in their work. The meetings enable them to compare the techniques used and to validate those that are most effective (Table 23-7).

Results

Several studies evaluating the effect of DBT for patients with BPD found that such therapy was positive. Patients had a low dropout rate from treatment, the incidence of parasuicidal behaviors declined, self-report of angry affect decreased, and social adjustment and work performance improved. The method is now being applied to other disorders, including substance use disorders, eating disorders, schizophrenia, and PTSD.

Table 23-7
Consultation Team Agreements in Dialectical Behavior Therapy

1. Meet weekly for 1–2 hr
2. Discuss cases according to the treatment hierarchy (i.e., self-injurious/life-threatening behavior, treatment-interfering behavior, and quality-of-life–interfering behavior)
3. Accept a dialectical philosophy

4. Consult with the patient on how to interact with other therapists, and do not tell other therapists how to interact with the patient

5. Do not expect consistency of therapists with one another (even across the same patient)

6. Allow all therapists to observe their own limits without fear of judgmental reactions from other consultation group members

7. Search for nonpejorative, empathic interpretation of patient's behavior

8. Acknowledge that all therapists are fallible

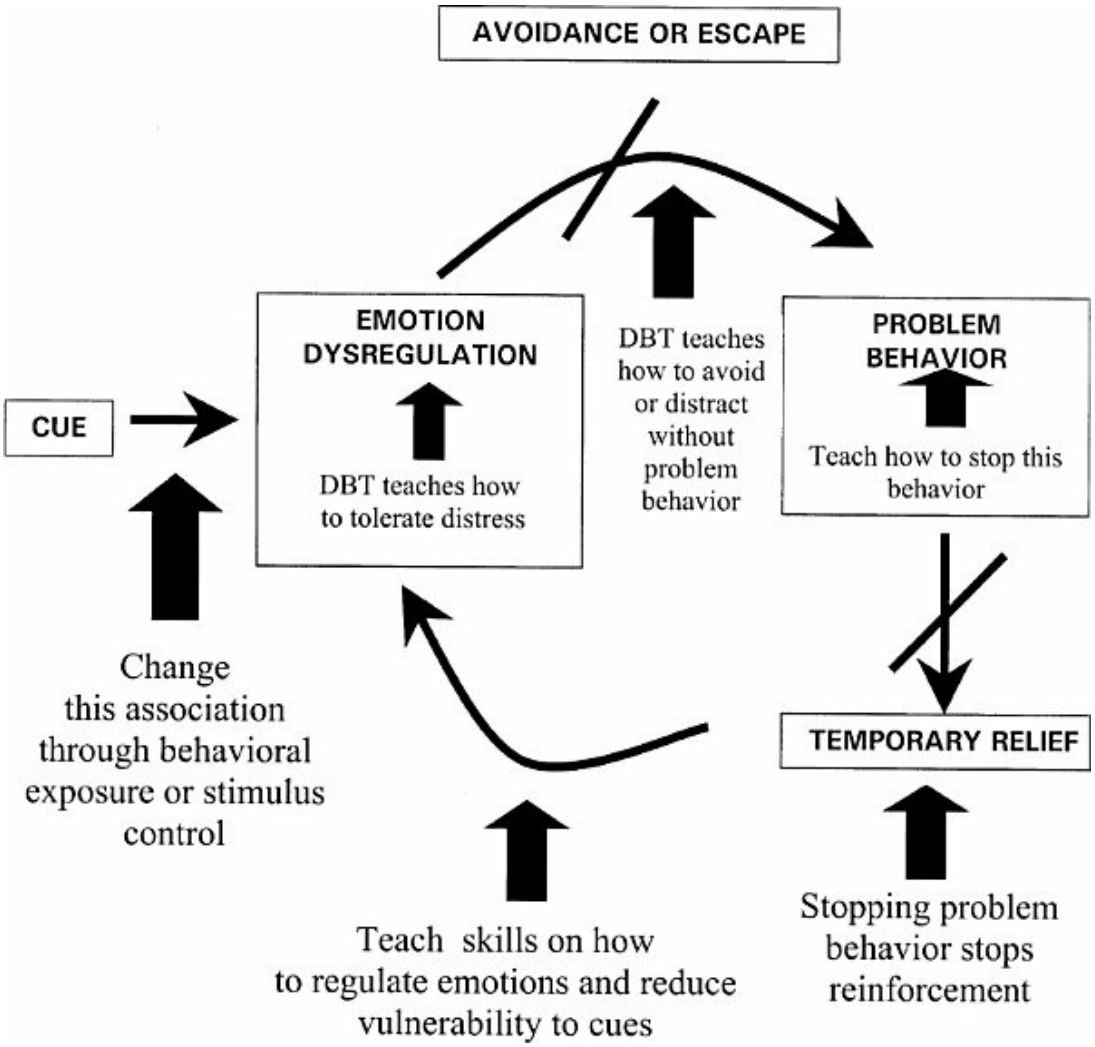

FIGURE 23-1
How dialectical behavior therapy (DBT) works.

BIOFEEDBACK

Biofeedback involves the recording and display of small changes in the physiologic levels of the feedback parameter. The display can be visual, such as a big meter or a bar of lights, or auditory. Therapists instruct patients to change the levels of the parameter, using the feedback from the display as a guide. The basis of biofeedback is the idea that the autonomic nervous system can come under voluntary control through operant conditioning. Biofeedback can be used by itself or in combination with relaxation. For example, patients with urinary incontinence use biofeedback alone to regain control over the pelvic musculature. The rehabilitation of neurologic disorders also uses biofeedback. The relaxation that patients learn to facilitate may augment the benefits of biofeedback.

Theory

Neal Miller demonstrated the medical potential of biofeedback by showing that the normally involuntary autonomic nervous system is susceptible to operant conditioning by the use of appropriate feedback. Utilizing instruments, patients acquire information about the status of involuntary biologic functions, such as skin temperature and electrical conductivity, muscle tension, blood pressure, heart rate, and brain wave activity. Patients then learn to regulate one or more of these physiologic states that affect symptoms. For example, a person can learn to raise the temperature of his or her hands to reduce the frequency of migraines, palpitations, or angina pectoris. Presumably, patients lower the sympathetic activation and voluntarily self-regulate arterial smooth muscle vasoconstrictive tendencies.

Methods

Instrumentation. The feedback instrument used depends on the patient and the specific problem. The most effective instruments are the electromyogram (EMG), which measures the electrical potentials of muscle fibers; the electroencephalogram (EEG), which measures alpha waves that occur in relaxed states; the galvanic skin response (GSR) gauge, which shows decreased skin conductivity during a relaxed state; and the thermistor, which measures skin temperature (which drops during tension because of peripheral

vasoconstriction). Patients are attached to one of the instruments that measure a physiologic function and translate the measurement into an audible or visual signal that patients use to gauge their responses. For example, in the treatment of bruxism, an EMG is attached to the masseter muscle. The EMG emits a high tone when the muscle contracts and a low tone when at rest. Patients can learn to alter the tone to indicate relaxation. Patients receive feedback about the masseter muscle, the tone reinforces the learning, and the condition ameliorates—all of these events interacting synergistically.

Many less-specific clinical applications (e.g., treating insomnia, dysmenorrhea, and speech problems; improving athletic performance; treating volitional disorders; achieving altered states of consciousness; managing stress; and supplementing psychotherapy for treating anxiety associated with somatic symptom and related disorders) use a model in which frontalis muscle EMG biofeedback is combined with thermal biofeedback and verbal instructions in progressive relaxation.

Relaxation Therapy. Muscle relaxation is used as a component of treatment programs (e.g., systematic desensitization) or as a treatment in its own right (relaxation therapy). Relaxation involves (1) immobility of the body, (2) control over the focus of attention, (3) low muscle tone, and (4) cultivation of a specific frame of mind, described as contemplative, nonjudgmental, detached, or mindful.

Edmund Jacobson developed progressive relaxation in 1929. Jacobson observed that when an individual lies “relaxed,” in the ordinary sense, the following clinical signs reveal the presence of residual tension: respiration is slightly irregular in time or force; the pulse rate, although often normal, is in some instances moderately increased as compared with later tests; voluntary or local reflex activities are evident in such slight marks as wrinkling of the forehead, frowning, movements of the eyeballs including frequent or rapid winking, restless shifting of the head, a limb, or even a finger; and finally, the mind continues to be active, and once started, worry or oppressive emotion will persist. It is incredible that a faint degree of tension can be responsible for all of this.

Learning relaxation, therefore, involves cultivating a muscle sense. To develop the muscle sense further, patients learn to isolate and contract specific muscles or muscle groups, one at a time. For example, patients flex

the forearm while the therapist holds it back to observe tenseness in the biceps muscle. (Jacobson used the word “tenseness” rather than “tension” to emphasize the patient’s role in tensing the muscles.) Once the patient reports this sensation, Jacobson would say, “This is your doing! What we wish is the reverse of this—simply not doing.” The therapist repeatedly reminds the patient that relaxation involves no effort. In fact, “making an effort is being tense and therefore is not to relax.” As the session progresses, the therapist instructs the patient to let go further and further, even past the point when the body part seems perfectly relaxed.

Patients would work in this fashion with different muscle groups, often over more than 50 sessions. For example, an entire session might involve relaxing the biceps muscle. Another feature of Jacobson’s method was to give instructions tersely so they would not interfere with a patient’s focus on muscle sensations; suggestions commonly used today (e.g., “*Your arm is becoming limp*”) were avoided. Patients were also frequently left alone, while the therapist attended to other patients.

In psychiatry, relaxation therapy is primarily a component of multifaceted broad-spectrum programs. Its use in desensitization was mentioned previously. Relaxing breathing exercises are often helpful for patients with panic disorder, especially when considered to be related to hyperventilation. In the treatment of patients with anxiety disorders, relaxation can serve as an occasion-setting stimulus (i.e., as a context of safety in which to try other specific interventions confidently). Table 23-8 describes some common relaxation techniques.

Table 23-8
Example Relaxation Techniques

Technique	Approach
Autogenic training	The patient is instructed to concentrate on feelings of warmth, heaviness, and relaxation throughout their body.
Biofeedback-assisted relaxation	The patient uses real-time biofeedback data to concentrate on certain physiologic functions, such as muscle

	tension.
Deep breathing/breathing exercises	The patient focuses on taking slow, deep, even breaths.
Guided imagery	The patient is taught to focus on pleasant images as a replacement for negative ones.
Progressive relaxation/progressive muscle relaxation	The patient is instructed to tighten and relax various muscle groups.
Self-hypnosis	The patient is taught to produce a relaxation response when prompted by a suggestion (usually a phrase or a nonverbal cue).

Adapted from National Center for Complementary and Integrative Health. Relaxation technique for health. https://www.nccih.nih.gov/health/relaxation-techniques-for-health

Later Adaptation of Progressive Muscular Relaxation. Joseph Wolpe chose progressive relaxation as a response incompatible with anxiety when designing his systematic desensitization treatment (discussed below). For this purpose, Jacobson's original method was too lengthy to be practical. Wolpe abbreviated the program to 20 minutes during the first six sessions (devoting the remainder of these sessions to other things, such as behavioral analysis). In a later modification of progressive relaxation, patients completed work with all the principal muscle groups in one session. Once patients have mastered this procedure (typically after three sessions), they learn to combine these groups into larger groups. Finally, patients practice relaxation by recall (i.e., without tensing the muscles).

Autogenic Training. Autogenic training is a method of self-suggestion that originated in Germany. It involves the patients directing their attention to specific bodily areas and hearing themselves think certain phrases reflecting a relaxed state. In the original German version, patients progressed through six themes over many sessions. Table 23-9 contains a list of these six areas,

along with representative autogenic phrases. Autogenic relaxation is an American modification of autogenic training, in which one session covers all six areas.

Applied Tension. Applied tension is a technique that is the opposite of relaxation; applied tension can counteract the fainting response. The treatment extends over four sessions. In the first session, patients learn to tense the muscles of the arms, legs, and torso for 10 to 15 seconds (as if they were bodybuilders). The tension is maintained long enough for a sensation of warmth to develop in the face. The patients then release the tension but do not progress to a state of relaxation. The maneuver is repeated five times at half-minute intervals. Feedback of the patient's blood pressure during the muscle contraction can augment this method; increased blood pressure suggests the achievement of appropriate muscle tension. The patients continue to practice the technique five times a day. An adverse effect of treatment that sometimes develops is headache. In this case, the patient reduces the intensity of the muscle contraction and the frequency of treatment.

Table 23-9
Sample Autogenic Phrases

Theme	Examples of Self-Statements
Heaviness	"My left arm is heavy."
Warmth	"My left arm is warm."
Cardiac regulation	"My heartbeat is calm and regular."
Breathing adjustment	"It breathes me."
Solar plexus	"My solar plexus is warm."
Forehead	"My forehead is cool."

Patients with blood and injury phobia show a unique, biphasic response when exposed to a phobic stimulus. The first phase is associated with increased heart rate and blood pressure. In the second phase, however, blood

pressure suddenly falls, and the patient faints. To treat the problem, the therapist shows the patient a series of slides that are provocative (e.g., mutilated bodies). The patient learns to identify early warning signs of fainting, such as queasiness, cold sweats, or dizziness, and to apply the learned muscle tension response quickly, contingent on these warning signs. Patients can also perform applied tension while donating blood or watching a surgical operation. The technique of isometric tension raises blood pressure, which prevents fainting.

Table 23-10
Steps in Applied Relaxation

Technique	Instructions
Progressive relaxation	Session 1: hands, arms, face, neck, and shoulders. Session 2: back, chest, stomach, breathing, hips, legs, and feet.
Release-only relaxation	As with progressive relaxation, except that the tension phase is omitted; when release-only relaxation is mastered, the patient can relax within 5–7 min.
Cue-controlled relaxation	A stimulus—the word *relax*—is presented just before exhalation; patients focus on their breathing while already in a relaxed state; the therapist says the word *inhale* just before each inhalation and the word *relax* just before each exhalation; after approximately five cycles, the patient mentally says these words (optionally dropping the *inhale*).
Differential relaxation	Patients can remain relaxed and move at the same time by differentially keeping muscles unrelated to the movement in a relaxed state; after achieving a relaxed state, patients lift an arm or a leg or look around in the room, while keeping movements and tension in other body parts at a minimum; patients

	also perform differential relaxation in other settings, including sitting in different chairs, sitting at a desk while writing, talking on the phone, and walking.
Rapid relaxation	Patients relax by taking one to three breaths with slow exhalations, thinking the word *relax* before each exhalation and scanning their bodies for areas of tension; with this practice, relaxation is shortened to 20–30 s; patients are instructed to relax in this manner 15–20 times per day at certain predetermined events in their natural environment (e.g., when they look at a watch or make a telephone call. As a reminder, colored dots might be taped on the watch or phone. After some time, the dots are changed to a different color to keep their reminding power fresh).
Application training	Patients relax just before entering the target situation; they stay in the situation for 10–15 min, using their relaxation skills as a coping technique; patients may initially be accompanied by the therapist; alternatively, if the patient's problem is panic attacks or generalized anxiety, imagery or physical exercise is used to induce fearful sensations, which then are used for application training.

Applied Relaxation. Applied relaxation involves eliciting a relaxation response in the stressful situation itself. The previous discussion showed that this is not advisable right away because of the possible ironic effects of relaxation. Therefore, patients should first practice relaxation in nonstressful circumstances. The method developed by Lars-Göran Öst and coworkers in Sweden has been proven efficacious for panic disorder and generalized anxiety disorder. Establishing the relaxation response in the patient's natural environment consists of seven phases of one to two sessions each: progressive relaxation, release-only relaxation, cue-controlled relaxation, differential relaxation, rapid relaxation, application training, and

maintenance. Table 23-10 provides details.

Results

Biofeedback, progressive relaxation, and applied tension are effective treatment methods for a broad range of disorders. They form one basis of behavioral medicine in which the patient changes (or learns how to change) behavior that contributes to illness. They form a basis on which many complementary and alternative medical procedures are effective (e.g., yoga and Reiki) in which relaxation is a critical component. Relaxation also informs more mainstream treatments, such as hypnosis.

COGNITIVE THERAPY

Cognitive therapy, developed by Aaron T. Beck, MD, is based on the cognitive model, which has been widely studied and has received substantial empirical support. The cognitive model posits that it is not situations that directly impact one's reaction (emotional, behavioral, and physiologic). Rather, it is one's automatic *perception* of the situation that is more closely associated with the reaction. A depressed individual, for example, who is reading this chapter (situation), might think, "I can't concentrate. There is something seriously wrong with me. I'll never get better" ("automatic thoughts"). As a result, his sadness and hopelessness increase (emotional reaction); he stops reading altogether (behavioral reaction); and he feels a weight in his chest (physiologic reaction). On the other hand, another individual might think, "I don't want to read this. I don't want to know anything about this topic, but I have to." She then feels annoyed, her body becomes somewhat tense, and she skims the pages instead of reading the article carefully. One important component of cognitive therapy involves teaching patients to identify the thoughts that lead to distress or dysfunction, to evaluate their thinking, and to effectively respond to these cognitions. Figure 23-2 depicts the cognitive model.

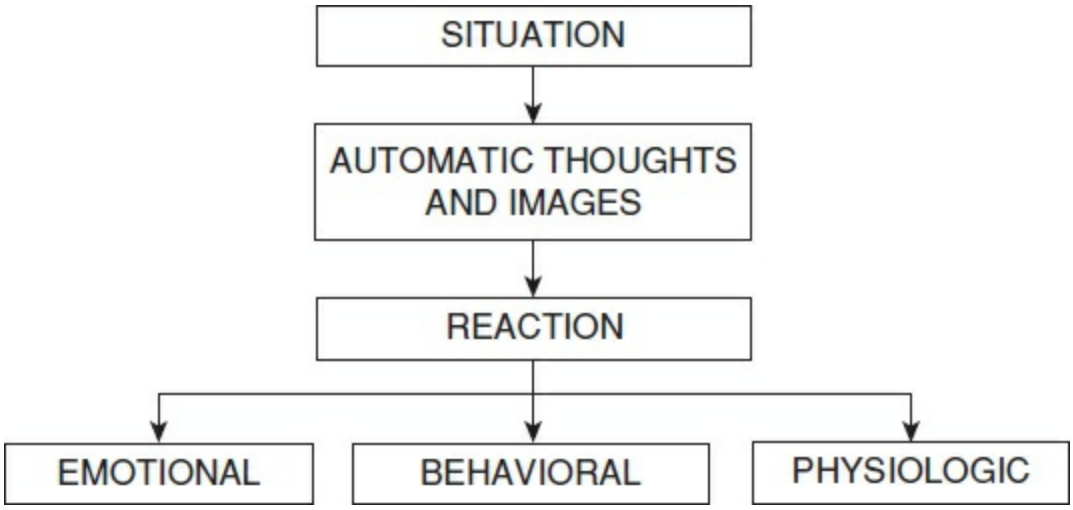

FIGURE 23-2
Cognitive model.

A strong therapeutic alliance is essential for effective treatment, and the relationship is collaborative. Both patients and clinicians are active in solving problems, evaluating cognitions, and modifying behavior. Cognitive therapy is educative; clinicians teach patients how to use the techniques at home that they have employed in session. The clinician's stated goal is to help patients become their own therapists. They emphasize that the way patients get better is to apply what they have learned in session to make small changes in their thinking and behavior every day.

Originally designed as a short-term treatment for depression, cognitive therapy has evolved over the years. Patients with straight-forward cases of anxiety and depression, who were relatively psychologically healthy before the onset of their disorder, often benefit from a short course of treatment, perhaps 6 to 12 sessions. At the other end of the spectrum are patients whose disorders are chronic or complex, or those for whom standard treatment needs to be varied due to personality disorders. They may need many more sessions over a significantly longer period of time. Those with recurrent episodes or with serious mental illnesses may require intermittent treatment through their lifetime.

Cognitive Theory of Depression

According to the cognitive theory of depression, cognitive dysfunctions are the core of depression, and affective and physical changes and other

associated features of depression are consequences of cognitive dysfunctions. For example, apathy and low energy result from a person's expectation of failure in all areas. Similarly, paralysis of will stems from a person's pessimism and feelings of hopelessness. From a cognitive perspective, depression can be explained by the cognitive triad, which explains that negative thoughts are about the self, the world, and the future.

The goal of therapy is to alleviate depression and to prevent its recurrence by helping patients to identify and test negative cognitions, to develop alternative and more flexible schemas, and to rehearse both new cognitive and behavioral responses. Changing the way a person thinks can alleviate the psychiatric disorder.

Strategies and Techniques

The goal of cognitive therapy is to facilitate remission and prevent or reduce relapse by teaching skills patients can use for their lifetime, within a highly supportive, collaborative relationship. Both patients and clinicians are active participants, jointly solving current problems, evaluating patients' cognitions in specific situations, and working toward needed behavior change. As a result, patients' symptoms decrease and their mood and day-to-day functioning improves.

As with other psychotherapies, therapists' attributes are important to successful therapy. Therapists must exude warmth, understand the life experience of each patient, and be genuine and honest with themselves and with their patients. They must be able to relate skillfully and interactively with their patients. Cognitive therapists set the agenda at the beginning of each session, assign homework between sessions, and teach new skills. The therapist and patient collaborate actively. There are several techniques utilized in cognitive therapy; three common components are described below.

Didactic Aspects. The therapy's didactic aspects include explaining to patients the cognitive triad, schemas, and faulty logic. Therapists must tell patients that they will formulate hypotheses together and test them throughout the treatment. Cognitive therapy requires a full explanation of the relation between symptoms and thinking, affect, and behavior, as well as the rationale for all aspects of treatment. This explanation contrasts with

psychoanalytically oriented therapies, which require little explanation.

Cognitive Techniques. The therapy's cognitive approach includes four processes: eliciting automatic thoughts, testing automatic thoughts, identifying maladaptive underlying assumptions, and testing the validity of maladaptive assumptions.

ELICITING AUTOMATIC THOUGHTS. Automatic thoughts, also called *cognitive distortions,* are cognitions that intervene between external events and a person's emotional reaction to the event. For example, the belief that "people will laugh at me when they see how badly I bowl" is an automatic thought that occurs to someone who receives an invitation to go bowling and responds negatively. Another example is the thought, "She doesn't like me," when someone passes in the hall without saying, "Hello." Examples of cognitive distortions are illustrated in Figure 23-3.

TESTING AUTOMATIC THOUGHTS. Acting as a teacher, a therapist helps a patient test the validity of automatic thoughts. The goal is to encourage the patient to reject inaccurate or exaggerated automatic thoughts after careful examination. Patients often blame themselves when things that are outside their control go awry. The therapist reviews the entire situation with the patient and helps reassign the blame or cause of the unpleasant events. Generating alternative explanations for events is another way of undermining inaccurate and distorted automatic thoughts.

IDENTIFYING MALADAPTIVE ASSUMPTIONS. As the patient and therapist continue to identify automatic thoughts, patterns usually become apparent. The patterns represent rules or maladaptive general assumptions that guide a patient's life. Samples of such rules are, "In order to be happy, I must be perfect," and, "If anyone doesn't like me, I'm not lovable." Such rules inevitably lead to disappointments and failure and, ultimately, to psychiatric symptoms such as depression. See Figure 23-4 for a sample automatic thought record.

All-or-nothing thinking *(also called black-and-white, polarized, or dichotomous thinking)*: You view a situation in only two categories instead of on a continuum. Example: "If I'm not a total success, I'm a failure."

Catastrophizing *(also called fortune-telling)*: You predict the future negatively without considering other, more likely outcomes. Example: "I'll be so upset, I won't be able to function at all."

Disqualifying or discounting the positive: You unreasonably tell yourself that positive experiences, deeds, or qualities do not count. Example: "I did that project well, but that doesn't mean I'm competent; I just got lucky."

Emotional reasoning: You think something must be true because you "feel" (actually believe) it so strongly, ignoring or discounting evidence to the contrary. Example: "I know I do a lot of things okay at work, but I still feel like I'm a failure."

Labeling: You put a fixed, global label on yourself or others without considering that the evidence might more reasonably lead to a less disastrous conclusion. Example: "I'm a loser. He's no good."

Magnification/minimization: When you evaluate yourself, another person, or a situation, you unreasonably magnify the negative and/or minimize the positive. Example: "Getting a mediocre evaluation proves how inadequate I am. Getting high marks doesn't mean I'm smart."

Mental filter *(also called selective abstraction)*: You pay undue attention to one negative detail instead of seeing the whole picture. Example: "Because I got one low rating on my evaluation [which also contained several high ratings] it means I'm doing a lousy job."

Mind reading: You believe you know what others are thinking, failing to consider other, more likely possibilities. Example: "He's thinking that I don't know the first thing about this project."

Overgeneralization: You make a sweeping negative conclusion that goes far beyond the current situation. Example: "[Because I felt uncomfortable at the meeting] I don't have what it takes to make friends."

Personalization: You believe others are behaving negatively because of you, without considering more plausible explanations for their behavior. Example: "The repairman was curt to me because I did something wrong."

"Should" and "must" statements *(also called imperatives)*: You have a precise, fixed idea of how you or others should behave, and you overestimate how bad it is that these expectations are not met. Example: "It's terrible that I made a mistake. I should always do my best."

Tunnel vision: You only see the negative aspects of a situation. Example: "My son's teacher can't do anything right. He's critical and insensitive and lousy at teaching."

FIGURE 23-3
Cognitive distortions. (From Beck JS. *Cognitive Behavior Therapy: Basics and Beyond*. 2nd ed; 2011. Reprinted with permission of Guilford Press.)

TESTING THE VALIDITY OF MALADAPTIVE ASSUMPTIONS. Testing the accuracy of maladaptive assumptions is similar to testing the validity of automatic thoughts. In a particularly effective test, therapists ask patients to defend the validity of their assumptions. For example, patients may state that they should always work up to their potential, and a therapist may ask, "*Why is that so important to you?*" Table 23-11 gives examples of some interventions designed to elicit, identify, test, and correct the cognitive distortions that lead to depressive and other painful affects.

A woman presented for therapy with anger control problems. Before therapy, she sent a slew of hostile voicemail and e-mail messages to a colleague, alienated her neighbors with her noise complaints, and received a request to leave her bowling league after two physical altercations with members of other teams. A careful review of the patient's thoughts and beliefs surrounding these situations revealed a common denominator of a sense of *mistrust* and *entitlement.* In each situation, she believed that others had gone out of their way to mistreat her. Furthermore, she had an exaggerated sense of self-importance represented by beliefs such as, "Nobody has the right to treat me that way," "I shouldn't have to deal with these people and their stupidity," and "I have to show them they can't ever push me around." To this patient, her anger was justified, as she was trying to defend herself from the misbehavior of others. However, to the outside observer, the patient was a "loose cannon" who took offense at the drop of a hat and whose behavior was outrageous and indefensible. In therapy, the patient at first was not open to viewing her anger problem in the manner just described. However, as she learned to recognize the activation of her schemas of *mistrust* and *entitlement,* she became more willing to consider ways in which she could modify her viewpoints and behaviors. This positive change was facilitated by the therapist's empathic responses to the patient's more credible stories of mistreatment she had received from her family, whose abusive behavior gave her the message that she should never trust anyone, and that she should never put up with being mistreated again. (Courtesy of C. F. Newman, Ph.D. and A. T. Beck, M.D.)

Behavioral Techniques. Behavioral and cognitive techniques go hand in hand; behavioral techniques test and change maladaptive and inaccurate cognitions. The overall purposes of such techniques are to help patients understand the inaccuracy of their cognitive assumptions and learn new strategies and ways of dealing with issues.

AUTOMATIC THOUGHT RECORD

Directions: When you notice your mood getting worse, ask yourself, **"What's going through my mind right now?"** and as soon as possible jot down the thought or mental image in the Automatic Thoughts column.

DATE/ TIME	SITUATION	AUTOMATIC THOUGHT(S)	EMOTION(S)	ALTERNATIVE RESPONSE	OUTCOME
	1. What event, daydream, or recollection led to the unpleasant emotion? 2. What (if any) distressing physical sensations did you have?	1. What thought(s) and/or image(s) went through your mind? 2. How much did you believe each one at the time?	1. What emotion(s) (sad, anxious, angry, etc.) did you feel at the time? 2. How intense (0-100%) was the emotion?	1. (optional) What cognitive distortion did you make? (e.g., all-or-nothing thinking, mind-reading, catastrophizing) 2. Use questions at bottom to compose a response to the automatic thought(s). 3. How much do you believe each response?	1. How much do you now believe each automatic thought? 2. What emotion(s) do you feel now? How intense (0-100%) is the emotion? 3. What will or did you do?
Friday 7:30 PM	I called Sally to go out, as we talked about. I got her answering machine. Felt a sinking sensation.	1) They have all gone out and forgotten about me, because I'm not important to them anymore. (90% believable) 2) I'm left out again. (90% believable) 3) I'm going to have to spend another Friday night alone. (100% believable) 4) I just don't fit in anywhere in this world. (70% believable)	1) Angry (60% intensity) 2) Lonely (95% intensity) 3) Depressed (95% intensity)	I'm engaging in arbitrary inference, overgeneralization, personalization, and catastrophization. 1) It could all be an innocent misunderstanding. (40% believable) 2) I have spent a lot of time with Sally and the others and I know they like me. (60% believable) 3) Being at home alone is not the end of the world. (50% believable)	1) 30% 2) 10% 3) 50% 4) 0% Angry (5%) Lonely (40%) Depressed (20%) Calm (70%) I will call back in an hour if I don't hear from Sally.

Questions to help compose an alternative response: (1) What is the evidence that the automatic thought is true? Not true? (2) Is there an alternative explanation? (3) What's the worst that could happen? Could I live through it? What's the best that could happen? What's the most realistic outcome? (4) What's the effect of my believing the automatic thought? What could be the effect of changing my thinking? (5) What should I do about it? (6) If _____ (friend's name) was in the situation and had this thought, what would I tell him/her?

FIGURE 23-4
Sample automatic thought record.

Among the behavioral techniques in cognitive therapy are scheduling activities, mastery and pleasure, graded task assignments, cognitive rehearsal, self-reliance training, role-playing, and diversion techniques. One of the first tasks in therapy is to schedule activities on an hourly basis. Patients keep records of the activities and review them with the therapist. In addition to scheduling activities, patients rate the amount of mastery and pleasure their activities bring them. Patients often express surprise that they have much more mastery of activities and enjoy them more than they had thought.

To simplify the situation and allow mini-accomplishments, therapists often break tasks into subtasks, as in graded task assignments, to show patients that they can succeed. In cognitive rehearsal, patients imagine and rehearse the various steps in meeting and mastering a challenge.

Patients (especially inpatients) are encouraged to become self-reliant by doing such simple things as making their own beds, doing their own shopping, and preparing their own meals. This process is called self-reliance training. Role-playing is a particularly powerful and useful technique to elicit automatic thoughts and to learn new behaviors. Diversion techniques are effective in helping patients get through difficult times and include physical activity, social contact, work, play, and visual imagery.

Imagery or thought stoppage can treat impulsive or obsessive behavior. For instance, patients imagine a stop sign with a police officer nearby or another image that evokes inhibition at the same time that they recognize an impulse or obsession that is alien to the ego. Similarly, obesity can be treated by having patients visualize themselves as thin, athletic, trim, and well-muscled, and then training them to evoke this image whenever they have an urge to eat. Hypnosis or autogenic training can enhance such imagery. In a technique called guided imagery, therapists encourage patients to have fantasies that can be interpreted as wish fulfillments or attempts to master disturbing affects or impulses.

Indications

Cognitive therapy may be used to (1) eliminate or moderate the symptoms of a psychiatric disorder or psychological distress as an independent treatment or in combination with medication; (2) modify underlying beliefs and schemas that contribute to the development and maintenance of disorders; (3) address psychosocial problems (e.g., marital discord, job stress, caregiver burnout) that may have preceded, coincided with, or been caused by the disorder; (4) reduce the likelihood of relapse or recurrence of a disorder after symptoms have resolved; (5) increase adherence to recommended medical treatment (e.g., medication, weight loss, diabetes management); or moderate

the impact of a medical condition on level of functioning (e.g., chronic pain, cancer).

BEHAVIOR THERAPY

The term *behavior* in *behavior therapy* refers to a person's observable actions and responses. Behavior therapy involves changing the behavior of patients to reduce dysfunction and to improve quality of life. Behavior therapy includes a methodology, referred to as *behavior analysis*, for the strategic selection of behaviors to change, and a technology to bring about behavior change, such as modifying antecedents or consequences or giving instructions. Behavior therapy has not only influenced mental health care but, under the rubric of behavioral medicine, it has also made inroads into other medical specialties.

Behavior therapy represents clinical applications of the principles developed in learning theory. Behavioral psychology, or behaviorism, arose in the early 20th century in reaction to the method of introspection that dominated psychology at the time. John B. Watson, the father of behaviorism, had initially studied animal psychology. This background made it a small conceptual leap to argue that psychology should concern itself only with publicly observable phenomena (i.e., overt behavior). According to behavioristic thinking, because mental content is not publicly observable, it cannot be subjected to rigorous scientific inquiry. Consequently, behaviorists developed a focus on overt behaviors and their environmental influences.

Today, different behavioral schools continue to share a focus on verifiable behavior. Behavioral views differ from cognitive views in holding that physical, rather than mental, events control behavior. According to behaviorism, mental phenomena or speculations about them are of little or no scientific interest.

History

As early as the 1920s, scattered reports about the application of learning principles to the treatment of behavioral disorders began to appear, but they had little effect on the mainstream of psychiatry and clinical psychology. Not until the 1960s did behavior therapy emerge as a systematic and comprehensive approach to psychiatric (behavioral) disorders; at that time, it

arose independently on three continents. Joseph Wolpe and his colleagues in Johannesburg, South Africa, used Pavlovian techniques to produce and eliminate experimental neuroses in cats. From this research, Wolpe developed systematic desensitization, the prototype of many current behavioral procedures for the treatment of maladaptive anxiety produced by identifiable stimuli in the environment. At about the same time, a group at the Institute of Psychiatry of the University of London, particularly Hans Jurgen Eysenck and M. B. Shapiro, stressed the importance of an empirical, experimental approach to understanding and treating individual patients, using controlled, single-case experimental paradigms and modern learning theory. The third origin of behavior therapy was work inspired by the research of Harvard psychologist B. F. Skinner. Skinner's students began to apply his operant-conditioning technology, developed in animal-conditioning laboratories, to human beings in clinical settings.

Systematic Desensitization

The foundation of systematic desensitization is the behavioral principle of counterconditioning, whereby a person overcomes maladaptive anxiety elicited by a situation or an object by approaching the feared situation gradually, in a psychophysiological state that inhibits anxiety. In systematic desensitization, patients attain a state of complete relaxation and are then exposed to the stimulus that elicits the anxiety response. The relaxed state inhibits the negative reaction of anxiety, a process called *reciprocal inhibition.* Rather than using actual situations or objects that evoke fear, patients and therapists prepare a graded list or hierarchy of anxiety-provoking scenes associated with a patient's fears. Treatment systematically pairs the learned relaxation state and the anxiety-provoking scenes. Thus, systematic desensitization consists of three steps: relaxation training, hierarchy construction, and desensitization of the stimulus.

Relaxation Training. Relaxation produces physiologic effects opposite to those of anxiety: slow heart rate, increased peripheral blood flow, and neuromuscular stability. A variety of relaxation methods exist. Some, such as yoga and Zen, have been known for centuries. Most methods use the so-called progressive relaxation, discussed above. Patients relax major muscle

groups in a fixed order, beginning with the small muscle groups of the feet and working cephalad or vice versa. Some clinicians use hypnosis to facilitate relaxation or use tape-recorded exercises to allow patients to practice relaxation on their own. Mental imagery is a relaxation method in which patients imagine themselves in a place associated with pleasant, relaxed memories. Such images allow patients to enter a relaxed state or experience (as Herbert Benson termed it) the *relaxation response*.

The physiologic changes that take place during relaxation are the opposite of those induced by the adrenergic stress responses that are part of many emotions. Muscle tension, respiration rate, heart rate, blood pressure, and skin conductance decrease. Finger temperature and blood flow to the finger usually increase. Relaxation increases respiratory heart rate variability, an index of parasympathetic tone.

Hierarchy Construction. When constructing a hierarchy, clinicians determine all the conditions that elicit anxiety, and then patients create a hierarchy list of 10 to 12 scenes in order of increasing anxiety. For example, an acrophobic hierarchy may begin with a patient imagining standing near a window on the second floor and end with being on the roof of a 20-story building, leaning on a guard rail and looking straight down.

Desensitization of the Stimulus. In the final step, called *desensitization,* patients proceed systematically through the list from the least to the most anxiety-provoking scene while in a deeply relaxed state. Their responses to the stimuli determine the rate at which patients progress through the list. When patients can vividly imagine the most anxiety-provoking scene of the hierarchy with equanimity, they experience little anxiety in the corresponding real-life situation.

ADJUNCTIVE USE OF DRUGS. Clinicians have used various drugs to hasten relaxation, but drugs should be used cautiously and only by clinicians trained and experienced in potential adverse effects. Either the ultra-rapidly acting barbiturate sodium methohexital or diazepam is given intravenously in subanesthetic doses. By implementing the procedural details carefully, almost all patients find the procedure pleasant, with few unpleasant side effects. The advantages of pharmacologic desensitization are a shortening of preliminary

training in relaxation, the ability for nearly all patients to relax adequately, and a more rapid progression of treatment than without the drugs.

INDICATIONS. Systematic desensitization works best in cases of a clearly identifiable anxiety-provoking stimulus. Phobias, obsessions, compulsions, and certain sexual disorders have been treated successfully with this technique.

Therapeutic-Graded Exposure

Therapeutic-graded exposure is similar to systematic desensitization, except that relaxation training is not involved, and treatment usually occurs in a real-life context. The individual must be brought in contact with (i.e., be exposed to) the warning stimulus to learn firsthand that no dangerous consequences will ensue. Exposure is graded according to a hierarchy. Patients afraid of cats, for example, might progress from looking at a picture of a cat to holding one.

Flooding

Flooding (sometimes called *implosion*) is similar to graded exposure in that it involves exposing the patient to the feared object in vivo; however, there is no hierarchy. The basis of flooding is the premise that escaping from an anxiety-provoking experience reinforces the anxiety through conditioning. Thus, clinicians can extinguish the anxiety and prevent the conditioned avoidance behavior by not allowing patients to escape the situation. Clinicians encourage patients to confront feared situations directly, without a gradual buildup, as in systematic desensitization or graded exposure. No relaxation exercises are used, as in systematic desensitization. Patients experience fear, which gradually subsides after a time. The success of the procedure depends on having patients remain in the fear-generating situation until they are calm and feel a sense of mastery. Prematurely withdrawing from the situation or prematurely terminating the fantasized scene is equivalent to an escape, which then reinforces both the conditioned anxiety and the avoidance behavior and produces the opposite of the desired effect. In a variant, called *imaginal flooding,* the feared object or situation is confronted only in the imagination, not in real life. Many patients refuse flooding

because of the psychological discomfort involved. Contraindications include situations when intense anxiety would be hazardous to a patient (e.g., those with heart disease or fragile psychological adaptation). The technique works best with specific phobias. The case study below presents an example of in vivo flooding.

The patient was a 33-year-old woman with social fears of eating in public. In particular, she was afraid of being observed by others when chewing and swallowing, particularly at dinner parties. The therapist arranged a contrived situation in which the patient came to the session with a prepared meal and drink. She entered a conference room in which five persons in professional attire were already seated at a table. The therapist instructed the patient to eat her meal in front of these individuals. Between bites, she was instructed to look at them often, and they had been coached to avoid staring contests. She was not to distract herself from her anxiety symptoms. She was to eat her meal slowly, paying attention to the behavior of the observers and to her anxiety symptoms (e.g., dry mouth or difficulty swallowing). No conversation between the patient and the observers was permitted. The observers would look at her and observe her chewing and swallowing behaviors, at times writing comments in a notebook. Occasionally, observers would communicate by whispering to each other, exchanging written notes, or giving knowing glances and smiles.

The only other communication occurred between the patient and therapist, and this was limited to the patient providing her subjective units of distress rating. The session lasted 90 minutes. Note: this situation may seem quite traumatizing. Because the exposure session is long and continues until ratings decline, the patient becomes desensitized. (Courtesy of Rolf G. Jacob, M.D. and William H. Pelham, M.D.)

In most cases, flooding (exposure) is accompanied by response prevention. Response prevention involves discontinuing all avoidance and other anxiety-reducing behaviors. In order for exposure to produce extinction, avoidance behaviors that typically reduce fear need to be prevented (e.g., looking at the floor when talking can reduce social anxiety; during exposure, therefore, to

incorporate response prevention, the patient looks directly at people and not at the floor). Over time, while the patient remains in the fear-producing situation, the anxious emotional response will decrease. *Exposure and response prevention* (ERP) is actually the treatment of choice for obsessive compulsive disorder. In ERP, patients are exposed to feared stimuli and obsessions while rituals, which typically serve to reduce anxiety, are prevented.

Participant Modeling

In participant modeling, patients learn a new behavior by imitation, primarily by observation, without having to perform the behavior until they feel ready. Just as a person can acquire irrational fears by learning, a person may unlearn them by observing a fearless model confront the feared object. The technique is effective with phobic children who observe other children of their own age and sex who approach the feared object or situation. With adults, a therapist may describe the feared activity in a calm manner that a patient can identify. Or, the therapist may act out the process of mastering the feared activity with a patient. Sometimes a hierarchy of activities is established, and the patient tackles the least anxiety-provoking activity first. The participant-modeling technique is successful in treating agoraphobia by having a therapist accompany a patient into the feared situation. In a variant of the procedure, called *behavior rehearsal,* the patient acts out real-life problems under a therapist's observation or direction.

The following is a self-report by a patient with a contamination phobia, who is afraid to touch objects for fear of being infected or contaminated. She describes her reactions.

[The therapist] started touching everything very slowly. I was told to follow behind and touch everything she touched. It was like we were spreading the contamination. She touched doorknobs, light switches, walls, pictures, and woodwork. She opened drawers in each bedroom and touched the contents. She opened closets and touched clothes hanging on the rods. She touched the towels and sheets in the linen closet. She went through the children's rooms, touching dolls, stuffed animals, models, Star Wars figures, Transformers, and books.

[The therapist] kept talking to me quietly and calmly all the time we went along. I had been anxious when we started, but as we continued, my anxiety level decreased. At one point, when I had begun to think the worst was over, she pointed to the attic door and said we were going inside. I said, "No, that's where the mice were." She told me I didn't want to have a place in my home that was off-limits. I agreed but became very anxious. It was very hard for me to go inside. I began touching the boxes too, but I was very upset. Then, she put her hands down on the floor and wanted me to do the same. I said, "I can't. I just can't." [The therapist] said, "Yes, you can."

[The therapist] spent several hours with me that day. Before she left, she made a list of things for me to do by myself. Twice a day, I was to go through the house, touching everything the way she had done with me. I was to invite my friend who had a pet to come and visit, as well as friends of my children who had pets. (Courtesy of Rolf G. Jacobs, M.D. and William H. Pelham, M.D.)

Exposure to Stimuli Presented in Virtual Reality

Advances in computer technology have made it possible to present environmental cues in virtual reality for exposure treatment. Beneficial effects have been reported with virtual reality exposure of patients with height phobia, fear of flying, spider phobia, and claustrophobia. Much experimental work is ongoing. One model uses an avatar of the patient walking through a crowded supermarket filled with other avatars (including one of the therapist) as a way of conquering agoraphobia.

Assertiveness Training

Assertiveness is assertive behavior that enables a person to act in his or her own best interest, to stand up for herself or himself without undue anxiety, to express honest feelings comfortably, and to exercise personal rights without denying the rights of others.

Two types of situations frequently call for assertive behaviors: (1) setting limits on pushy friends or relatives and (2) commercial situations, such as countering a sales pitch or being persistent when returning defective

merchandise. Early assertiveness training programs tended to define specific behaviors as assertive or nonassertive. For example, individuals were encouraged to assert themselves if somebody got in front of them in a supermarket checkout line. Context has received increasing attention; that is, what would be assertive behavior in this situation depends on circumstances.

Social Skills Training

The negative symptoms in patients with schizophrenia constitute behavioral deficits that go beyond difficulties with assertiveness. These patients have inadequate expressive behaviors and inappropriate stimulus control of their social behaviors (i.e., they do not pick up social cues). Similarly, patients with depression often experience a lack of social reinforcement because of a lack of social skills, and studies have found social skills training to be efficacious for depression. Patients with social phobia similarly often have not acquired adolescents' social skills. In fact, their social defensive behaviors (e.g., avoiding eye contact, making brief statements, and minimizing self-disclosure) increase the probability of the rejection that they fear.

Social skills training programs for patients with schizophrenia cover skills in the following areas: conversation, conflict management, assertiveness, community living, friendship and dating, work and vocation, and medication management. Each of these skills has several components. For example, assertiveness skills include making requests, refusing requests, making complaints, responding to complaints, expressing unpleasant feelings, asking for information, making apologies, expressing fear, and refusing alcohol and street drugs. Each component involves specific steps. For example, conflict management includes skills in negotiating, compromising, tactful disagreeing, responding to untrue accusations, and leaving overly stressful situations. A situation in which a patient would use conflict management skills could be when the patient and a friend decide to go to a movie, and their choice of movie differs.

Negotiating and compromising, for example, involves the following steps:

1. Explain one's viewpoint briefly.
2. Listen to the other person's viewpoint.
3. Repeat the other person's viewpoint.

4. Suggest a compromise.

At his initial appointment, Phillip described severe symptoms of obsessive-compulsive disorder (OCD). He was 23 years old and living at home because he was no longer able to work or go to school. His days were consumed with behaviors related to checking, repeating, and hoarding. Phillip was unable to throw away anything—he saved junk mail, used tissues and napkins, old papers and magazines, and any kind of receipt for fear that he might lose something important. Phillip spent many hours checking his trash, his car, and his home to be sure that he had not thrown away anything important. He also checked everything he wrote (e.g., checks, school exams and papers, letters and e-mails) to be sure that he had not made a mistake, and he read and reread books, magazines, and articles to be sure he understood the written material adequately. Phillip constantly worried that he had done something wrong and would disappoint his parents. He was also depressed because he was unable to function well in life, and he had tremendous social anxiety that had plagued him for many years, making it difficult to make and keep friends.

By the end of Phillip's second session, his therapist was beginning to get a good idea of the general nature and severity of his symptoms and some of the maintaining factors. However, to plan the treatment in more detail and to get a better idea of how the symptoms occurred during his daily life, she asked Phillip to keep daily records over the next week using a form that she had prepared for him. The form had a place for recording the amount of time he spent in rituals each morning, afternoon, and evening, as well as another place to record more details about at least one episode of rituals each day (e.g., what was happening before, during, and after the rituals; see Table 23-12).

Phillip's therapist determined that his difficulties with obsessions, rituals, depression, and social fears reflected a core fear of negative evaluation. Phillip was overly concerned with making mistakes, being imperfect, and disappointing others. Even as a child, Phillip was worried about not doing well enough, and he had difficulty making friends for fear that others would not like him. His highly anxious parents provided

much adulation when Phillip did things well (e.g., learned to ride a bike, got good grades in school), and they spent a great deal of time instructing him on improving his performance when an activity or grade was not perfect. As Phillip took on more responsibility at school and with part-time work, he became more concerned about doing things right. He learned that going back and checking his work relieved his anxiety. He also learned that saving his papers for future checking reassured him that he would be able to fix any unrecognized mistakes at a later time. His parents helped him to reduce his anxiety when he was uncertain about his work by reassuring him that he was doing okay. As Phillip progressed from elementary school to middle school to high school, his workload and anxiety gradually increased, but he was able to manage things with some moderate checking and saving. When he began attending college, however, the workload increased extensively, and he found himself doing even more checking and hoarding to reduce his fears about making mistakes. Phillip began to feel that these behaviors were getting out of control, but he could not stop them. He had to check and recheck to be sure that he was not making mistakes. The cycle of anxiety to ritual to reduced anxiety was so powerfully reinforcing that he could not stop. He needed help to break this cycle and to address his persistent fear of negative evaluation.

Phillip's therapist decided to begin treatment with a course of exposure and response prevention (ERP) to get his obsessions and rituals under control and begin to address his core fear of making mistakes and being evaluated negatively. Given that Phillip's depression had grown from the disability associated with his OCD, the therapist expected that a successful course of ERP might also help to reduce his depressive symptoms. ERP for Phillip began with a home visit, where the therapist helped him to complete common daily activities with adherence to his RP plan, which included the following:

- No more checking: After eating, leave the table immediately without inspecting your plate and the surrounding areas (including under the table and chair) for lost items. Leave the restroom immediately after using it, without checking the toilet, trash, and sink for lost items. When leaving the car, do not check seats, floors, and windows.

Write everything (papers, checks, etc.) only once; no checking to be sure that letters and words are correct.

- No more repeating: No more rereading books. No staring repeatedly at items to ensure that nothing is lost.
- No more saving. Throw tissues away immediately after using them. Discard trash and junk mail immediately. Do not look into the trash can for lost items.

Phillip's parents also were asked to stop reassuring him and to discontinue doing rituals for him. This session was very difficult for Phillip and his family, but they understood the logic of ERP, and they were willing to try anything.

For the next 3 weeks, Phillip and his therapist met three times a week to conduct in vivo exposure sessions that helped him to face his core fears. For many of these sessions, the therapist asked Phillip to bring hoarded items from home and to discard all unnecessary items during the therapy session. At first, this created tremendous anxiety, but over time, Phillip was able to throw things away with less fear of losing something important. He also developed the ability to conduct self-directed exposure at home. Other exposure sessions involved writing letters and mailing them without checking, reading passages from magazines and books only once, and sorting through junk mail to make quick decisions about what to save or discard. As Phillip was able to take on more responsibility for home-based exposure, session frequency decreased to two times per week, and then to once per week. After 3 months of treatment, Phillip's scores on the YBOCS (Yale-Brown Obsessive-Compulsive Scale) and BDI (Beck Depression Inventory) had decreased to 20 and 19, respectively, demonstrating significant improvement in obsessive-compulsive symptoms and depression. His SPAI (Social Phobia and Anxiety Inventory) score, however, remained relatively unchanged, suggesting that he was still experiencing significant social anxiety.

Next, while Phillip worked on maintaining the gains he had made following ERP, he and his therapist conducted some role-plays to evaluate his social skills. It was apparent that Phillip had extreme difficulty with initiating and maintaining conversations. His eye contact also was quite poor in social interactions. Thus, the therapist devised a

plan for teaching and practicing new skills, which also involved additional exposure to Phillip's core fears as the therapist asked him to resume contact with old friends and identify activities where he could meet new people. He practiced new behaviors first in session with his therapist and then developed a hierarchy of feared social situations in which he could practice his new behaviors. These practice exercises also involved a form of exposure, as the therapist asked Phillip to make social contact, which produced fears of negative evaluation. After another 3 months of treatment focused on social skills training (and associated exposure), Phillip's scores on the YBOCS and BDI had decreased further (YBOCS = 15; BDI = 13), and his SPAI score had decreased to 100. Phillip had gone back to school to take one class, he was spending small amounts of time with old friends, and he was volunteering a few hours each week at his church. (Courtesy of M. A. Stanley, Ph.D. and D. C. Beidel, Ph.D.)

Table 23-12
Daily Monitoring of Rituals

Each day, record the amount of time spent doing rituals in the morning, afternoon, and evening.							
	Tuesday	Wednesday	Thursday	Friday	Saturday	Sunday	Monday
Morning	2 hr	1.5 hr					
Afternoon	3 hr	2 hr					
Evening	1.5 hr	3 hr					

Once a day, record the following details about an episode of rituals:						
Day	Time	Situation	Feelings	Thoughts (Obsessions)	Type of Ritual	Feelings After Rituals
Saturday	8 AM	Finished breakfast	Afraid Scared Worried	Shouldn't have thrown away my napkin Might have left something under my plate What if I lost something important?	Checking through trash Looking under plate Staring to see if I lost something	Better For now, I think I have not lost anything
Sunday	2 PM	At the store; signed a check	Worried Anxious	Did I sign my name correctly? Did I write the correct amount? What if I give them the check and it is wrong?	Staring at the check Tracing the lines I wrote Standing there	Anxious because I couldn't finish checking

Aversion Therapy

When a noxious stimulus (punishment) is presented immediately after a specific behavioral response, theoretically, the response is eventually inhibited and extinguished. Aversion therapy can use many types of noxious

stimuli: electric shocks, substances that induce vomiting, corporal punishment, and social disapproval. The therapist pairs the negative stimulus with the behavior, resulting in suppression of the behavior. The unwanted behavior may disappear after a series of such sequences. Aversion therapy has been used for alcohol abuse, paraphilias, and other behaviors with impulsive or compulsive qualities, but this therapy is controversial for many reasons. For example, punishment does not always lead to the expected decreased response and can sometimes be positively reinforcing.

Eye Movement Desensitization and Reprocessing

Saccadic eye movements are rapid oscillations of the eyes that occur when a person tracks an object that is moved back and forth across the line of vision. Several studies have demonstrated that inducing saccades while a person is imagining or thinking about an anxiety-producing event can yield a positive thought or image that results in decreased anxiety. Eye movement desensitization and reprocessing therapy is effective in the treatment of PTSDs and phobias.

Positive Reinforcement

When a generally rewarding event, such as food or praise, follows a behavioral response, the response tends to be strengthened and to occur more frequently than before the reward. This principle can be applied to a variety of situations. On inpatient hospital wards, patients with mental disorders receive a reward for performing a desired behavior, such as tokens that they can use to purchase luxury items or certain privileges. The process, known as *token economy*, has successfully altered behavior.

Behavioral Activation

Based on behavioral theory, depression persists because: (a) reinforcement for nondepressed (healthy) behavior is low or nonexistent, (b) depressed behavior produces positive (e.g., sympathy from others) or negative reinforcement (decrease in responsibilities or avoidance of undesirable situations), (c) exposure to aversive or unpleasant life experiences is significant, or (d) some combination of these factors. Severely depressed mood leads to behavioral withdrawal, which in turn results in loss of

reinforcement from pleasurable events or activities.

Behavioral activation emphasizes structured attempts to increase overt behaviors that bring patients into contact with reinforcing environmental contingencies and corresponding improvements in thoughts, mood, and quality of life. Patients begin by engaging in a self-monitoring (or daily diary) exercise to examine already occurring daily activities to provide a baseline measurement and to provide some potential activities to target during treatment. For each behavior, they indicate their levels of reward, difficulty, and importance. Emphasis then shifts to identifying patients' values and goals within life areas that include family, social, and intimate relationships, education, employment/career, hobbies/recreation, volunteer work/charity, physical/health issues, spirituality, and anxiety-eliciting situations. An activity hierarchy is constructed, where activities are rated from "easiest" to "most difficult" to accomplish. Patients progressively move through the hierarchy, moving from easier behaviors to the more difficult.

Charles was a 70-year-old retired business executive. Throughout his life, his work consumed him. Although he married and had a family, his job was his primary focus. He went to the office early and came home late. He enjoyed what he did—it was stimulating and made him feel important and useful. But as he got older, his performance was not what it used to be, and he decided it was time to retire. However, his mood was pretty low when he no longer had a job. He did not have the energy to get more involved in his church or to develop other hobbies, so he sat around all day, without any social contacts. His wife and best friend encouraged him to talk to someone. The therapist suggested that they try behavioral activation. Charles was somewhat skeptical, as it seemed too simple, but he needed to do something. The therapist spent some time with Charles talking about the kinds of activities that used to make him feel good and some of the things he used to enjoy. They then put together a list of things he might be able to do—even if he did not feel much like it—just to see what would happen. The list included looking for volunteer work where he could use his job skills, spending more time with his wife in some of the activities they once had enjoyed (e.g., watching movies, taking walks), and rejuvenating an old hobby from his college days—

fishing. Charles initially agreed to do some easy activities—go to one movie a week, take one walk a week, and contact his church activity leader about possible volunteer activities. He was surprised to find that even these "baby steps" helped him feel better. He had the chance to talk with other people and began to see that, even in retirement, he could find useful and fun things to do. (Courtesy of M. A. Stanley, Ph.D. and D. C. Beidel, Ph.D.)

Results

Behavior therapy has a wide range of applications and is useful for a wide variety of psychiatric disorders (e.g., anxiety, depression, schizophrenia, and bipolar disorder), psychological problems (e.g., marital discord, school refusal, and stress), and medical problems (e.g., adjustment to chronic illness, medication adherence, and healthy behaviors). Behavioral treatments have also been administered effectively with individual patients, couples, families, and groups, and they are useful in a range of treatment settings, including inpatient, outpatient, day treatment, and community settings.

HYPNOSIS

The concept of hypnosis conjures up myriad perceptions among clinicians and the lay public. Even the term *hypnosis* can be misleading, coming as it does from the Greek root *hypnos* (meaning "sleep"). In reality, hypnosis is not sleeping. It is more likely a complex process that requires alert focus and receptive attention. Hypnosis is a powerful means of directing innate capabilities of imagination, imagery, and attention. Many also believe the myth that the clinician projects the hypnotic trance onto the patient or has the power to influence the patient. In reality, it is the patient who has the hypnotic gift, and the clinician's role is to assess the patient's capacity to capitalize on this asset and to help the patient discover and use it effectively. Patient motivation, personality style, and biologic predisposition may contribute to the manifestation of this talent.

The hypnotic trance enhances focal attention and imagination and simultaneously decreases peripheral awareness. A hypnotist may induce this trance through formalized induction procedures, but it can also occur

spontaneously. The capacity to be hypnotized and, relatedly, the occurrence of spontaneous trance states, is a trait that varies among individuals but is relatively stable throughout a person's life cycle.

History

Descriptions of trance states, ecstatic states, and spontaneous dissociative states abound in the Eastern and Western religious, literary, and philosophical traditions. Anton Franz Anton Mesmer (1734–1815) first formally described hypnosis as a therapeutic modality in the 18th century and believed it to be the result of magnetic energy or an invisible fluid that the therapist channels into the patient to correct imbalances, restoring health. James Braid (1795–1860), an English physician and surgeon, used eye fixation and closure to induce trance states. Later, Jean Martin Charcot (1825–1893) theorized the hypnotic state to be a neurophysiologic phenomenon that was a sign of mental illness. Contemporaneously, Hippolyte Bernheim (1840–1919) believed it to be a function of the normal brain.

Early in his career, Sigmund Freud (1856–1939) used hypnosis as part of his psychoanalysis and noticed that patients in a trance could relive traumatic events, a process called *abreaction.* Later, Freud switched from hypnosis to free association because he wanted to minimize the transference that sometimes accompanies the trance state. Importantly, the switch did not eliminate the occurrence of spontaneous trance during the analysis.

World War I produced many shell-shocked soldiers, and Ernst Simmel (1882–1947), a German psychoanalyst, developed a technique for accessing repressed material that he named *hypnoanalysis.* During World War II, hypnosis played a prominent role in the treatment of pain, combat fatigue, and neurosis. Formal recognition of hypnosis as a therapeutic modality did not occur, however, until the 1950s. The British Medical Society recommended its teaching in medical schools in 1955, and the American Medical Association and American Psychiatric Association officially stated its safety and efficacy in 1958.

Definition

The current understanding of hypnosis is that it is a normal activity of a normal mind through which attention is more focused, critical judgment is

partially suspended, and peripheral awareness is diminished. The trance state, being a function of the subject's mind, cannot be forcibly projected by an outside person. The hypnotist, however, may aid in the achievement of the state and use its uncritical, intense focus to facilitate the acceptance of new thoughts and feelings, thereby accelerating therapeutic change. For the subject, hypnosis typically involves a sense of involuntariness, and movements seem automatic.

Trait of Hypnotizability

A person's degree of hypnotizability is a trait that is relatively stable throughout the life cycle and is measurable. The process of hypnosis takes the hypnotizability trait and transforms it into the hypnotized state. Experiencing the hypnotic concentration state requires a convergence of three essential components: absorption, dissociation, and suggestibility.

Absorption is an ability to reduce peripheral awareness that results in greater focal attention. A metaphorical description is that of a psychological zoom lens that increases attention to the given thought or emotion to the increasing exclusion of all contexts, even including orientation to time and space.

Dissociation is the separating out from consciousness elements of the patient's identity, perception, memory, or motor response as the hypnotic experience deepens. The result is that components of self-awareness, time, perception, and physical activity can occur without being known to the patient's consciousness and so may seem involuntary.

Suggestibility is the tendency of the hypnotized patient to accept signals and information with a relative suspension of normal critical judgment; it is controversial whether a person can completely suspend critical judgment. This trait will vary from an almost compulsive response to input in the highly hypnotizable to a sense of automaticity in the less hypnotizable individual.

Quantification of Hypnotizability. Quantifying a patient's degree of hypnotizability is useful in a clinical setting because it predicts the effectiveness of hypnosis as a therapeutic modality. Quantification also provides useful information about the way patients relate to themselves and the social environment. Highly hypnotizable patients have an increased

incidence of spontaneous trance-like states and so may be unduly influenced by ideas and emotions that are not being appropriately self-critiqued.

Induction

Many different induction protocols follow the same basic principles and pattern but may be better suited to patients with different levels of hypnotizability.

Doctor: Take a long, deep breath—inhale and exhale; now close your eyes and relax. Pay particular attention to the muscles in and about your eyes—relax them to the point that they just won't work. Are you trying to do that? Good. If you really have them relaxed, right at this very moment, no matter how hard you try, they just won't open. Test them. The harder you try, the faster they stick together, just as if they were glued together. That's fine!

Now you can open your eyes; that's good. When I tell you to and not before, open and close your eyes once more, and, when you close them this time, you will be ten times as relaxed as you are right now. Go ahead, open and close, and feel that surge of relaxation go through your whole body, from the top of your head to the tip of your toes. Very good!

Now once again, open and close your eyes, and this time, when you close them, you will double the relaxation that you currently have. Fine.

If you have followed my suggestions, right at this very moment, when I lift your hand and let it drop into your lap, it will drop like a wet cloth, heavy and limp. That's very, very good.

You now have good physical relaxation, but medical hypnosis consists of two phases: physical, which you currently have, and mental, which I will now show you how to achieve.

When I ask you to, and not before, I want you to start counting backward from 100. I know you can count; that is not what we're after. I just want you to relax mentally. As you say each number, pause momentarily until you feel a wave of relaxation cover your whole body, from the top of your head to the tip of your toes. When you feel this wave of relaxation, then say the next number, and each time you

say a number, you will double the relaxation you had before you said the number. If you do this properly, an interesting thing will happen—as you say the numbers and relax, the succeeding numbers will start to disappear and vanish from your mind. Command your mind to dispel these numbers. Now, aloud and slowly, start counting backward from 100.

Patient: One hundred.

Doctor: Very good.

Patient: Ninety-nine.

Doctor: Make them start to disappear now.

Patient: Ninety-eight.

Doctor: Now they're fading away, and after the next number, they'll all be gone. Make them disappear. Let the numbers go.

Patient: Ninety-seven.

Doctor: And now they're all gone. Are they gone? Fine. If there are any numbers still lurking in your mind, when I lift your hand and drop it, they will all disappear.

(Courtesy of William Holt, M.D.)

Indications

A patient's degree of hypnotizability and the technique of hypnosis are clinically useful in diagnosis and treatment, respectively. The existence of spontaneous, trance-like states in everyday life and the potential of individuals to uncritically accept emotions and information in these states make a person's degree of hypnotizability a factor in the way the world is viewed and processed.

Therapeutically, hypnosis's effectiveness in facilitating acceptance of new thoughts and feelings makes it useful in treating habitual problems and also with symptom management. Smoking, overeating, phobias, anxiety, conversion symptoms, and chronic pain are all indications for hypnosis. They can often be treated in a single session, in which a patient learns to perform self-hypnosis. Hypnosis can also aid in psychotherapy, notably for PTSD, and may also be useful for memory retrieval.

A 32-year-old man presented to the emergency department with a severe headache. He was a chronic migraine sufferer and was unable to control the pain on this occasion with his propranolol. The emergency department recognized that he had a high hypnotic capacity. The physician suggested imagery of an icepack resting on his forehead. Initially, they placed some real ice on his forehead to help. The patient was able to control his pain completely with this imagery. He did not require narcotics, as he had on previous visits. On follow-up several weeks later, the patient reported being able to use this strategy to control, as well as prevent, migraine attacks, and he no longer had to rely on frequent emergency department visits for pain relief. (Courtesy of A. D. Axelrad, M.D., D. Brown, Ph.D., and H. J. Wain, Ph.D.)

A 22-year-old male patient presented to the emergency room with bilateral blindness. An evaluation by ophthalmology revealed that the blindness was psychogenic. The emergency physician referred the patient to psychiatry. After an initial evaluation and the development of a therapeutic alliance, the psychiatrist used hypnosis to take the patient to a safe place and then back to the time immediately before the blindness. After two sessions, the patient described seeing his wife in an adulterous relationship. At that moment, the patient vocalized a desire to harm his wife and her suitor. Immediately after this vocalization, he became amnesic for the event and blind. On describing this under hypnosis, the therapist suggested that, when he became alert, “He would only remember what he felt comfortable remembering.” After the patient became alert, he had no idea what had occurred, and each day after initiation of the hypnotic intervention, the patient’s anger was reframed. When the patient felt comfortable, he then confronted his wife. The patient became aware that the amnesia was being used to prevent him from acting out. The use of a psychodynamic, cognitive reframing approach with a hypnotic milieu helped this patient to gain control and understanding of his symptoms. The therapist referred the patient and his wife for marital counseling. (Courtesy of A. D. Axelrad, M.D., D. Brown, Ph.D., and H. J. Wain, Ph.D.)

A 29-year-old woman presented for evaluation and treatment of ongoing facial pain that was not responding to traditional methods of intervention. The neurologic evaluation showed no objective physical correlations. Initially, hypnotic intervention controlled the pain, but it returned 24 hours later. Her self-hypnotic technique ceased to be effective. The therapist decided to explore more completely the meaning of the pain. Using age regression under hypnosis, the patient regressed to a time before the pain. She related that her brother had been injured by a car while he was running in the street. The patient was babysitting at the time, and her father was so angry that he hit her. Recently her friend's dog ran away, and she felt responsible. As she began to recognize her need to punish herself because of her guilt over what occurred, she was able to understand her feelings and reframe her thoughts more productively. An "affect bridge" was also used, and the patient went back to a previous time when she felt guilty and received punishment. She then described her feelings of being hit by her alcoholic, abusive father. She continued to gain insight and mastery over the past and was able to ablate her pain. (Courtesy of A. D. Axelrad, M.D., D. Brown, Ph.D., and H. J. Wain, Ph.D.)

A 42-year-old married mother of three children was kidnapped and locked in a large packing trunk. After she freed herself and broke out, her abductors stabbed her multiple times, tied her up, put her back in the trunk, and threw her down a cliff. She eventually managed to break out and crawl to safety. Eventually, a passerby called 911, and paramedics transported her to a hospital. She reported that others saw her lying on the road and appeared frightened to approach her.

Following medical stabilization, she was discharged from the hospital and found herself developing nightmares, reexperiencing avoidance, and having hyperarousal symptoms. Her internist referred her for treatment. The psychiatrist initiated sertraline. She was found to be a mid- to high-range hypnotic subject. She learned to go to a safe place and to use a

split-screen technique. The therapist also gave her permission to describe her nightmares, reexperiences, and overwhelming anxieties and fears that she faced while being captive, as well as her feelings of abandonment while lying on the road. The therapist reinforced her ingenuity in breaking out of the trunk. She responded to a reframing of the feeling of blame for her capture while under hypnosis. She learned to calm herself and to reframe her negative feelings about her helplessness. Hypnotic age regression helped her master her experiences and facilitate their becoming like a bad movie. Initially, her startle response was a signal for her to go to her comfort zone. Age progression helped her to rehearse the future. The treatment used the milieu of hypnosis along with exposure, cognitive reframing, psychodynamic approaches, and pharmacology. (Courtesy of A. D. Axelrad, M.D., D. Brown, Ph.D., and H. J. Wain, Ph.D.)

Contraindications

No intrinsic dangers to the hypnotic process exist. Because of the increased dependence that the hypnotized patient has toward the therapist, a strong transference may occur, however, in which the patient exhibits feelings for the therapist that are inappropriate in regard to their relationship. Strong attachments may occur, and these must be respected and properly interpreted. Negative emotions may also surface in the patient, especially in those who are emotionally fragile or who have poor reality testing. To minimize the likelihood of this negative transference, the therapist must use caution when choosing patients who have problems with basic trust, such as those who are paranoid or who require high levels of control. The hypnotized patient also has a reduced ability to evaluate hypnotic suggestions critically and, thus, the hypnotist must have a strong ethical value system. Controversy exists about whether patients can perform acts during a trance state that they would otherwise find repugnant or that run contrary to their moral system.

INTERPERSONAL THERAPY

Interpersonal psychotherapy (ITP) is a time-limited treatment for major depressive disorder developed by Gerald L. Klerman and Myrna Weissman

in the 1970s. The initial formulation of ITP was an attempt to represent the current practice of psychotherapy for depression. It assumes that the development and maintenance of some psychiatric illnesses occur in a social and interpersonal context and that interpersonal relations between the patient and significant others influence the onset, response to treatment, and outcomes of these illnesses. The overall goal of ITP is to reduce or eliminate psychiatric symptoms by improving the quality of the patient's current interpersonal relations and social functioning.

The typical course of ITP lasts 12 to 20 sessions over a 4- to 5-month period. ITP moves through three defined phases: (1) the initial phase identifies the problem area that will be the target for treatment; (2) the intermediate phase works on the target problem area(s); and (3) the termination phase focuses on consolidating gains made during treatment and preparing the patients for future work on their own (Table 23-13).

Techniques

Individual Interpersonal Psychotherapy

INITIAL PHASE. Sessions one through five typically constitute the initial phase of ITP. After assessing the patient's current psychiatric symptoms and obtaining a history of these symptoms, the therapist gives the patient a formal diagnosis. The therapist and patient then discuss the diagnosis, as well as what to expect from treatment. Assignment of the sick role during this phase serves the dual function of granting the patient both the permission to recover and the responsibility to recover. The therapist explains the rationale of ITP, underscoring that therapy will focus on identifying and altering dysfunctional interpersonal patterns related to psychiatric symptomatology. To determine the precise focus of treatment, the therapist conducts an interpersonal inventory with the patient and develops an interpersonal formulation based on this. In the interpersonal formulation, the therapist links the patient's psychiatric symptomatology to one of the four interpersonal problem areas—grief, interpersonal deficits, interpersonal role disputes, or role transitions. The patient's concurrence with the therapist's identification of the problem area and agreement to work on this area are essential before beginning the intermediate treatment phase.

Table 23-13
Phases of Time-Limited Interpersonal Psychotherapy

Initial Phase: Sessions 1–5

Give the syndrome a name; provide information about the prevalence and characteristics of the disorder

Describe the rationale and nature of the therapy

Conduct the interpersonal inventory to identify the current interpersonal problem area(s) associated with the onset or maintenance of the psychiatric symptoms

Review significant relationships, past and present

Identify interpersonal precipitants of episodes of psychiatric symptoms

Select and reach consensus about the interpersonal problem area(s) and treatment plan with patient

Intermediate Phase: Sessions 6–15

Implement strategies specific to the identified problem area(s)

Encourage and review work on goals specific to the problem area

Illuminate connections between symptoms and interpersonal events during the week

Work with the patient to identify and manage negative or painful affects associated with his or her interpersonal problem area

Termination Phase: Sessions 16–20

Discuss termination explicitly

Educate the patient about the end of treatment as a potential time of grieving; encourage the patient to identify associated emotions

Review progress to foster feelings of accomplishment and competence

Outline goals for remaining work; identify areas and warning signs of anticipated future difficulty

Formulate specific plans for continued work after termination of treatment

INTERMEDIATE PHASE. The intermediate phase—typically sessions 6 to 15—constitutes the "work" of the therapy. An essential task throughout the intermediate phase is to strengthen the connections the patient makes between the changes in his or her interpersonal life and the changes in psychiatric symptoms. During the intermediate phase, the therapist implements the treatment strategies specific to the identified problem area, as specified in Table 23-14.

TERMINATION PHASE. In the termination phase (usually, sessions 16 through 20), the therapist discusses termination explicitly with the patient and assists him or her in understanding that the end of treatment is a potential time of grief. During this phase, the therapist encourages patients to describe specific changes in their psychiatric symptoms, especially as they relate to improvements in the identified problem area(s). The therapist also assists the patient in evaluating and consolidating gains, detailing plans for maintaining improvements in the identified interpersonal problem area(s), and outlining remaining work for the patient to continue on his or her own. The therapist also encourages patients to identify early warning signs of symptom recurrence and to identify plans of action.

Table 23-14
Interpersonal Problem Areas: Description, Goals, and Strategies

Problem Area	Description	Goals	Strategies
Grief	Complicated bereavement after death of a loved one	Facilitate the mourning process Help the patient to establish interest in new activities and relationships to substitute for what has been	Reconstruct t patient's relationship with the deceased Explore associated feelings (negative and positive

		lost	Consider way of becomin reinvolved with others
Interpersonal deficits	A history of social impoverishment, inadequate or unsustaining interpersonal relationships	Reduce patient's social isolation Enhance quality of any existing relationships Encourage the formation of new relationships	Review past significant relationship including negative ar positive aspects Explore repetitive patterns in relationship Note problematic interperson patterns in the session and relate them to similar patterns in the patient's life
Interpersonal role disputes	Conflicts with a significant other —a partner, other family member, coworker, or close friend	Identify the nature of the dispute Explore options to resolve dispute Modify	Determine the stage of the dispute: renegotiatic (calm down participants to facilitate

		expectations and faulty communication to bring about a satisfactory resolution If modification is unworkable, encourage patient to reassess the expectations for the relationship and to generate options to either resolve it or dissolve it and mourn its loss	resolution); impasse (increase disharmony to reopen negotiation) dissolution (assist mourning and adaptation) Understand how nonreciproc role expectation relate to the dispute Identify available resources t bring about change in th relationship
Role transitions	Economic or family change—the beginning or end of a relationship or career, a move, promotion, retirement, graduation, diagnosis of a medical illness	Mourn and accept the loss of the old role Recognize the positive and negative aspects of the new role and assets and liabilities of the old role	Review positiv and negativ aspects of old and new roles Explore feelings about what lost Encourage developme

	Restore self-esteem by developing a sense of mastery regarding the demands of the new role	of social support system and new skills called for in new role

Reprinted with permission from Wilfley D, Stein R, Welch R. Interpersonal psychotherapy. In: Treasure J, van Furth E, Schmidt U, eds. *Handbook of Eating Disorders*. 2nd ed. Hoboken, NJ: Wiley; 2003:253.

Ms. G is a 51-year-old woman who presented for treatment of binge eating disorder. She is college-educated, has her own business, and is a divorced mother of one adult son in his early 20s. Before treatment, she had a body mass index (BMI) of 42, and her binge eating occurred approximately 10 to 15 days per month over the past 8 years. Along with her current diagnosis of binge eating disorder, Ms. G struggled with recurrent major depression.

During the initial phase, Ms. G and her therapist began to review her history and the interpersonal events that were associated with her binge eating. Ms. G shared that she began overeating and gaining weight at age 14. When she was 18 years of age, she moved to a foreign country with her parents. Soon after the move, Ms. G's father left her and her mother to return to the United States. Ms. G was enraged at her father for leaving them and still gets very tearful and angry when discussing the separation. She and her mother decided to stay abroad because she had started university, and her mother was working. Both had developed strong social ties and felt comfortable in their new home. During this time, Ms. G continued to gain weight and started dieting. Shortly after graduating from university, Ms. G met and married a foreign national and, at the age of 28, delivered their only son. Two years later, she and her husband went through a very bitter divorce. Although Ms. G described this as a terrible time in her life, she maintained close ties with her friends and her mother. During this time, she began to diet and reached her lowest adult weight.

At the age of 35, when her mother died of a heart condition, Ms. G had her first episode of major depression, which was treated and resolved with antidepressants and a brief course of psychotherapy. Although she had previous cycles of weight loss and weight regain, she did not evidence any sign of eating disturbance at this point. She continued to maintain close social ties and enjoyed her close relationship with her son. When Ms. G was in her early 40s, an economic downturn in her adopted country forced her to return to the United States. Having lost all of her savings, she struggled financially while she looked for work. During this time, she started binge eating and gaining weight. Within 1 year of this move, Ms. G's son decided to return to live with his father (who was very wealthy). Ms. G felt angry and betrayed. Yet, when her son would visit, she would assume a subservient role with him, because she was afraid of losing his affection. He, in turn, became quite demanding and critical of her. Before seeking treatment, her heightened feelings of isolation and loneliness were leading to increased binge eating, depression, and weight gain.

By session three of the initial phase, Ms. G's therapist began to consider which problem area would be the focus of the remainder of treatment. Ms. G had a history of important relationship losses and subsequent grief—the loss of her father, her husband, her mother, and, most recently, her son. However, none of these losses led to the development of binge eating problems (although her dieting clearly linked to her feelings of anger after the divorce from her husband, and her depression intimately related to her mother's death). Ms. G's anger at her son for returning to live with the enemy was clearly a role dispute, yet her binge eating had begun 2 years before his departure (although it clearly worsened after he left). Because neither of these problem areas directly linked to the onset of the eating disorder, Ms. G's therapist decided that the focus of treatment would be to assist her in managing her role transition. Her move back to the United States, with the subsequent loss of her support and friendship networks, was clearly associated with the onset and continued maintenance of her binge eating. During session four of the initial phase, Ms. G's therapist shared her formulation of the problem area with her: "From what you have described, your binge eating really began after you returned to the United States. After that transition,

you felt more isolated and alone than you have ever been. It seems that binge eating was a way for you to manage that transition and the subsequent feelings of isolation and loneliness. Your transition has also negatively impacted your relationship with your son. Even though you are a very social person and enjoy the company of others, you have yet to develop the kind of support that you had before you moved. Although you have struggled with some very significant issues throughout your life—your father leaving, the pain of the divorce, and the death of your mother—your friends and support systems sustained you. If we work together to help you find and develop more intimate and supportive relationships here, I believe you will be much less likely to turn to food and binge eating as a source of support or comfort."

Ms. G agreed with the formulation and worked with her therapist to establish some treatment goals to help her resolve the problem area. First, the therapist encouraged her to become more aware of her feelings (notably isolation and loneliness) when she was binge eating and of how binge eating seemed to be the way she managed those feelings. A second goal was for her to take steps to increase her social contacts and develop more friendships. The third goal, which was a secondary problem area, centered on helping Ms. G resolve the role dispute with her son. Specifically, the therapist developed a goal with her to help her establish a clearer parental role with her son.

During the intermediate phase, the therapist helped Ms. G to grieve the loss of her previous role and the extensive support that she once had. Ms. G and her therapist worked to identify several sources of support and friendships of which she had not been aware. Soon after, Ms. G reported significant progress in initiating and establishing relationships with others. This change appeared to help give her confidence in her new roles. In fact, she began to receive a few social invitations. She became more attuned to the ways that she would rely on food, especially when she felt lonely or felt that she was not receiving enough time from others. The connection between the lack of supportive contacts and binge eating was becoming very clear to her in these intermediate sessions. During this phase, the therapist also assisted her in setting appropriate limits in her relationship with her adult son and in recognizing his adult-like responses in return. By the termination phase, Ms. G reported that she no

longer felt so lonely and isolated and that her binge eating had all but disappeared. She remarked how the quality of her relationship with her son had changed dramatically. He was more supportive and respectful, visited more frequently, and stayed with her for more extended periods. In the final sessions, she talked about her need to let go of the past and move on with her life as it is now, assuming her new roles more fully. She worked closely with her therapist to develop a plan to maintain the gains that she made in treatment and used the final session to review the important work that she accomplished. (Courtesy of D. E. Wilfley, Ph.D. and R. W. Guynn, M.D.)

Interpersonal Psychotherapy Delivered in a Group Format. ITP delivered in a group format has many potential benefits in comparison with individual treatment. For example, a group format based on members' diagnostic similarity (e.g., depression, social phobia, eating disorders) can help alleviate patients' concerns that they are the only one with a particular psychiatric disorder, while offering a social environment for patients who are isolated, withdrawn, or disconnected from others. Given the number and different types of interpersonal interactions in a group setting, the interpersonal skills that develop may be more readily transferable to the patient's outside social life than are the relationship patterns that develop in a one-on-one setting. Moreover, a group modality has therapeutic features not present in individual psychotherapy (e.g., interpersonal learning). The group format also facilitates the identification of problems common to many patients and provides a cost-effective alternative to individual treatment. Table 23-15 links the phases of ITP to the stages of group development.

TIMELINE AND STRUCTURE OF TREATMENT. The typical course of group ITP lasts 20 sessions over 5 months. The recommended group size ranges from six to nine members, with one or two group leaders, depending on resources and training needs. Three individual meetings (pregroup, midgroup, and postgroup), sequenced to correspond with critical time points in the three phases of ITP, in combination with other techniques, maintain the exclusive and strategic focus on individual patients' interpersonal problem areas—the hallmark of ITP.

Table 23-15
Linking the Phases of Interpersonal Psychotherapy to the Stages of Group Development

Phases/Tasks	Group Stages	Members' Work	Therapist Interventions
Initial: Sessions 1–5; identify problem areas	Engagement: Sessions 1–2	Members look for structure as they grapple with the anxiety of being in a group and sharing their problems	Establish a structure that encourages appropriate self-disclosure; facilitate norms for effective communication
	Differentiations: Sessions 3–5	Members work to manage negative feelings over interpersonal differences as they emerge in the group	Help members to understand their reactions in the context of interpersonal differences in their outside social lives
Middle: Sessions 6–15; work on goals	Work: Sessions 6–15	Members work out differences and strive toward common goals	Facilitate connections among members as they share their work with each other; encourage practice of newly acquired

			interpersonal skills in and outside of the group
Final: Sessions 15–20; consolidate treatment	Terminations: Sessions 16–20	Members struggle with how to manage the impending loss of connection with other group members	Help members to consolidate their work and to plan continued work; assist members in grieving the loss of the group

PREGROUP MEETING. The pretreatment meeting is crucial for facilitating a patient's individualized work in the first phase of group ITP. The focus of the 2-hour pretreatment meeting is to identify interpersonal problem areas, establish an explicit treatment contract to work on problem areas, and prepare patients for group treatment. After identifying a patient's interpersonal problem(s) (i.e., interpersonal deficits, role disputes, role transitions, or grief), the therapist works collaboratively with the patient to formulate concrete prescriptions for change, in addition to the specific steps the patient will take to improve social relationships and patterns of relating. The therapist expresses these goals of treatment in language that is as specific and personally meaningful to the patient as possible. Before the start of the group, each group member receives a written summary of his or her goals and instructions that these goals will guide his or her work in the group.

Another important element of the pregroup meeting involves adequately preparing patients for group treatment. That is, the therapist encourages patients to think of the group as an "interpersonal laboratory" in which they can experiment with new approaches to handle challenging interpersonal situations. In this regard, patients hear about the important interpersonal skills

that they will learn while participating in a group (e.g., interpersonal confrontation, honest communication, expression of feelings) and receive encouragement to learn from others as they see changes occur. The therapist stresses to patients the importance of keeping their work in the group focused on changing their current interpersonal situations or intensifying important existing relationships and not using the group as a substitute social network.

INITIAL PHASE. The first five sessions of the group treatment comprise the initial phase in group ITP. During this phase, the therapist works to cultivate positive group norms and group cohesion, while emphasizing the commonality of symptoms among members and how the group context will address these. During this phase, group members review their goals with the group and begin to make some initial changes in their respective interpersonal problem areas. As members begin to experiment with the changes outlined in their goals, the therapist works collaboratively with each group member to refine and make any alterations in the target areas before the beginning of the intermediate phase.

INTERMEDIATE PHASE. During the intermediate "work" phase of group ITP (sessions 6 through 15), the therapist works to facilitate connections among members as they share the work on their goals with one another. In contrast to other interactive group approaches, the group interpersonal psychotherapist is much less likely to focus on intragroup processes and relationships unless they are specific to the work on a member's interpersonal problem area (e.g., interpersonal deficits). The therapist, however, consistently and continuously encourages group members to practice newly acquired interpersonal skills both inside and, most importantly, outside the group. As is the case with individual ITP, an essential task throughout the intermediate phase is to strengthen the connections the group members make between difficulties in their interpersonal lives and their psychiatric problems.

MIDTREATMENT MEETING. The midtreatment meeting is held midway (usually between sessions 10 and 11) through the intermediate phase. This meeting provides an opportunity to conduct a detailed review of each group member's progress on his or her individual problems and to refine interpersonal goals. The therapist recontracts with group members during this meeting to outline

and emphasize the work that remains, both inside and outside of the group, before treatment concludes.

TERMINATION PHASE. In the termination phase (sessions 16 through 20), the therapist discusses termination explicitly with the group members and begins to help them recognize that the end of treatment is a time of possible grief and loss. The therapist helps members recognize their own progress and the progress made by other group members. During this phase, group members describe the specific changes in their psychiatric symptoms, especially as they relate to improvements in the identified problem area(s) and relationships. Although it is common for group members to want to keep meeting on their own or to have frequent reunions, the therapist encourages group members to use this phase of the group to formally say goodbye to one another and the therapist. The therapist also uses this time to encourage members to detail their plans for maintaining improvements in their identified interpersonal problem area(s) and to outline their remaining work.

POSTTREATMENT MEETING. The posttreatment meeting occurs within 1 week after the final group session. The therapist uses this final individual meeting to develop an individualized plan for each group member's continued work on his or her interpersonal goals. The therapist reviews the group experience and the changes the patient has made in his or her interpersonal problem area and significant relationships.

NARRATIVE PSYCHOTHERAPY

More than anything else psychiatrists do, they listen to stories. These stories so saturate the clinical encounter that it would be impossible to imagine a clinical encounter without them. In the very first meeting between psychiatrist and patient, the psychiatrist begins with an open-ended invitation to a story: "*What brings you here?*" or "*What seems to be the problem?*" Patients respond to these questions by telling psychiatrists about their lives, their troubles, when the troubles began, what seems to have caused them, how they create difficulty, and what kinds of problem-solving they have tried. Such stories may be rudimentary, they may be only partially worked out, and they may even be baffled and confused. The patient may also be perplexed enough to answer, "I don't know why I came," or "I'm not really sure what's wrong; my family sent me." Nonetheless, the patient's response to the psychiatrist's initial questions always involves a story.

Narrative psychotherapy emerges out of this increased interest in clinical stories. The two main tributaries that lead to narrative psychotherapy come from the two different sides of psychiatry: narrative medicine and narrative psychotherapy. Narrative psychiatrists are psychiatrists who combine the wisdom of these two domains. Following the lead of narrative medicine, narrative psychiatrists recognize that psychiatric patients, like medical patients, come to clinics with intense stories to tell. Contemporary narrative medicine has developed from 30 years of work in bioethics and medical humanities devoted to humanizing the clinical encounter through a better understanding of patient stories. The term *narrative medicine* comes from Rita Charon, an internist and literary scholar, who used it to describe an approach to medicine that uses narrative approaches to augment scientific understandings of illness. Narrative medicine brings together insights from human-centered medical models, such as George Engel's biopsychosocial model and Eric Cassel's person-centered model, with research and insights from phenomenology, the humanities, and interpretive social sciences.

Narrative medicine uses these resources to understand the illness experience better, "to recognize, absorb, interpret, and be moved by the stories of illness." As Charon argued, when clinicians possess narrative competency, they can enter the clinical setting with a nuanced capacity for

“attentive listening…, adopting alien perspectives, following the narrative thread of the story of another, being curious about other people’s motives and experiences, and tolerating the uncertainty of stories.” She further argued that doctors “*need* rigorous and disciplined training” in narrative reading and writing not just for their own sake (helping them to deal with the strains and traumas of clinical work), but also “*for the sake of their practice.*” Without such narrative competency, clinicians lack the ability to understand their client’s experience of illness fully. For Charon and others in narrative medicine, narrative study is not a mere adornment to a doctor’s medical training; it is a crucial and basic science that physicians should master for medical practice.

A major task of narrative medicine, and therefore narrative psychotherapy, is to be a good listener and to connect empathically with the patient’s story. A narrative psychiatrist, like a narrative physician, seeks to understand the patient first and foremost. This understanding brings patient and clinician together into a shared experience of the patient’s world. This narrative understanding is much more than a causal explanation of problem A or problem B that the patient might have. It does not simply abstract from the person’s situation a categorical label that groups problems under a well-known abstract grid. Instead, narrative understanding tunes in to the uniqueness of the individual and the unrepeatability of their experience and difficulties. Narrative understanding, in short, is a deep appreciation of the person as a whole—what it feels like for this person, in this particular context, going through these particular problems.

In addition to following the lead of narrative medicine colleagues, narrative psychiatrists also follow the lead of contemporary colleagues in narrative psychotherapy. The history of narrative psychotherapy goes back to Sigmund Freud’s early work at the inception of psychoanalysis. At that time, Freud lamented how his case histories sounded more like narrative fiction than hard science.

Contemporary narrative psychotherapy’s motivation for returning to the role of narrative comes partly from the broader turn to narrative in humanities, psychology, and social science and partly from the history of psychotherapy since Freud. The past century of psychotherapy has been a century of strife, with one faction after another splitting off from psychoanalysis. Leading alternatives to psychoanalysis included behavioral,

humanistic, family, cognitive, feminist, and interpersonal, just to name some. These splits are characterized by further splits within splits, fragmenting the field of psychotherapy to the point of more than 400 approaches to psychotherapy. Narrative approaches emerge at this particular moment as part of an important trend away from further fragmentation and toward psychotherapy reintegration. Narrative approaches are invaluable for psychotherapy integration because they provide a metatheoretical orientation from which to understand and practice psychotherapy.

Metaphor

Metaphor performs this function by allowing us to understand and experience one thing in terms of something else. The metaphor selects, accentuates, and backgrounds aspects of two systems of ideas so that they come to be seen as similar: “Men are seen to be more like wolves after the wolf metaphor is used, and wolves seem to be more human.”

In narrative psychotherapy, understanding metaphor connects to broader work in continental linguistic philosophy, and that work, as a whole, attempts to shift standard ideas about truth and objectivity. It sidesteps the binary concepts of relativism (anything goes) and realism (there is only one correct or true way to describe the world). Rather than using the binary distinction between true and false, narrative psychotherapy instead uses a postmodern language of semiotic realism and pluridimensional consequences.

Plot

Plot works like metaphor in that it also orders experiences and provides form for narratives. Plot, or the process of emplotment, adds to metaphor two key dimensions: (1) it brings together what would otherwise be separate and heterogeneous elements, and (2) it organizes understanding and experience or time, or what could be called temporal perception.

The critical function of plot for narrative is that plot creates a narrative synthesis between multiple individual events and brings them together into a single story, making an intelligible connection between them. Remarkably, plot can create a synthesis between events and elements that are surprisingly incongruous or heterogeneous—events that do not seem to fit together.

Plot also configures these multiple elements into a temporal order. This

temporal order is of two sorts. First, each plot comprises a discrete series of incidents, of theoretically infinite *nows.* Second, each plot takes these infinite nows, proceeding one after another in succession, and organizes them into a humanly manageable experience.

Character

In narrative theory, the concept of character connects directly to contemporary controversy surrounding the related and, some may argue, more basic concept of identity. The controversy around identity may be understood as a tension between essentialist and nonessentialist approaches. Essentialist notions of identity tell us that each person has a fixed personality, perhaps biologically stamped, that authentically belongs to that person and is at the core of that person's being. This "true self" or "core self" may be distorted or covered over, but it is nonetheless there for the discovery if individuals apply themselves patiently and persistently to the task. Nonessentialist critiques, however, have deconstructed this ideal of identity and its notion of an integral, originary, and unified self. One of the most productive ways to navigate the tension between essentialist and nonessentialist understandings of identity is to draw a comparison between identity (in life) and character (in fiction). Rather than adopting a linear logic that understands identity as a more fundamental concept to character, this approach uses a circular logic to argue that people understand themselves in the same way they understand characters.

Narrative approaches to identity allow people to navigate the tension between essentialist and nonessentialist identities because narrative identity allows for a kind of continuity over time, a relative stability of self, without implying a substantial or essentialist core to this stability. People's interpretations of themselves use the cultural stories surrounding them to tell a story of self that escapes the two poles of random change and absolute identity. In this way, a narrative identity is also a cultural identification. A person's identification may seem original, but he or she narrates them with the resources of history, language, and culture.

Narrative Psychiatry

With this brief introduction to narrative medicine, narrative psychotherapy,

and narrative theory, it is possible further to draw out the meaning of narrative for psychiatry.

Fortunately, one of the most helpful aspects of narrative theory for psychiatry is that it provides an overarching, or metatheoretical, rationale for understanding how these many psychotherapies work. From a narrative perspective, all therapies involve a process of storytelling and story retelling. No matter which style of psychotherapy one uses, the process of therapy involves an initial presentation of problems that the client is unable to resolve. The client and therapist work together to bring additional perspectives to these problems, allowing the client to understand them in a new way. These additional perspectives vary greatly depending on the style of psychotherapy used. It matters, in other words, whether the therapy is psychodynamic, cognitive, humanistic, feminist, spiritual, or expressive. From the vantage point of narrative theory, however, what these different approaches all have in common is that they rework, or "reauthor," the patient's initial story into a new story. This new story allows new degrees of flexibility for understanding the past and provides new strategies for moving into the future.

Future Directions

Recent work in narrative medicine, narrative psychotherapy, and narrative theory has opened the door for the development of narrative psychiatry. This development provides a critical corrective to contemporary psychiatric practice that helps self-correct from an overreliance on biologic models without falling into a morass of antipsychiatry and without throwing away the bioscience baby with the bathwater. When psychiatrists take a narrative turn, they do not throw out their other skills and knowledge. The shift to narrative is, as much as anything else, an attitude shift and an opening out to additional sources of information. It starts by bringing to the foreground that the clinical encounter is a human encounter, and it follows by opening out to colleagues in the humanities, interpretive social sciences, and the arts to help to understand this human encounter better.

Most of all, narrative psychotherapy joins with other contemporary efforts in psychiatry—such as the recovery movement—to make clinical encounters much more client-focused and collaborative. Narrative psychotherapy, at its

core, recognizes that there are many ways to tell the story of one's life. The choice among these different options is a key way in which people create their identity. These choices should not be reduced to expert choices or scientific choices because they are always also personal and ethical choices. In the end, they are choices about what kind of life one wants to live.

Furthermore, clinicians must come to understand the value of biography, autobiography, and literature for developing a repertoire of narrative frames and options. In the end, narrative competency in psychiatry means a tremendous familiarity with the many possible stories of psychic pain and psychic difference. The more stories clinicians know, the more likely they are to help their clients to find a narrative frame that works for them.

For patients and potential service users, a narrative understanding means that there is a range of possible therapists and healing solutions that might be helpful. An approach that is right for one person may not be right for another. There must be a fit between the person and the approach, and people should feel empowered to take their intuitions and feelings seriously. If the person getting help does not feel this fit, he or she is likely right. There may well be another approach that would work better with the person's proclivities. Like everything else, however, judgment is critical. Therapeutic experiences of all kinds can be frustrating, slow, and uncertain. How, for example, does one know when an approach misses his or her needs and when it is something that will take time, patience, and perseverance to be helpful? From a narrative perspective, there can be no gold standard or simple answers. Only judgment, wisdom, and trial and error can decide.

COMBINED PSYCHOTHERAPY AND PHARMACOTHERAPY

The use of psychotropic drugs, in combination with psychotherapy, has become widespread. It has become the standard of care for many patients seen by psychiatrists. In this therapeutic approach, the use of pharmacologic agents augments psychotherapy. It should not be a system in which the therapist meets with the patient only on an occasional or irregular basis to monitor the effects of medication, to make notations on a rating scale to assess progress, or to assess side effects. Instead, it should be a system in which both therapies are integrated and synergistic. In many cases, studies

demonstrate that the results of combined therapy are superior to either type of therapy used alone. The term *pharmacotherapy-oriented psychotherapy* is used by some practitioners to refer to the combined approach. The methods of psychotherapy used can vary immensely, and all can be combined with pharmacotherapy when indicated.

Indications for Combined Therapy

A major indication for using medication when conducting psychotherapy, particularly for those patients with major mental disorders such as schizophrenia or bipolar disorder, is that psychotropics reduce anxiety and hostility. This improves the patient's capacity to communicate and to participate in the psychotherapeutic process. Another indication for combined therapy is to relieve distress when the signs and symptoms of the patient's disorder are so prominent that they require more rapid amelioration than psychotherapy alone may be able to offer. In addition, each technique may facilitate the other; psychotherapy may enable the patient to accept a much-needed pharmacologic agent, and the psychoactive drug may allow the patient to overcome resistance to entering or continuing psychotherapy (Table 23-16).

The reduction of symptoms, especially anxiety, does not decrease the patient's motivation for psychoanalysis or other insight-oriented psychotherapy. In practice, drug-induced symptom reduction improves communication and motivation. All therapies have a cognitive base, and anxiety generally interferes with the patient's ability to gain a cognitive understanding of the illness. Drugs that decrease anxiety facilitate cognitive understanding. They can improve attention, concentration, memory, and learning in patients who suffer from anxiety disorders.

Number of Treating Clinicians

Any number of clinicians can be involved in the treatment of a psychiatric disorder. In *one-person therapy*, the psychiatrist provides individual psychotherapy and medication treatment. Multiperson therapy is a form of treatment in which one clinician conducts psychotherapy while the other clinician prescribes medications. Other therapists may oversee marriage or family therapy or group therapy. The terms *cotherapy* or *triangular therapy*

also describe permutations of multiperson therapy.

Table 23-16
Benefits of Combined Therapy

Improved medication adherence
Better monitoring of clinical status
Decreased number and length of hospitalizations
Decreased risk of relapse
Improved social and occupational functioning

Communication among Therapists

Whenever more than one clinician is involved in treatment, there should be regular exchanges of information. Some patients split the transference between the two; the patient may view one therapist as giving and nurturing and may view the other as withholding and aloof. Similarly, countertransference issues, such as one therapist's identifying with the patient's idealized or devalued image of the other therapist, can interfere with therapy. Therapists must address those issues with the patient, and the cotherapists must be compatible and respectful of each other's orientation so that the therapy program can succeed.

A therapist may have some concerns about the quality of the psychopharmacology or a need to reevaluate the existing regimen. For example, a patient may not be doing well on medication, experiencing significant side effects, or showing a lack of sufficient improvement. Some patients may also be taking many different medications. When and if it is deemed in the patient's interest to question the medication regimen or the prescriber's skill, these misgivings should not be shared with the patient without first conferring with the prescribing physician.

If the therapist or pharmacologist, after a good-faith effort to understand the methods and course of treatment, still has misgivings about treatment, he or she should inform his or her counterpart that a second opinion would be useful. The therapist can then suggest to the patient that he or she consider a second opinion without raising undue alarm. Communication between treating clinicians should take place as frequently as needed. No standard

exists for how frequent that should be.

Orientations of Treating Clinicians

The orientation of the treating psychiatrist or other clinician can influence the therapeutic process during combination treatment. Clinicians invariably bring a theoretical bias to the treatment setting. Some, for example, are oriented, by preference and training, to practice a specific form of psychotherapy, such as psychoanalysis, CBT, or group therapy. These clinicians view psychotherapy as the primary treatment modality, with pharmacologic agents being an adjunct to treatment. Conversely, psychopharmacologically oriented psychiatrists view psychotherapy as augmenting the use of medication. Although disagreement may arise on which approach represents the most active ingredient in clinical response, the optimal use of both modalities should complement each other.

In addition to having extensive training in one or more psychoanalytic or psychotherapeutic techniques, the psychiatrist who practices pharmacotherapy-oriented psychotherapy must have a comprehensive knowledge of psychopharmacology. That knowledge must include a thorough understanding of the indications for the use of each drug, the contraindications, the pharmacokinetics and pharmacodynamics, the drug–drug interactions (with all pharmacologic agents, not only the psychoactive agents), and the adverse effects of medications. The psychiatrist must be able both to identify adverse effects and to treat them.

Nonpsychiatric physicians often use psychoactive agents inaccurately (too small or too large a dose for too short or too long a course), because they lack the requisite psychopharmacological knowledge, training, and experience. Psychotherapists who work with primary care physicians instead of psychiatrists should understand the limitations in depth of knowledge that these practitioners have and should seek a consultation with a psychiatrist if a patient is not responding to, or tolerating, medication. In some situations, the same clinician should deliver both psychotherapy and pharmacotherapy; however, this is often not possible for a variety of reasons, including therapist availability, time limitations, and economic restraints, among others.

Therapist Attitudes. Psychiatrists trained primarily as psychotherapists

may prescribe medication more reluctantly than those more oriented toward biologic psychiatry. Conversely, those who view medication as the preferred intervention for most psychiatric disorders may be reluctant to refer patients for psychotherapy. Therapists who are pessimistic about the value of psychotherapy or who misjudge the patient's motivation may prescribe medications because of their own beliefs; others may withhold medication if they overvalue psychotherapy or undervalue pharmacologic treatments. When a patient is in psychotherapy with someone other than the clinician prescribing medication, it is essential to recognize treatment bias and to avoid contentious turf battles that put the patient in the middle of such conflict.

Linkage Phenomenon. At some point, patients may view the improvement achieved in therapy as the result of a conscious or unconscious linkage between the psychopharmacological agent and the therapist. In fact, after being weaned from medication, patients often carry a pill with them for reassurance. In that sense, the pill acts as a transitional object between the patient and the therapist. Some patients with anxiety disorders, for example, may carry a single benzodiazepine tablet, which they take when they think they are about to have an anxiety attack. Then, the patient may report that the medication aborted the attack—before the medication could even have entered the bloodstream. In other cases, the patient never takes the pill because the patient knows that the pill is available and gains reassurance from that fact. The linkage phenomenon is usually not seen unless the patient is in a positive transference to the therapist. Indeed, the therapist may use this phenomenon to his or her advantage by suggesting that the patient carry medication to use as needed. Eventually, the behavior has to be analyzed, and patients frequently attribute magical properties to the therapist and then transfer those properties to the medication. Some clinicians believe this effect results from conditioning. After repeated trials, the sight of the medicine can decrease anxiety. The positive transference may also cause *transference cure* or *flight into health*, in which the patient feels better in an unconscious attempt to meet the presumed expectations of the prescribing physician. Therapists should consider this phenomenon if the patient reports rapid improvement well before a particular medication may reach its therapeutic level.

Rachel, a 25-year-old woman, presented with depressive symptoms and abdominal pain. After an extensive psychiatric and medical evaluation, she received a diagnosis of major depression of moderate severity and irritable bowel disorder. She began a course of CBT targeting her negative attributional style and low self-esteem, and she learned relaxation and distraction techniques for her pain. After a 12-week trial, she experienced only partial remission of her symptoms, and the psychiatrist offered her an antidepressant, citalopram at 20 mg per day. Her depressive symptoms remitted within 1 month, and she was able to function better at work but socially remained hesitant to engage with her peers. Her abdominal pain persisted, and she began to exhibit a pattern of disordered eating, severely restricting her intake to 500 calories per day due to the "pain." She experienced a 15-lb weight loss over the next several months. An intensive behavioral plan to target eating was begun, as well as continued probing of her negative cognitions relating to eating, pain, and newly emerging concerns that she would regain the weight too quickly and would become "fat." She did not meet the criteria for anorexia nervosa, although her cognitive distortions about her body image were significant. These new concerns resulted in a relapse of her depressive symptoms, including suicidal ideation, and the psychiatrist increased her citalopram to 40 mg/day. She reported severe akathisia on this dose and refused to take any more medication, including an antidepressant of another class. Rachel did agree to intensify her therapy to twice weekly, and this allowed her to explore some of the conflicts, feelings, and thoughts that fostered her treatment-refractory illness. The psychiatrist used a combination of psychotherapy and hypnosis for this work. Over the next 6 months, Rachel revealed a history of sexual abuse as a child, and this made her feel that she did not "deserve" to live or to eat and that the pain served to "punish" her for being bad. She also admitted that she resisted the medication "psychologically" because she felt that she did not deserve to get well. Her newly found insight, as well as the coping skills she developed in therapy, resulted in a reduction of her depressive symptoms, marked improvement in her eating habits with normalization of her weight, and decreased abdominal pain. She maintained these gains over the next year, including the normalization of

her daily functioning, a promotion at work, and the ability to tolerate the intimacy of a boyfriend. (Courtesy of E. M. Szigethy, M.D., Ph.D. and E. S. Friedman, M.D.)

Adherence and Patient Education

Adherence. Adherence is the degree to which a patient carries out the recommendations of the treating physician. A positive doctor–patient relationship fosters adherence, and the patient's refusal to take medication may provide insight into a negative transferential situation. In some cases, the patient acts out hostilities by nonadherence, rather than by becoming aware of, and ventilating, such negative feelings toward the doctor. Medication nonadherence may provide the psychiatrist with the first clue that a negative transference is present in an otherwise adherent patient who had appeared to be agreeable and cooperative.

Education. Patients should know the target signs and symptoms that the drug is supposed to reduce, the length of time they will be taking the drug, the expected and unexpected adverse effects, and the treatment plan to be followed if the current drug is unsuccessful. Although some psychiatric disorders interfere with patients' abilities to comprehend that information, the psychiatrist should relay as much of the information as possible. The clear presentation of such material is often less frightening than are patients' fantasies about drug treatment. The psychiatrist should tell patients when they may expect to begin receiving benefits from the drug. That information is most critical when the patient has a mood disorder and may not observe any therapeutic effects for 3 to 4 weeks.

Some patients' ambivalent attitudes toward drugs often reflect the confusion about drug treatment that exists in the field of psychiatry. Patients often believe that taking a psychotherapeutic medication means they are not in control of their lives, or they may become addicted to the drug and have to take it forever. Psychiatrists should explain the difference between drugs of abuse that affect the normal brain and psychiatric medications that treat emotional disorders. They should also point out to patients that antipsychotics, antidepressants, and antimanic drugs are not addictive in the

way in which, for example, heroin is addictive. The psychiatrist's straightforward and honest explanation of how long the patient should take the drug helps the patient adjust to the idea of chronic maintenance medication if that is the treatment plan. In some cases, the psychiatrist may appropriately give the patient increasing responsibility for adjusting the medications as the treatment progresses. Doing so often helps the patient feel less controlled by the drug and supports a collaborative role with the therapist.

Attribution Theory

Attribution theory is concerned with how persons perceive the causes of behavior. According to attribution theory, persons are likely to attribute changes in their own behavior to external events but are likely to attribute another's behavior to internal dispositions, such as that person's personality traits. Research on drug effects by attribution theorists has shown that, when patients take medication and their behaviors change, they attribute it to the drug and not to any changes that occur within themselves. Accordingly, it may be unwise to describe a drug as extremely strong or effective, because if it does have the desired effect, the patient may believe that is the only reason he or she got better. If the drug does not work, the patient may assume his or her condition is incurable. Therapists do best by presenting the use of drugs and psychotherapy as complementary or adjunctive, as neither standing alone and both being needed for improvements or cure to occur.

Mental Disorders

Depressive Disorders. Some patients and clinicians fear that medication covers over the depression and impedes psychotherapy. Instead, clinicians should view medication as a facilitator in overcoming the anergia that can inhibit the communication process between doctor and patient. The psychiatrist should explain to the patient that depression interferes with interpersonal activity in a variety of ways. For instance, depression produces withdrawal and irritability, which alienate significant others who may otherwise gratify the strong dependency needs that make up much of depressive psychodynamics.

When the patient is no longer taking medication, the psychiatrist should be alert for signs and symptoms of a recurrent major depressive episode. The psychiatrist may need to reinstitute medication. Before doing so, however, carefully review any stress, especially rejections, that could have precipitated recurrent major depressive disorder. A new episode of depression may occur because the patient is in a stage of negative transference, and the psychiatrist must try to elicit negative feelings. In many cases, the ventilation of angry feelings toward the therapist without an angry response can serve as a corrective emotional experience and can forestall a major depressive episode necessitating medication. Depressed patients are generally maintained on their medication for 6 months or longer after clinical improvement. The cessation of pharmacotherapy before that time is likely to result in a relapse.

Combined treatment is superior to either therapy used alone in the treatment of major depression. It is associated with improved social and occupational functioning and enhanced quality of life compared with either therapy alone.

Bipolar I Disorder. Patients taking lithium or other treatments for bipolar I disorder are usually medicated for an indefinite period to prevent episodes of mania or depression. Most psychotherapists insist that patients with bipolar I disorder take medication before starting any insight-oriented therapy. Without such premedication, most patients with bipolar I disorder are unable to make the necessary therapeutic alliance. When those patients are depressed, their abulia seriously disrupts their flow of thoughts, and the sessions are less productive. When they are manic, their flow of associations can be rapid, and their pressured speech can flood the therapist with material and prevent him or her from making appropriate interpretations or assimilating the material into the patient's disrupted cognitive framework.

Combined therapy for bipolar disorder increases adherence, decreases relapse, and reduces the need for hospitalization.

Substance Use Disorders. Patients with substance use disorders present the most difficult challenge in combined therapy. They are often impulsive, and, although they may promise not to use a substance, they may do so repeatedly. In addition, they frequently withhold information from the psychiatrist about episodes of substance use. For that reason, some

psychiatrists do not prescribe any medication to such patients, especially not those substances with high abuse potential, such as benzodiazepines, barbiturates, and amphetamines. Drugs with no abuse potential, such as antidepressants, have an important role in treating the anxiety or depression that frequently accompanies substance-related disorders. The psychiatrist conducting psychotherapy with such patients should have no reservations about sending the patient to a laboratory for random urine toxicologic tests.

Anxiety, Obsessive-Compulsive, and Trauma-Related Disorders. These disorders encompass OCD, PTSD, generalized anxiety disorder, phobic disorders, and panic disorder with or without agoraphobia. Many drugs are effective in managing distressing signs and symptoms. As the medication controls patients' symptoms, patients are reassured and develop confidence that the disorder will not incapacitate them. That effect is particularly strong in panic disorder, which is often associated with anticipatory anxiety about the attack. Depression can also complicate the symptom picture in patients with anxiety disorders and requires pharmacologic and psychotherapeutic intervention. Studies have shown that patients with anxiety disorders who receive ongoing psychotherapy are less likely to experience relapse compared with patients who receive medication alone.

Schizophrenia and Other Psychotic Disorders. Included in the group of schizophrenia and other psychotic disorders are schizophrenia, delusional disorder, schizoaffective disorder, schizophreniform disorder, and brief psychotic disorder. Drug treatment for those disorders is always indicated, and hospitalization is often necessary for diagnostic purposes, to stabilize medication, to prevent danger to self or others, and to establish a psychosocial treatment program that may include individual psychotherapy. In attempting individual psychotherapy, the therapist must establish a treatment relationship and a therapeutic alliance with the patient. The patient with schizophrenia defends against closeness and trust and often becomes suspicious, anxious, hostile, or regressed in therapy. Before the advent of psychotropics, many psychiatrists were fearful for their safety when working with such patients. Indeed, many assaults occurred.

Individual psychotherapy for schizophrenia is labor-intensive, expensive,

and not often attempted. The recognition that combined psychotherapy and pharmacotherapy have a greater chance of success than either type of therapy alone may reverse that situation. The psychiatrist who conducts such combined therapy must be especially empathic and must be able to tolerate the bizarre manifestations of the illness. The patient with schizophrenia is exquisitely sensitive to rejection, and the therapist should never start individual psychotherapy unless he or she is willing to make a total commitment to the process.

Other Issues

Evidence suggests that therapy can induce physical changes in the nervous system. Eric Kandel has provided elegant proof, winning the Nobel Prize for demonstrating that environmental stimuli produce lasting changes in the synaptic architecture of living organisms. Imaging studies have shown that patients who exhibit clinical improvement from psychotherapy show changes in brain metabolism that are similar to those seen in patients successfully treated with medications.

Still, some patients do well on only one form of treatment. Even with identical diagnoses, not all patients respond to the same treatment regimens. Success may be as dependent on the knowledge and quality of the clinician as on the potential benefit of a particular drug.

A real dilemma when combining treatment is the additional direct costs of two treatments. Although successful treatment results in reduced costs to society, the cost of treatment is usually narrowly defined by the patient as out-of-pocket expenses and by insurance and managed care companies as payments to the physician or hospital. Restrictions placed on the frequency and cost of visits to mental health professionals by managed care organizations, however, encourage the use of medication rather than psychotherapy.

MENTALIZATION-BASED TREATMENT

Mentalizing is the social cognitive ability to understand actions by other people and oneself in terms of mental states, including thoughts, feelings, wishes, and desires; it is a very human capability that underpins everyday interactions. In nontechnical language, it is attentiveness to thinking and

feeling in oneself and others. It is beyond question that mental states influence behavior. Beliefs, wishes, feelings, and thoughts, whether within or outside people's awareness, always influence what people do. Mentalizing involves a whole spectrum of capacities: critically, this includes the ability to experience one's *own* behavior as coherently organized by mental states, and to differentiate oneself psychologically from others. Individuals with a personality disorder, who lose cognitive and emotional coherence, particularly at moments of interpersonal (relational) stress, have reduced mentalizing capacities. Mentalization-based treatment (MBT) is a psychotherapy developed for BPD that focuses specifically on the mentalizing vulnerabilities of the patient in the context of an understanding of the attachment process, which is the developmental context in which individuals initially acquire mentalizing.

Techniques

MBT is a group and individual treatment. It is anticipated that, at times, the patient will experience strong affect while focusing on identified problems in treatment sessions, and their mentalizing will be limited or failing, and/or the patient's understanding of the way mental states link to behavior is inadequate.

The clinician addresses this by a structured process (the sessional intervention trajectory) of: (1) empathy and validation about problem areas; (2) clarification, exploration, and where necessary, challenge; (3) following a structured process to gently expand mentalizing and encourage the patient to identify the mental states previously outside their awareness.

The process is primarily in the here and now of the session, but increasingly, as the patient's mentalizing improves, it comes to concern core attachment relationships, including how these are activated with the clinician and key figures in the patient's life and how they influence mentalizing itself. Gradually, improvements in mentalizing serve to enable the patient to address their distorted representations of personal and social relationships.

The assessment and introductory process in MBT facilitates the alliance between patient and clinician (see Table 23-17) and introduces the patient to the treatment frame. An MBT-Introductory group of 10 to 12 sessions assists in the development of the formulation and facilitates the alliance. This

psychoeducational intervention covers all areas of mentalizing, attachment processes, personality disorder, emotion management, and the treatment itself. This preparatory work aims to ensure patients know what they are facing in trying to address their problems and are fully aware of the method and focus of treatment.

MBT is collaborative. Nothing can occur without joint discussion, taking into account the mental experiences and ideas of both patient and clinician. The process of mentalizing requires an authentic desire to understand the mental processes of oneself and others. This applies as much to the clinician as to the patient. The therapeutic process has to become a shared endeavor aimed at extending the influence of explicit, reflective, cognitive, internally focused mentalizing. Initial goals, on the road to improved mentalizing, are jointly developed and given focus. The goals cannot solely be those of the patient, although the patient's aims take priority unless they are antithetical to the whole process of treatment. The sharing of responsibility for the therapeutic process is at the core of the effectiveness of the treatment approach in the pursuit of improved mental state understanding.

Assessment involves delineation of the patient's mentalizing vulnerabilities and mentalizing profile, identification of nonmentalizing cycles, and a shared formulation, which includes specific detail of attachment patterns and areas of vulnerability to emotional dysregulation. This has to be understood by the patient and is for both patient and clinician. The formulation identifies common relational fears, for example, abandonment, which stimulate the patient's attachment system and result in the use of maladaptive attachment strategies in interpersonal interactions. In brief, the pattern of the patient's relationships informs an understanding of the relationship in treatment, and the relationship in treatment is used to reappraise the relationships in life outside treatment. Finally, it is important that the patient and clinician consider establishing a goal of improving social function. This goal will include work, social activity, voluntary work, education, and other constructive life-affirming activity.

Table 23-17
Alliance Building in MBT

Identification of patient's mentalizing vulnerabilities in an

understandable form
Formulation of problems—agreed between patient and clinician
Identification of patient's risk profile and crisis management strategies
Agreement of short- and long-term goals

Indications

MBT is effective in treatment for severe BPD. Patients in the early studies of the intervention had made serious suicide attempts, been admitted to a psychiatric hospital for risk, and/or had acted on thoughts of self-harm. Trials involved both men and women, and patients showed high levels of comorbidity. Analysis of the data suggested that patients with comorbidity for a number of personality disorders, including antisocial personality disorder, did preferentially better in MBT than comparison treatment. At a clinical level, patients with marked interpersonal problems who have a personality disorder rooted in mentalizing vulnerability and attachment problems may benefit from MBT.

Contraindications

MBT is a generic treatment constructed to optimize access both by creating a low-demand treatment protocol and by facilitating access to training by a range of professionals. Individuals who have problems with mentalizing rooted in nonattachment contexts—for example, those with psychosis—may not benefit from MBT; if they do, the mechanism of change is likely to be different from that in BPD. Individuals with relatively simple problems, such as phobias or uncomplicated depression, may do better with more direct approaches, such as CBT. Even within a population of patients with BPD, patients with more complex presentations (more than one personality disorder diagnosis) are more likely to require MBT than those with a single BPD diagnosis, who may do as well in structured clinical management.

PSYCHOEDUCATIONAL INTERVENTIONS

Psychoeducation is the process of helping individuals to understand a psychiatric illness affecting them or their loved ones. Through this process,

patients and/or family members learn about common signs and symptoms of the disease, treatment options, and prognosis for recovery. Psychoeducation moves beyond merely providing information and includes teaching individuals problem-solving skills, coping strategies, support resources, and tools to improve communication. Essentially, psychoeducational interventions provide strategies to support patients and families as they adjust to living with and managing a psychiatric illness.

Psychoeducation can be delivered individually or in a group setting. Interventions can be brief and incorporated into other treatment modalities (e.g., medication management, inpatient hospitalization, outpatient psychotherapy) or they can be structured and take place across several weeks or months. Common areas addressed by psychoeducation include treatment adherence, identifying signs of relapse, lifestyle factors relevant to the illness, and management of crises.

Individuals and families dealing with serious mental illnesses, such as schizophrenia and bipolar disorder, often benefit from psychoeducation. However, psychoeducation may be useful for a variety of disorders, including, for example, major depression, anxiety, autism, dementia, personality disorders, eating disorders, and substance use disorders.

Effectiveness of Psychoeducational Interventions

Psychoeducational interventions have been shown to improve outcomes for patients and families, particularly for those dealing with serious or chronic mental illness. A Cochrane review demonstrated that individuals with schizophrenia who participated in psychoeducation had improved medication adherence and lower relapse rates as compared to those without psychoeducational intervention. Individuals with bipolar disorder who participate in psychoeducation are also reported to have improved treatment adherence and reduced relapse, particularly reduced manic/hypomanic relapse. In addition, psychoeducational interventions for depression have been associated with better illness prognosis and reduced psychosocial burden for family members.

Psychiatric Rehabilitation and Other Interventions

PSYCHIATRIC REHABILITATION

Psychiatric rehabilitation denotes a wide range of interventions designed to help people with disabilities caused by mental illness improve their functioning and quality of life by enabling them to acquire the skills and supports needed to be successful in usual adult roles and the environments of their choice. Normative adult roles include living independently, attending school, working in competitive jobs, relating to family, having friends, and having intimate relationships. Psychiatric rehabilitation emphasizes independence rather than reliance on professionals, community integration rather than isolation in segregated settings for persons with disabilities, and patient preferences rather than professional goals.

Vocational Rehabilitation

In the late 1980s, the emphasis of vocational rehabilitation began to shift to place-and-train models, termed supported employment, which were borrowed from the field of developmental disabilities. According to the federal definition, supported employment involves "competitive work in integrated settings…consistent with the strengths, resources, priorities, concerns, abilities, capabilities, interests, and informed choice of the individuals, for individuals with the most significant disabilities for whom competitive employment has not traditionally occurred; or for whom competitive employment has been interrupted or intermittent as a result of a significant disability." In contrast to other vocational approaches, supported employment

programs (a) did not screen people for work readiness but helped anyone who says they wanted to work; (b) did not provide intermediate work experiences, such as prevocational work units, transitional employment, or sheltered workshops; (c) actively facilitated job acquisition, often accompanying clients on interviews; and (d) provided ongoing support once the person is employed.

Antonio is a 45-year-old man who has been a client of a mental health agency for more than 10 years. He attended the rehabilitative day treatment program until it was converted to a supported employment program. His case manager encouraged him to think about the possibility of working part-time. Antonio told his case manager that he could not work because of his schizophrenia and because he was helping to raise his two kids and needed to be home at 3 PM when they returned from school every day. The case manager explained to Antonio that getting a job does not necessarily mean working 40 hours a week and that lots of people in the agency's supported employment program were working in part-time jobs, even jobs that only require a few hours a week.

Antonio agreed to meet one of the employment specialists to discuss the possibility of work. Over the next couple of weeks, the employment specialist met with Antonio several times, read his clinical record, and talked with his case manager and psychiatrist. The employment specialist learned that Antonio loved to drive his car. He also learned that Antonio had attendance problems in past jobs because he felt unappreciated. The employment specialist found Antonio to be a sociable and likable person.

Antonio told the employment specialist that he was willing to do any job. He did not have one specific job in mind. After discussing options with Antonio and with the team, the employment specialist suggested a job at Meals on Wheels as a driver for the lunch delivery. Antonio was hired and loved it right from the start. Absenteeism was never a problem because he liked driving around and knew that people were counting on him for their meals. The hours were perfect (10 AM to 2 PM), so Antonio could be at home when his kids returned from school. He became good friends with the other workers. He told his case manager that it was wonderful to be bringing home a paycheck again. Moreover, best of all,

he said, was that his kids saw him going to work just like their friends' dads. (Courtesy of Robert E. Drake, M.D., Ph.D. and Alan S. Bellack, Ph.D.)

Social Skills Rehabilitation

Social dysfunction is a defining characteristic of schizophrenia. People with the illness have difficulty fulfilling social roles, such as worker, spouse, and friend, and they have difficulty meeting their needs when social interaction is required (e.g., negotiating with merchants, requesting assistance to solve problems). Social dysfunction is semi-independent of symptomatology and plays an essential role in the course and outcome of the illness. As shown in Table 24-1, social competence involves three component skills: (1) social perception or receiving skills; (2) social cognition, or processing skills; and (3) behavioral response, or expressive skills. Social perception is the ability to read or decode social inputs accurately, including accurate detection of affect cues, such as facial expressions and nuances of voice, gesture, and body posture, as well as verbal content and contextual information. Social cognition involves an effective analysis of the social stimulus, integration of current information with historical information, and planning an adequate response. *Social problem-solving* is another term to describe this domain.

Methods. The primary modality of social skills training is the role-play of simulated conversations. The trainer first provides instructions on how to perform the skill and then models the behavior to demonstrate its performance. After identifying a relevant social situation in which the skill might be appropriate, the patient engages in role-playing with the trainer. The trainer next provides feedback and positive reinforcement, which are followed by suggestions for how the response can be improved. The sequence of role-playing followed by feedback and reinforcement repeats until the patient can perform the response adequately. Training typically occurs in small groups (six to eight patients), in which case patients each practice role-playing for three to four trials and provide feedback and reinforcement to one another. The therapist tailors the teaching to the individual—for example, a highly impaired group member might simply practice saying "no" to a simple request, whereas a less cognitively impaired

peer might learn to negotiate and compromise.

Table 24-1
Components of Social Skill

Expressive behaviors

Attention to and interpretation of relevant cues
Emotion recognition
Processing skills
Analysis of the situation demands
Incorporation of relevant contextual information
Social problem solving
Interactive behaviors
Response timing
Use of social reinforcers
Turn taking
Situational factors
Social “intelligence” (knowledge of social mores and the demands of the specific situation)

Richard was a single white man first diagnosed with schizophrenia at age 22 when he was in college. He was hospitalized briefly but was unable to return to school and moved back home with his parents. He attended a day treatment program intermittently over the next 6 years before he received a referral for help with getting a job and dating.

Richard had missed out on a critical period of adult development and had never learned dating skills or the social skills needed to get or maintain a job. He was appropriately groomed and did not present himself as a patient, but he seemed quite uncomfortable in social interactions. He scarcely made eye contact, staring at the floor when he spoke, and did not initiate conversation, responding to questions with brief answers.

Richard joined a social skills training group for 3 months with six other patients. The focus of the group was employment skills. Patients were taught critical social skills for getting and maintaining a job, such as how to participate in job interviews; how to approach a supervisor to understand how to do a job or for help with work-related problems; how and when to make requests or explain problems, such as getting to work late because of traffic or needing to leave early to go to a doctor's appointment; and socializing with coworkers. Simultaneously, Richard enrolled in a supported employment program and worked with a case manager to find a job as a computer support person. He found a 24-hour-per-week job at a small company and continued to attend the skills group, using the sessions to work on interpersonal issues at work, including engaging in casual conversation with coworkers and dealing with unreasonable requests from people.

When the vocational skills group ended, Richard joined a dating group with seven other male and female patients who had similar interests. This group focused on finding someone to date, dating etiquette, asking someone out (or being asked out), appropriate conversation for dates, sexual interactions, and safe sex practices. In addition to role play and discussion, the group shared ideas on how to meet people and what to do on dates.

Richard responded well to treatment. He had maintained the computer job at follow-up, 6 months after he concluded the dating skills group. His

case manager also reported that he had a girlfriend, a woman whom he had met at his church group. He had also expressed an interest in enrolling in college classes at night. He was still living at home with his parents, but, for the first time, was seriously considering what he would need to do to move out. (Courtesy of Robert E. Drake, M.D., Ph.D. and Alan S. Bellack, Ph.D.)

Goals. In a treatment setting, there are four major goals of social skills training: (1) improved social skills in specific situations, (2) moderate generalization of acquired skills to similar situations, (3) acquisition or relearning of social and conversational skills, and (4) decreased social anxiety. Learning, however, is tedious or almost nonexistent when patients are floridly ill with positive symptoms and high levels of distractibility.

Some findings limit the applicability of social skills training. It is more challenging to teach complex conversational skills than to teach briefer, more discrete verbal and nonverbal responses in social situations. Because complex behaviors are more critical for generating social support in the community, therapy includes methods to improve the learning and durability of conversational skills. These training methods, focusing on training in social skills and information-processing skills, are discussed below.

Training in Social Perception Skills. There is a need for strategies for training patients in affect and social cue recognition. Patients with chronic psychotic disorders, such as schizophrenia, often have difficulty perceiving and interpreting the subtle affective and cognitive cues that are critical elements of communication. Social perception abilities are considered the first step in effective interpersonal problem solving; difficulties in this area are likely to lead to a cascade of deficits in social behavior. Training skills in social perception address these deficits and help provide a foundation for developing more specific social and coping skills.

Despite attending several social gatherings, Matt felt apart from the rest of the group. He reported that these events seemed like “a jumble of sights and sounds.” His therapist, recognizing Matt’s difficulty with social perception, gave him a series of questions designed to help him

organize and give meaning to the social stimuli he encountered. For example, when Matt was confused about a conversation someone was having with him, he would ask himself, “What is this person’s short-term goal? At what level of disclosure should I be? Should I be talking now or listening?” Identifying the rules and goals of a particular social interaction provided a template for Matt to recognize and react to a greater variety of social cues, thus enhancing his behavioral repertoire. (Courtesy of Robert Paul Liberman, M.D., Alex Kopelowicz, M.D., and Thomas E. Smith, M.D.)

INFORMATION-PROCESSING MODEL OF TRAINING. Methods of training that follow a cognitive perspective teach patients to use a set of generative rules that can be adapted for use in various situations. For example, a six-step problem-solving strategy has developed as an outline for helping patients overcome interpersonal dilemmas: (1) adopt a problem-solving attitude, (2) identify the problem, (3) brainstorm alternative solutions, (4) evaluate solutions and pick one to implement, (5) plan the implementation and carry it out, and (6) evaluate the efficacy of the effort and, if ineffective, choose another alternative. Although the step-wise, structured, linear process of problem-solving occurs intuitively, without conscious awareness in normal persons, it can be a useful interpersonal crutch to help cognitively impaired mental patients cope with the information needed to fill their social and personal needs.

Milieu Therapy

The locus of milieu is a living, learning, or working environment. The defining characteristics of treatment are the use of a team to provide treatment and the time the patient spends in the environment. Recent adaptations of milieu therapy include 24-hour-a-day programs situated in community locales frequented by patients, which provide in vivo support, case management, and training in living skills.

Most milieu therapy programs emphasize group and social interaction; peer pressure mediates rules and expectations for normalization of adaptation. When clinical staff views patients as responsible human beings, the patient role becomes blurred. Milieu therapy stresses a patient’s rights to goals and to

have freedom of movement and informal relationship with staff; it also emphasizes interdisciplinary participation and goal-oriented, clear communication.

Token Economy. The use of tokens, points, or credits as secondary or generalized reinforcers normalizes a mental hospital or day hospital environment with a program mimicking society's use of money to meet instrumental needs. Token economies establish the rules and culture of a hospital inpatient unit or partial hospitalization program, offering coherence and consistency to the interdisciplinary team as it struggles to promote therapeutic progress with challenging patients. These programs are challenging to establish, however, and their widespread dissemination has suffered because of the organizational prerequisites and the additional resources and rewards needed to create a truly positively reinforcing environment.

Cognitive Rehabilitation

Increased recognition of the prevalence and importance of neurocognitive deficits over the past decade has stimulated a growing interest in remediation strategies. Much of the work in this area has focused on psychopharmacological approaches, especially on the new-generation antipsychotics. New-generation medications appear to have a positive effect on neurocognitive test performance. However, the effect size for any of the medications is small to medium, and little evidence indicates that these medications have a clinically meaningful impact on neurocognitive functioning in the community. As a result, a parallel interest has arisen in the potential for *rehabilitation* or *cognitive remediation.* This body of work is distinct from cognitive-behavioral therapy and cognitive therapy, which focus on reducing psychotic symptoms.

Ethical Issues

The ethics of conducting rehabilitation strategies are generally the same as for conducting other psychotherapies. Two issues come up regularly, however: avoiding infantilization and maintaining confidentiality. The first issue concerns the risk of viewing the patient as unable to make adult

choices, such as whether to participate in rehabilitation, where to live, whether or not to work, and whether or not to use drugs and alcohol. Although it may be more of a value than an ethical standard, psychiatric rehabilitation assumes that the practitioner and the patient are in a partnership to facilitate recovery and improve quality of life. The basic model involves collaboration and shared decision-making and does not portray the practitioner as an authority or parental figure. When patients make what appear to be bad choices, the practitioner must consider the patient's right to choose and whether the choice is dangerous versus merely not the choice the practitioner would make. If the choice is potentially harmful, a collaborative process of considering alternatives is more likely to produce good quality choices than an authoritative, admonitory approach.

Failure to consider the patient as a partner also leads to violations of confidentiality. Practitioners sometimes assume that they are the primary arbiters of what information to share with parents, other clinicians, and other agencies. In fact, in most circumstances that do not involve the safety of patients or others, the patient should be the arbiter of what information to share with whom. For example, in supported employment, the patients always determine whether to disclose information about their illnesses to employers.

GENETIC COUNSELING

Medical geneticists and specially trained and qualified genetic counselors have traditionally provided genetic counseling to patients in need of such help. Many psychiatrists, however, are also well placed to provide genetic education and counseling because they often have knowledge of their patient's needs and family histories and have ongoing therapeutic relationships. The ideal approach for providing psychiatric genetic counseling is through a multidisciplinary team approach, with collaboration between genetics and mental health professionals. Genetic professionals are available for consultation with psychiatry regarding advanced risk assessment, collection and construction of complicated family medical history (FMH), and the availability and limitations of genomic testing. Precision medicine is evolving to include the use of panels of genetic variants and genome sequencing to assess the origins of conditions in families where multiple

individuals are affected, or psychiatric symptoms accompany signs of rare disorders.

Definitions

Genetic counseling is the process of helping people to understand and adapt to the medical, psychological, and familial implications of genetic contributions to disease. According to the National Society of Genetic Counseling, it integrates three factors: (1) interpretation of family and medical histories to assess the chance of disease occurrence or recurrence; (2) education about inheritance, testing, management, prevention, resources, and research; and (3) counseling to promote informed choices and adaptation to the risk or condition. The process aims to minimize distress and facilitate adaptation, to increase one's feeling of personal control, and to facilitate informed decision-making and life planning.

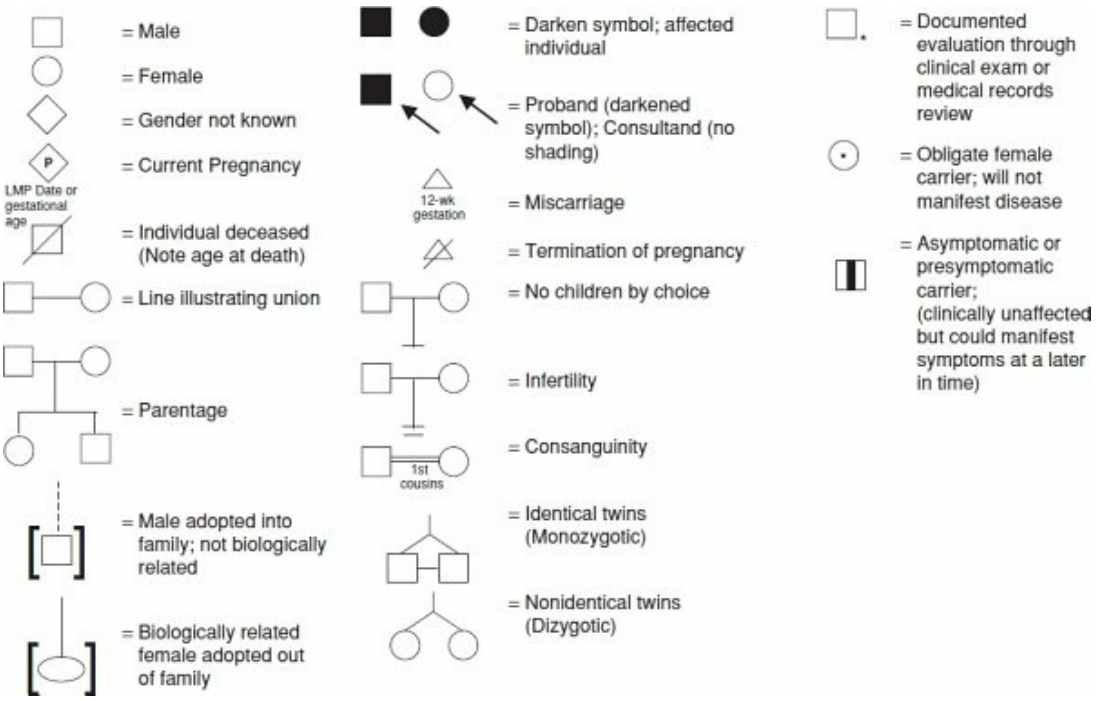

FIGURE 24-1
Standard symbols used in pedigree construction. LMP, last menstrual period.

Although the term *genetic counseling* suggests a primary focus on the genetic contributions to disease, it is not limited to that domain. Genetic counseling entails risk assessment, education, and counseling for common,

complex diseases and necessarily considers both *genetic* and *environmental* components of the presenting illness. The growing awareness of the complex interplay between genes and the environment dictates a comprehensive approach to care.

To facilitate comprehension and application of the material in this section, Figure 24-1 demonstrates standard symbols used in pedigree construction, and Figure 24-2 illustrates a complex FMH presented in the form of a pedigree.

Genetics and Psychiatric Disorders

It is widely accepted that psychiatric illnesses tend to run in families (Table 24-2). Disorders can recur in families for several reasons, including the functioning of the genome (rarely, due to one genomic variation with a large effect on susceptibility, or more commonly due to multiple variations that each have a small effect on susceptibility) or shared environmental exposures. Thus, genetic counseling for a complex disorder entails discussion around *both* genetic and environmental risk factors. For example, consider a case in which a father with obsessive-compulsive disorder (OCD) has concerns about symptoms developing in his children. Genetic counseling may focus on the following: (1) the family history, indicative of both genetic and shared environmental risk in the family; (2) risk factors for the children, stemming from those genetic and environmental factors; (3) early symptom identification and early intervention (aiming to modify the environment and thus affect genetically mediated disease progression); (4) a discussion of the benefits and limitations of environmental modifications aimed at reducing the risk or minimizing emerging symptoms.

Table 24-2
Examples of Psychiatric Disorders Recognized as Having a Genetic Component to Their Etiology

Psychotic disorders: Schizophrenia, schizoaffective disorder
Mood disorders: Bipolar disorder, recurrent unipolar depression
Personality disorders: Antisocial personality disorder, schizotypal disorder

Anxiety disorders: Generalized anxiety disorder, obsessive-compulsive disorder, panic disorder, phobia
Substance-related disorders: Substance dependence and abuse
Eating disorders: Anorexia nervosa, bulimia
Childhood disorders: Attention-deficit/hyperactivity disorder, autism, chronic tic disorders, including Tourette syndrome
Memory disorders: Alzheimer disease

The concept of complex disease (which has replaced *multifactorial* as an etiologic category for common disorders) not only takes into account the interplay of the genome and the environment but also includes the broader biologic and physiologic mechanisms of evolution and development that operate with societies and cultures. The onset of most cases of psychiatric disease, like the onset of other common disorders, is thought to arise when an individual has several risk-increasing genomic variants and has experienced one or more environmental triggers; development, growth, and maturation influence the overall risk. The modern perception that psychiatric symptomatology causes disadvantageous “disease” is related to the effects of the symptoms on the ability of the individual to interact successfully with his or her social and cultural environment.

The first evidence that genetic factors were operating in psychiatric disorders came from the analysis of families with multiple affected members, twin studies, and adoption studies. Family studies indicated familial etiology, although the relative contributions of genes and environmental factors were unclear. Twin and adoption studies provided insights into the relative contributions of etiologic risk factors, and for all major psychiatric disorders, consistently indicated the importance of genes and environment. Family, twin, and adoption studies also provided insight into the genetic heterogeneity and phenotypic variability of mental disorders.

Pedigree of a family with velocardiofacial (VCF) syndrome. ADHD, attention-deficit/hyperactivity disorder; Dx, diagnosed; MR, mental retardation. (From Sadock BJ, Sadock VA, Ruiz P, eds. *Kaplan & Sadock's Comprehensive Textbook of Psychiatry*. 9th ed. Philadelphia: Lippincott Williams & Wilkins; 2009, with permission.)

Priorities of Psychiatric Genetic Counseling

Requests for genetic counseling often arise from the patient's or relatives' questions about the disorder that is present in the family. One can conceptualize the provision of information on the potential genomic origins of the condition and the options for genome testing or assessment of the family as shared decision-making. Patient preference dictates risk assessment

and genome testing. It is important to weigh how much the patient prefers to pursue and for what purpose against the estimated likelihood that useful information will come from testing. Table 24-3 outlines the essential components of genetic counseling.

Obtaining the Data Needed for Risk Assessment. The FMH is used to assess the likely etiology of the disorder and estimate risks for recurrence in the family. Confirmation or clarification of the diagnosis or diagnoses in the family is essential to the provision of valid information.

Table 24-3
Steps and Process of Genetic Counseling

Solicit and clarify the client's presenting questions and goals for genetic counseling.
Explore client's existing explanation for cause of illness.
Collect and review medical and family medical history.
Identify support systems.
Verify diagnoses in proband and other affected family members when possible.
Address issues and concerns identified through the genetic counseling process.
Assess the client's emotional and intellectual capacity before proceeding to determine the approach to the provision of education and counseling.
Provide information at cognitively appropriate levels.
Note that the processing of emotional reactions is intertwined with the provision of information.
Assess the personal meaning of the information and the client's willingness to negotiate various risks and burdens.
When applicable, assist the client in arriving at a decision by discussing available options; discuss benefits and limitations of each alternative.
Assist the client with adapting to the risk status in the family.
Assist in formulating a plan that the client is able to carry out.

Provide follow-up counseling and support. Continue to assess the client's and family's understanding of the information and the effect of the information, risks, or decisions.

Topics that are specific to psychiatric disorders and are essential to include in the FMH are: (1) any psychiatric diagnosis, whether childhood, adult, postpartum, or geriatric; (2) age at symptom onset and diagnosis; (3) subjective assessment of illness severity and treatment response; (4) potentially significant environmental exposures (e.g., obstetrical complications, cannabis use, head injury); (5) symptomatic, undiagnosed individuals or undiagnosed individuals treated with psychiatric medication; (6) developmental history (e.g., has the individual achieved typical milestones for age, such as independent living and employment for adults?); (7) social history; (8) substance abuse; (9) suicide and self-harm; (10) congenital disabilities, intellectual disability or learning disabilities, and unusual medical conditions; (11) the age and sex of at-risk family members.

As mental health providers will be aware, challenges to collecting the psychiatric FMH may include guilt and stigma that limit knowledge of diagnoses among family members, the frequency of undiagnosed psychiatric illness, and the dynamic nature of emerging psychiatric symptoms that may result in diagnostic change over time.

Risk Communication. Different clients seek different types of risk counseling, and they should be queried about their preferences before risk communication begins. Some may seek broad information about the underpinnings of risk for psychiatric disorders, while others prefer a qualitative discussion of the risk magnitude. These individuals may not welcome or benefit from receiving numerical risk information. For others who prefer a detailed numerical estimation of risk for recurrence, risks based on FMH should be presented as a range to reflect the ambiguity of the estimates. In some cases, it may be possible to suggest that one end of the range is more appropriate for a specific client than midrange.

Psychosocial Counseling and Support

Genetic counseling integrates psychological and social issues that result from

living with a psychiatric condition in the family with FMH and increasingly will also include genomic risk information. Historically, genetic counseling has been nondirective, which is deemed particularly appropriate within the context of reproductive decisions and presymptomatic testing for untreatable disorders, such as Huntington disease. However, nondirectiveness is challenging to practice and has been replaced with a person-centered approach, as improved treatments and risk behaviors realize health benefits. The following case exemplifies the personal experiences and meaning of psychiatric disorders.

A couple in their mid-30s with a 10-year history of infertility had been trying to adopt a child for several years. Recently, the adoption agency they were working with told them of a baby who was being placed for adoption because the biologic mother was affected with bipolar disorder and did not feel that she could provide adequate care for the baby. The FMH collected on the newborn baby did not identify others in his family with psychiatric disorders. The recurrence risk for bipolar disorder to the newborn was, therefore, estimated to be between 5 and 20 percent, with additional risks for other psychiatric disorders. The couple individually reacted quite disparately to the estimated risks. In attempting to help them clarify the factors contributing to their feelings regarding the risks, the husband shared his experience with a childhood neighbor who had “some kind of mental illness” and detailed the “torment and agony” that the child brought to the family. Retorting, the woman shared the fact that her coworker also had bipolar disorder and did “just fine” at work with the help of medication. She, therefore, did not feel that the risks for psychiatric disorders were of concern. The psychiatrist facilitated the couple’s discussion of the spectrum and meaning of mental illness, along with recurrence risks in the context of a genetic education and counseling session. Although the couple did not agree during that meeting over the potential for adopting the child, they did feel that the information and sharing of experiences and perspectives about psychiatric disorders were beneficial. They agreed to return in 1 week after further considering the issues to decide on the adoption. (Courtesy of Holly L. Peay, M.S. and Donald W. Hadley, M.S.)

Challenges Posed by Presymptomatic and Susceptibility Genetic Testing

As genomic technologies continue to improve and knowledge about variants that can increase vulnerability for psychiatric illness grows, we will more commonly identify individuals at a higher risk for psychiatric illness. Appropriate applications of such developments need careful consideration from both economic and ethical perspectives but may have critical clinical uses.

Psychiatrists will be on the front line for receiving requests for genetic counseling and testing because of their established relationship between patients and families with psychiatric disorders. The clinical identification of genomic risks will most likely occur before most individuals have access to preventative options. The option of knowing risks without preventative options raises concerns regarding the impact of such knowledge on the individual's mood, anxiety, distress, self-image, reproductive decisions, career decisions, family relationships, insurability, employment, and, potentially, other areas.

Across many disease indications, the majority of persons undergoing genomic testing and receiving their identified risk status do not experience long-term adverse effects. However, those receiving results indicating increased disease risk may experience elevated levels of disease-related anxiety and depression soon after receiving results, and a small number have prolonged difficulty in adjusting to their results. Supportive counseling should be available to facilitate adjustment.

The pursuit of genomic counseling and testing by an individual has clear and profound implications for other family members. Helping the client understand the potential reactions and effect that his or her decision to pursue genomic testing could have on close family members is an important consideration. The health professional can play a role in assisting the client in considering ways to share the information with selected significant others. Similarly, the effect of such information on the spouse or significant other requires consideration.

Ethical, Legal, and Social Considerations

Although there are many benefits of genomics knowledge, scientists and the lay public have worried, from the beginning of genetic research, about the potential for harmful consequences of knowing one's genetic makeup. How will family members, neighbors, communities, employers, health care providers, and insurance companies react to such information? Might health care providers request that those at increased genomic risk take psychiatric medications prophylactically? Might employers limit job opportunities for those with increased risk for psychiatric illness, keeping them in positions with lower levels of stress? Will persons at increased risk be pressured not to have children? Might providing such risk information induce significant enough anxiety/stress to trigger the onset of illness? Furthermore, how will families and the public be educated about the availability of susceptibility testing for psychiatric illness?

Some individuals and families may experience significant levels of stigma associated with the identification of a genetic disorder, a situation already familiar to individuals and families with psychiatric illness. The added knowledge of a hereditary component may heighten stigmatization. Conversely, having an identified, biologic basis may supplant current public perceptions that mental illness is somehow a personal or family failure in moral, spiritual, or attitudinal perspectives.

Consultation to Other Disciplines

Psychiatrists are often asked to consult with other doctors and health professionals to help with the psychiatric issues in their patients. Consultation-Liaison Psychiatry is devoted to this role. However, several other subspecialties have large consultative roles. These include geriatric psychiatrists, who may work in multidisciplinary settings with diseases that cross all disciplines (such as the dementias) or forensic psychiatrists who consult with other doctors, lawyers, and the courts. Much of the forensic psychiatrists' expertise concerns legal and ethical issues, and we discuss these in Chapters 27 and 28. Psychiatrists also work in the emergency department to help assess and treat psychiatric emergencies. In some larger hospitals, Emergency Psychiatry exists as a separate division with its own location. However, in most hospitals, psychiatrists consult in the general emergency setting. Some child psychiatrists may work in a consultative setting as well, particularly emergency settings. In this chapter, we cover the consultative role of consultation-liaison psychiatrists, geriatric psychiatrists, and both general and child psychiatrists working in the emergency setting.

25.1 Consultation-Liaison Psychiatry

Consultation-Liaison Psychiatry and the field of Psychosomatic Medicine have been a specific area of concern within psychiatry for more than 50 years. The term *psychosomatic* is derived from the Greek words *psyche* (soul) and *soma* (body). The term refers to how the mind affects the body. Unfortunately, it has come to be used, at least by the lay public, to describe an individual with medical complaints that have no physical cause and are

“all in your head.” For this and related reasons, in 2018, the Academy of Psychosomatic Medicine changed its name to the Academy of Consultation-Liaison Psychiatry. Before that, the DSM deleted the nosologic term psychophysiological (or psychosomatic) disorders and replaced it with psychological factors affecting physical conditions.

Nonetheless, the term continues to be used by researchers and is in the title of significant journals in the field (e.g., *Psychosomatic Medicine*, and the *Journal of Psychosomatic Research*). It is also used by some major national organizations in the field (the American Psychosomatic Society) as well as international organizations (e.g., the European Association for Consultation-Liaison Psychiatry and Psychosomatics). In 2003 the American Board of Medical Specialties and the American Board of Psychiatry and Neurology approved the specialty of Psychosomatic Medicine and in 2017 they changed the name to Consultation-Liaison psychiatry.

HISTORY

As Edward Shorter discusses in detail in his summary of the history of psychosomatic illness, ways of presenting illness vary over history because patients unconsciously select symptoms that are thought to represent actual somatic illnesses. Psychosomatic presentations have thus varied throughout recent history. Before 1800, physicians did not conduct clinical evaluations and could not distinguish somatic from psychogenic illness. As a result, the diagnoses of hysteria and hypochondriasis could easily be made in the presence of genuine medical illnesses and did not suggest any specific disease.

Sigmund Freud helped to bring psyche and soma together. He demonstrated the importance of emotions in producing mental disturbances and somatic disorders. His early psychoanalytic formulations detailed the role of psychic determinism in somatic conversion reactions. Using Freud’s insight, several workers in the early decades of the 20th century tried to expand the understanding of the interrelationship of psyche and soma. Karl Abraham proposed the influence on adult organ tissue of various unresolved pregenital impulses in 1927. Sándor Ferenczi described the application of the idea of conversion reaction to organs under the control of the autonomic nervous systems in 1926, and Georg Groddeck suggested the attaching of

symbolic meaning to fever and hemorrhage in 1929.

The field of consultation-liaison psychiatry has existed for many decades, and George W Henry described the practice in the United States in the 1920s. Divisions of consultation-liaison psychiatry began springing up in various academic departments, as did fellowship programs. The American Board of Psychiatry and Neurology offered the first examination for the subspecialty in 2005.

In Europe, particularly in Germany, pioneers such as Thure von Uexküll saw psychosomatic medicine more broadly, and not merely a subspecialty of psychiatry. The field was understood as central to the concept of all medical diseases. Diseases were conceived as being multifactorial, with both organic and psychological etiologies. It is notable that in Europe, most departments of psychosomatic medicine are independent of departments of psychiatry.

CURRENT TRENDS

The practice of Consultation-Liaison psychiatry has evolved considerably since its early clinical origins and has come to focus on psychiatric illnesses that occur in the setting of physical health care. In large part, this evolution has occurred as a result of the increased complexity of medicine, the increased understanding of the relationship of medical illness to psychiatric illness, and the greater appreciation of mind and body as one. Clinical care is now delivered in a variety of health care settings and utilizes an ever-expanding set of diagnostic tools, as well as many effective somatic and psychotherapeutic interventions. Research in the area has progressed to include a greater understanding of the relationship between chronic medical conditions and psychiatric disorders. It has examined the pathophysiologic relationships, the epidemiology of comorbid medical and psychiatric disorders, and the role that specific interventions play in physiologic, clinical, and economic outcomes (Table 25-1).

Table 25-1
Summary of Clinical Problems in Psychosomatic Medicine

Type of Clinical Problem	Example
Psychiatric symptoms	Delirium, dementia

secondary to medical conditions	
Psychiatric symptoms as a reaction to medical conditions or treatments	Anxiety related to chemotherapy, depression related to limb amputation
Psychiatric complications of medical conditions and treatments	Depression secondary to interferon treatment
Psychological factors precipitating medical symptoms	Somatic Symptom and related disorders
Medical complications of psychiatric conditions or treatments	Neuroleptic malignant syndrome, acute withdrawal from alcohol or another substance
Co-occurring medical and psychiatric conditions	Recurrence of depressive disorder in the setting of cancer treatment (conditions occur independently); schizophrenia in a patient with end-stage renal disease
Psychiatric/psychosocial assessment	Capacity evaluation; evaluation prior to organ transplantation

Psychiatric morbidity is prevalent in patients with medical conditions, with a prevalence ranging from 20 to 67 percent, depending on the illness and setting. Patients in the general hospital have the highest rate of psychiatric disorders when compared with community samples or patients in ambulatory primary care. For example, compared with community samples, depressive disorders in the general hospital are more than twice as prevalent, and substance abuse is two to three times as common. Delirium occurs in 18 percent of patients. Similarly, increased rates are seen in primary and long-term care.

Psychiatric morbidity has severe effects for medically ill patients and is often a risk factor for their medical conditions. It is well established that

depression is both a risk factor and a poor prognostic indicator in coronary artery disease. Psychiatric illness worsens cardiac morbidity and mortality in patients with a history of myocardial infarction, diminishes glycemic control in patients with diabetes, and decreases return to functioning in patients experiencing a stroke. Depressive and anxiety disorders compound the disability associated with stroke. In the context of neurodegenerative diseases such as Parkinson's or Alzheimer's, depression, psychosis, and behavioral disturbances are significant predictors of functional decline, institutionalization, and caregiver burden. Hospitalized patients with delirium are significantly less likely to improve in function compared with patients without delirium. Delirium is associated with worse outcomes after surgery, even after controlling for the severity of medical illness.

Also, depression and other mental disorders significantly impact the quality of life and the ability of patients to adhere to treatment regimens (e.g., in patients with diabetes mellitus or cancer). Psychiatric disorders are linked to nonadherence with antiretroviral therapy, adversely affecting the survival of human immunodeficiency virus (HIV)-infected patients. Psychiatric disorders are also linked to nonadherence with safe sex guidelines and with the use of sterile needles in HIV-infected injection drug users, thus having significant public health implications.

EVALUATION PROCESS IN PSYCHOSOMATIC MEDICINE

Psychiatric assessment in the medical setting includes a standard psychiatric assessment as well as a particular focus on the medical history and context of physical health care. In addition to obtaining a complete psychiatric history, including history, family history, developmental history, and a review of systems, the medical history and current treatment should be reviewed and documented. A full mental status examination, including a cognitive examination, should be completed, and components of a neurologic and physical examination may be indicated depending on the nature of the presenting problem.

Another essential objective of the psychiatric evaluation is to gain an understanding of the patient's experience of his or her illness. In many cases, this becomes the central focus for both the psychiatric assessment and

interventions. It is often helpful to develop an understanding of the patient's developmental and personal history as well as critical dynamic conflicts, which in turn may help to make the patient's experience with illness more comprehensible. Such an evaluation can include the use of the concepts of stress, personality traits, coping strategies, and defense mechanisms. Observations and hypotheses that are developed can help to guide a patient's psychotherapy aimed at diminishing distress and may also be helpful for the primary medical team in their interactions with the patient.

Finally, a full report synthesizing the information should be completed and include specific recommendations for additional evaluations and intervention. Ideally, the report should be accompanied by a discussion with the referring physician.

TREATMENTS USED IN PSYCHOSOMATIC MEDICINE

A host of interventions have been successfully utilized in psychosomatic medicine. Specific consideration must be given to medical illness and treatments when making recommendations for psychiatric medications. Psychotherapy also plays a vital role in psychosomatic medicine and may vary in its structure and outcomes as compared with therapy that occurs in mental health practice.

Psychopharmacologic recommendations need to consider several essential factors. In addition to targeting a patient's active symptoms, considering the history of illness and treatments, and weighing the particular side-effect profile of a particular medication, several other factors must be considered that relate to the patient's medical illness and treatment. It is critical to evaluate potential drug–drug interactions and contraindications to the use of potential psychiatric agents. Because the majority of psychiatric medications used are metabolized in the liver, awareness of liver function is essential. General appreciation of side effects, such as weight gain, risk of developing diabetes, and cardiovascular risk, must be considered in the choice of medications. Also, it is critical to incorporate knowledge of recent data that outlines the effectiveness and specific risks involved for patients with co-occurring psychiatric and physical disorders. For example, a greater understanding of the side effects of antipsychotic medications has raised concerns about the use of these medications in patients with dementia.

The use of psychosocial interventions also requires adaptation when used in this population. The methods and the goals of psychosocial interventions used in the medically ill are often determined by the consideration of disease onset, etiology, course, prognosis, treatment, and understanding of the nature of the presenting psychiatric symptoms in addition to an understanding of the patient's existing coping skills and social support networks. However, there are ample data that psychosocial interventions are effective in addressing a series of identified problems and that such interventions, in many cases, are associated with a variety of positive clinical outcomes.

Common C-L Problems

Suicide Attempt or Threat. Suicide rates are higher in persons with medical illness than in those without medical or surgical problems. High-risk factors for suicide are men over 45 years of age, no social support, alcohol dependence, previous suicide attempt, and incapacitating or catastrophic medical illness, especially if accompanied by severe pain. If suicide risk is present, the patient should be transferred to a psychiatric unit or started on 24-hour nursing care.

Depression. Suicidal risk must be assessed in every depressed patient. Depression without suicidal ideation is not uncommon in hospitalized patients, and treatment with antidepressant medication can be started if necessary. A careful assessment of drug–drug interactions must be made before prescribing, which should be undertaken in collaboration with the patient's primary physician.

Agitation. Agitation is often related to the presence of a cognitive disorder or associated with withdrawal from drugs (e.g., opioids, alcohol, sedative-hypnotics). Antipsychotic medications may be beneficial for excessive agitation. Physical restraints should be used with great caution and only as a last resort as sedation is preferable and safer. The patient should be examined for command hallucinations or paranoid ideation to which they are responding in an agitated manner. Toxic reactions to medications that cause agitation should always be ruled out.

Hallucinations. A common cause of hallucinations in the general hospital setting is delirium tremens, which usually begin 3 to 4 days after hospitalization. Patients in intensive care units (ICUs) who experience sensory isolation may respond with hallucinatory activity. Conditions such as brief psychotic disorder, schizophrenia, and neurocognitive disorders are associated with hallucinations, and they respond rapidly to antipsychotic medication. Fornication, in which the patient believes that bugs are crawling over the skin, is often associated with cocaine use.

Sleep–Wake Disorders. A common cause of insomnia in hospitalized patients is pain, which, when treated, solves the sleep problem. Early morning awakening is associated with depression, and difficulty falling asleep is associated with anxiety. Depending on the cause, antianxiety or antidepressant agents may be prescribed. Early substance withdrawal as a cause of insomnia should be considered in the differential diagnosis.

Confusion. Delirium is the most common cause of confusion or disorientation among hospitalized patients in general hospitals. The causes are myriad and relate to metabolic status, neurologic findings, substance abuse, and mental illness, among many others. Small doses of antipsychotics may be used when significant agitation occurs in conjunction with the confused state; however, sedatives, such as benzodiazepines, can worsen the condition and cause sundowner syndrome (ataxia, disorientation). If sensory deprivation is a contributing factor, the environment can be modified so that the patient has sensory cues (e.g., radio, clock, no curtains around the bed). Table 25-2 lists the probable causes of confusional states that require urgent attention.

Noncompliance or Refusal to Consent to Procedure. The relationship between the patient and their doctor may be a critical underlying factor when patients are noncompliant or refuse to consent to a procedure. A negative transference toward the physician is a common cause of noncompliance. Patients who fear medication or a procedure may respond to education and reassurance. Patients whose refusal to give consent is related to impaired judgment can be declared incompetent, but only by a judge. The leading cause of impaired judgment in hospitalized patients is cognitive

disorders.

No Physiologic Basis for Symptoms. The C-L psychiatrist is often called when the physician cannot find evidence of medical or surgical disease to account for the patient's symptoms. In these instances, several psychiatric conditions must be considered, including conversion disorder, somatization disorder, factitious disorders, and malingering. Glove and stocking anesthesia with autonomic nervous system symptoms is seen in conversion disorder; multiple bodily complaints are present in somatization disorder; the wish to be in the hospital occurs in factitious disorder, and apparent secondary gain is observed in patients who are malingering (e.g., compensation cases).

C-L Psychiatry in Special Situations

Intensive Care Units. All ICUs deal with patients who experience anxiety, depression, and delirium. ICUs also impose extraordinarily high stress on staff and patients, which is related to the intensity of the problems. Patients and staff members alike frequently observe cardiac arrests, deaths, and medical disasters, which leave them all autonomically aroused and psychologically defensive. ICU nurses and their patients experience exceptionally high levels of anxiety and depression. As a result, nurse burnout and high turnover rates are frequent.

The problem of stress among ICU staff receives much attention, especially in the nursing literature. Much less attention is given to the house staff, especially those on the surgical services. All persons in ICUs must be able to deal directly with their feelings about their extraordinary experiences and challenging emotional and physical circumstances. Regular support groups in which persons can discuss their feelings are recommended for the ICU staff and the house staff. Such support groups protect staff members from the otherwise predictable psychiatric morbidity that some may experience and also protect their patients from the loss of concentration, decreased energy, and psychomotor-retarded communications that some staff members otherwise exhibit.

Hemodialysis Units. Hemodialysis units present a paradigm of complicated modern medical treatment settings. Patients are coping with

lifelong, debilitating, and limiting disease; they are dependent on a multiplex group of caretakers for access to a machine controlling their well-being. Dialysis is scheduled three times a week and takes 4 to 6 hours; thus, it disrupts patients' previous living routines.

Table 25-2
Some Clues to Causes of Delirium Demanding Urgent Attention

Metabolic Disorders

1. Hypoglycemia: history of diabetes or alcoholism; reduced level of consciousness, shaky, sweaty, perhaps combative
2. Hyperglycemia: history of diabetes; complaints of increased thirst, urination, or flulike symptoms
3. Hyponatremia: underlying illness like lung cancer, recent stroke, chronic pulmonary infections, heart failure, cirrhosis, diuretic use
4. Hypernatremia: dehydration from inadequate fluid intake or excessive fluid loss without replacement
5. Hypercalcemia: underlying disorder such as cancer metastatic to bone, sarcoidosis, lung and renal cell cancer, multiple myeloma, and/or prolonged immobilization
6. Hypoxia: inadequate oxygen supplied to the brain because of poor pulmonary or cardiac function or carbon monoxide poisoning
7. Hypercarbia: history of chronic lung disease characterized by carbon dioxide retention; may use oxygen at home
8. Hepatic encephalopathy: history of chronic liver disease or alcoholism; probably jaundiced; ascites
9. Uremia: history of kidney disease, enlarged prostate, recent inability to pass urine
10. Thiamine deficiency (Wernicke encephalopathy): variable degrees of ophthalmoplegia, ataxia, and mental disturbance; history of nutritional deficiency secondary to alcoholism, particularly of thiamine; since remaining thiamine in the body is rapidly used when the patient is given intravenous glucose, any

patient with alcoholism should immediately receive intramuscular thiamine before glucose infusion to prevent precipitating this encephalopathy; untreated, the disorder rapidly progresses to a permanent memory disorder (Korsakoff syndrome) and, in some advanced cases, death

11. Hypothyroidism: history of progressive fatigue, constipation, sensitivity to cold, weight gain, coarsening of hair and skin, mental slowing; examination shows abnormally low temperature and enlarged heart and slow pulse; may be precipitated by the effects of lithium on thyroid function
12. Hyperthyroidism: patient may be either hyperactive or apathetic; history may reveal rapid weight loss, diarrhea, heat intolerance, and emotional instability; examination shows goiter, silky fine hair, warm moist skin, proptosis and wide-eyed stare, fine tremor, rapid or irregular pulse; in elderly patients, muscle weakness and heart failure may be most apparent

Systemic Illness

1. Decreased cardiac output from various causes, such as congestive heart failure, arrhythmia, pulmonary embolus, and myocardial infarction; acute myocardial infarction presents with confusion as the major symptom in 13% of elderly patients; aged patients do not complain of typical pain; often they complain of indigestion; vital signs may be abnormal, and patient may look ill (ashen coloring, weak, nauseated, sweaty) and be confused

2. Pneumonia: recent history of a cold, becoming bedridden and aspirating; fever may not be apparent, but tachycardia or hypotension are evident on vital signs

3. Urinary tract infection: especially in patients with indwelling urinary catheters, prostatic hypertrophy, diabetes, neurogenic bladder

4. Anemia: especially with acute blood loss (injury, intestinal bleeding), chronic illness, occult gastrointestinal malignancy

5. Acute surgical emergencies: infarction of the bowel, appendicitis,

and volvulus are common and often present only with confusion and no other complaints

6. Hypertension: sustained or rapid increase in blood pressure may cause encephalopathy; often has history of elevated blood pressure; may occur in patient on MAO inhibitor antidepressants who has eaten food containing tyramine

7. Vasculitides: e.g., systemic lupus erythematosus; confusion arises from cerebral involvement or treatment with steroids

8. Any febrile illness and infection can cause confusion in the aged

Central Nervous System Disorders

1. Subdural or epidural hematoma: may or may not have history of head trauma; fluctuating mental status often present; may have no focal neurologic signs

2. Seizure: unwitnessed seizure may be suggested if patient was found on floor with evidence of incontinence or vomiting; history of seizure disorder or alcoholism

3. Stroke: history of transient ischemic attacks or strokes; may have no signs except confusion

4. Infection: meningitis (bacterial, fungal, or tuberculous), viral encephalitis

5. Tumor, primary or metastatic: with a growing mass, raised intracranial pressure may cause local compression of vital structures or herniation of the brain; in the elderly, brain atrophy allows for greater space inside the skull so that symptoms may not appear until the mass is quite large

6. Normal pressure hydrocephalus: presents with triad of gait disturbance, incontinence, dementia; surgery may be curative

Drugs and Medication

1. Almost all drugs are capable of causing confusion in the elderly; the most commonly implicated drugs include those with strong

anticholinergic effects (antidepressants, antipsychotics, and antiparkinsonian drugs, and many over-the-counter preparations), sedative-hypnotics (barbiturates, benzodiazepines), cardiac medications (digoxin, propranolol, lidocaine, quinidine), antihypertensives, anticonvulsants, cimetidine, nonnarcotic and narcotic analgesics, and corticosteroids

2. Alcohol: intoxication and withdrawal syndromes occur as in young patients, but poor health in the elderly may put geriatric patients at greater risk

3. Drug abuse: far less common in elderly persons, but chronic intoxication with bromides, prescription tranquilizers occurs

From Minden SL. Elderly psychiatric emergency patients. In: Bassuk EL, Birk AW, eds. *Emergency Psychiatry*. New York: Plenum; 1984:360, with permission.

In this context, patients first and foremost fight the disease. Invariably, however, they also must come to terms with a level of dependence on others probably not experienced since childhood. Predictably, patients entering dialysis struggle for their independence; regress to childhood states; show denial by acting out against doctor's orders (by breaking their diet or by missing sessions); show anger directed against staff members; bargain and plead; or become infantilized and obsequious; however, most often they are accepting and courageous. The determinants of patients' responses to entering dialysis include personality styles and previous experiences with this or another chronic illness. Patients who have time to react and adapt to their disease are less challenged by the need to adapt to new circumstances. Those with recent renal failure and machine dependence may have more difficulty.

Although little has been written about social factors, the effects of culture in reaction to dialysis and the management of the dialysis unit are known to be necessary. Units are run with a firm hand, which is consistent in dealing with patients; clear contingencies are in place for behavioral failures; and adequate psychological support is available for staff members, which tend to produce the best results.

Complications of dialysis treatment can include psychiatric problems, such as depression, and suicide is not rare. Sexual problems can be neurogenic,

psychogenic, or related to gonadal dysfunction and testicular atrophy. Dialysis dementia is a rare condition that includes loss of memory, disorientation, dystonias, and seizures. The disorder occurs in patients who have been receiving dialysis treatment for many years. Although not entirely understood, the leading cause is probably aluminum toxicity, and reducing dialysate aluminum levels and minimizing aluminum intake decreases the incidence of the disease. Chelating agents, such as deferoxamine, may also help if given early. However, it should be used sparingly because of its serious adverse effects.

The psychological treatment of dialysis patients falls into two areas. First, careful preparation before dialysis, including the work of adaptation to chronic illness, is essential, especially in dealing with denial and unrealistic expectations. Before dialysis, all patients should have a psychosocial evaluation. Second, once in a dialysis program, patients need periodic specific inquiries about adaptation that do not encourage dependence or the sick role. Staff members should be sensitive to the likelihood of depression and sexual problems. Group sessions function well for support, and patient self-help groups restore a useful social network, self-esteem, and self-mastery. When needed, antidepressants can be used for dialysis patients. Psychiatric care is most effective when brief and problem-oriented.

The use of home dialysis units has improved attitudes toward treatment. Patients treated at home can integrate the treatment into their daily lives more efficiently, and they feel more autonomous and less dependent on others for their care than do those who are treated in the hospital.

Surgical Units. Some surgeons believe that patients who expect to die during surgery are more likely to die. This belief now seems less superstitious than it once did. Some patients who are scheduled for surgery and show evident depression or anxiety but deny it have a higher risk for morbidity and mortality than those who can express it. Even better results occur in those with a positive attitude toward impending surgery. The factors that contribute to an improved outcome for surgery are informed consent and education so that patients know what they can expect to feel, where they will be (e.g., it is useful to show patients the recovery room), what loss of function to expect, what tubes and gadgets will be in place, and how to cope with the anticipated pain. If patients will not be able to talk or see after surgery, it is helpful to

explain before surgery what they can do to compensate for these losses. If postoperative states such as confusion, delirium, and pain can be predicted, they should be discussed with patients in advance, so they do not experience them as unwarranted or as signs of danger. Constructive family support members can help both before and after surgery.

Transplantation Issues. Transplantation programs have expanded over the past decade, and C-L psychiatrists play an essential role in helping patients and families deal with the many psychosocial issues involved: (1) which and when patients on a waiting list will receive organs, (2) anxiety about the procedure, (3) fear of death, (4) organ rejection, and (5) adaptation to life after successful transplantation. After the transplant, patients require complicated aftercare, and achieving compliance with medication may be difficult without supportive psychotherapy. This challenge is particularly relevant to patients who have received liver transplants as a result of hepatitis C brought on by promiscuous sexual behavior and patients with a history of substance use disorder who used contaminated needles.

Group therapy with patients who have had similar transplantation procedures benefits members who can support one another and share information and feelings about particular stressors related to their disease. Groups may be conducted or supervised by the psychiatrist. Psychiatrists must be especially concerned about psychiatric complications. Within 1 year of transplant, almost 20 percent of patients experience major depression or an adjustment disorder with depressed mood. In such cases, evaluation for suicidal ideation and risk is essential. In addition to depression, another 10 percent of patients experience signs of posttraumatic stress disorder, with nightmares and anxiety attacks related to the procedure. Other issues concern whether or not the transplanted organ came from a cadaver or from a living donor who may or may not be related to the patient. Pretransplant consulting sessions with potential organ donors help them to deal with fears about surgery and concerns about who will receive their donated organ. Sometimes, both the recipient and donor may be counseled together, as with a family member donating a kidney. Peer support groups with both donors and recipients have also been used to facilitate coping with transplantation issues.

PSYCHO-ONCOLOGY

Psycho-oncology seeks to study both the impact of cancer on psychological functioning and the role that psychological and behavioral variables may play in cancer risk and survival. A hallmark of psycho-oncology research has been intervention studies that attempt to influence the course of illness in patients with cancer. A landmark study by David Spiegel found that women with metastatic breast cancer who received weekly group psychotherapy survived an average of 18 months longer than control patients randomly assigned to routine care. In another study, patients with malignant melanoma who received structured group intervention exhibited a statistically significant lower recurrence of cancer and a lower mortality rate than patients who did not receive such therapy. Patients with malignant melanoma who received the group intervention also exhibited significantly more large granular lymphocytes and natural killer (NK) cells as well as indications of increased NK cell activity, suggesting an increased immune response. Another study used a group behavioral intervention (relaxation, guided imagery, and biofeedback training) for patients with breast cancer, who demonstrated higher NK cell activity and lymphocyte mitogen responses than the controls.

Because new treatment protocols, in many cases, have transformed cancer from an incurable to frequently chronic and often curable disease, the psychiatric aspects of cancer—the reactions to both the diagnosis and the treatment—are increasingly important. At least half of the persons who contract cancer in the United States each year are alive 5 years later. Currently, an estimated 3 million cancer survivors have no evidence of the disease.

About half of all cancer patients have mental disorders. The largest groups are those with adjustment disorder (68 percent), and major depressive disorder (13 percent) and delirium (8 percent) are the next most common diagnoses. Most of these disorders are thought to be reactive to the knowledge of having cancer.

When persons learn that they have cancer, their psychological reactions include fear of death, disfigurement, and disability; fear of abandonment and loss of independence; fear of disruption in relationships, role functioning, and financial standings; and denial, anxiety, anger, and guilt. Although suicidal thoughts and wishes are frequent in persons with cancer, the actual incidence of suicide is only slightly higher than that in the general population.

Psychiatrists should make a careful assessment of psychiatric and medical

issues in every patient. Particular attention should be given to family factors, in particular, preexisting intrafamily conflicts, family abandonment, and family exhaustion.

25.2 Geriatric Psychiatry

PSYCHIATRIC PROBLEMS OF OLDER PERSONS

Despite the ubiquity of loss in old age, the prevalence of major depressive disorder and dysthymia is less than in younger age groups. Several explanations for this phenomenon have been proposed: rarity of late-onset depression, higher mortality among persons with depression, and a general decrease in disorders caused by emotional upheavals or substance abuse in older persons. Depression may, however, be underrecognized in the elderly as it sometimes presents differently than in younger persons. Depression in old persons is often accompanied by physical symptoms or cognitive changes that may mimic dementia.

The incidence of suicide among older persons is high (40 per 100,000 population) and is highest for older white men. The suicide of older persons is perceived differently by surviving friends and family members based on gender: men are thought to have been physically ill, and women are thought to have been mentally ill.

The relation between good mental and good physical health is apparent in older persons. Adverse effects on the course of chronic medical illness are correlated with emotional problems.

MENTAL DISORDERS OF OLD AGE

The National Institute of Mental Health's Epidemiologic Catchment Area (ECA) program found that the most common mental disorders of old age are depressive disorders, cognitive disorders, phobias, and alcohol use disorders. Older adults also have a high risk of suicide and drug-induced psychiatric symptoms. Many mental disorders of old age can be prevented, ameliorated, or even reversed. Of particular importance are the reversible causes of delirium and dementia; if not diagnosed accurately and treated in a timely

fashion, however, these conditions can progress to an irreversible state. Table 25-3 lists the general cognitive domains assessed in neuropsychological evaluation, with the tests used to measure that skill and a description of the specific behaviors measured by each test. The tests listed in the table constitute a comprehensive test battery generally appropriate for use with a geriatric population. The use of a comprehensive battery is preferable for confident determination of the presence and type of dementia or other cognitive disorder in elderly persons; in some circumstances, however, administering a several-hour battery is not possible.

Table 25-3
Cognitive Domains

Gross Cognitive Functioning
Mini-Mental State Examination: *orientation, repetition, following commands, naming, constructional skill, written expression, memory, mental flexibility, and calculations*
Intelligence
Wechsler Adult Intelligence Scale-Revised (WAIS-R) or Wechsler Intelligence Scale-III (WAIS-III): *verbal and nonverbal intelligence*
Basic Attention
WAIS-R or WAIS-III Digit Span: *repetition of digits forward and backward*
Information-Processing Speed
WAIS-R or WAIS-III Digit Symbol: *rapid graphomotor tracking*
Trailmaking Part A: *rapid graphomotor tracking*
Stroop A and B: *rapid word reading and color naming*
Motor Dexterity
Finger tapping: *right and left index finger dexterity*
Language
Boston Naming Test: *word retrieval*
WAIS-R or WAIS-III Vocabulary: *vocabulary range*
Visual Perceptual/Spatial

WAIS-R or WAIS-III Picture Completion: *visual perception*
WAIS-R or WAIS-III Block Design: *constructional ability*
Rey–Osterrieth Complex Figure Test: *paper-and-pencil copy of complex design*
Beery Developmental Test of Visual Motor Integration: *paper-and-pencil copy of simple-to-complex designs*

Learning and Memory

An 8- to 10-item word list learning task: *learning and recall of rote verbal information*
Wechsler Memory Scale-Revised (WMS-R) or Wechsler Memory Scale-III (WMS-III)
Logical Memory subtest: *immediate and delayed recall of paragraph information*
Visual Reproduction subtest: *immediate and delayed recall of visual designs*
Rey–Osterrieth Complex Figure Test and Recognition Trial: *3-minute immediate recall and 30-minute delayed recall of a complex design*

Executive Functions

Trailmaking Part B: *rapid alternation between tasks*
Stroop C: *inhibition of an overlearned response*
Wisconsin Card Sorting Test: *categorization and mental flexibility*
Verbal fluency (FAS and category): *rapid word generation*
Design fluency: *rapid generation of novel designs*

Courtesy of Kyle Brauer Boone, Ph.D.

Several psychosocial risk factors also predispose older persons to mental disorders. These risk factors include loss of social roles, loss of autonomy, the deaths of friends and relatives, declining health, increased isolation, financial constraints, and decreased cognitive functioning.

Many drugs can cause psychiatric symptoms in older adults. These symptoms can result from age-related alterations in drug absorption, a prescribed dosage that is too large, not following instructions and taking too large a dose, sensitivity to the medication, and conflicting regimens presented by several physicians. Drugs can cause almost the entire spectrum of mental

disorders.

Dementing Disorders

Only arthritis is a more common cause of disability among adults age 65 and older than dementia, a generally progressive and irreversible impairment of the intellect, the prevalence of which increases with age. About 5 percent of persons in the United States older than age 65 have severe dementia, and 15 percent have mild dementia. Of persons older than age 80, about 20 percent have severe dementia. Known risk factors for dementia are age, family history, and female sex.

In contrast to intellectual disability, the intellectual impairment of dementia develops over time—that is, previously achieved mental functions are lost gradually. The characteristic changes of dementia involve cognition, memory, language, and visuospatial functions, but behavioral disturbances are common as well and include agitation, restlessness, wandering, rage, violence, shouting, social and sexual disinhibition, impulsiveness, sleep disturbances, and delusions. Delusions and hallucinations occur during the dementias in nearly 75 percent of patients.

Cognition is impaired by many conditions, including brain injuries, cerebral tumors, acquired immune deficiency syndrome (AIDS), alcohol, medications, infections, chronic pulmonary diseases, and inflammatory diseases. Although dementias associated with advanced age typically are caused by primary degenerative central nervous system (CNS) disease and vascular disease, many factors contribute to cognitive impairment; in older persons, mixed causes of dementia are common.

About 10 to 15 percent of all patients who exhibit symptoms of dementia have potentially treatable conditions. The treatable conditions include systemic disorders, such as heart disease, renal disease, and congestive heart failure; endocrine disorders, such as hypothyroidism; vitamin deficiency; medication misuse; and primary mental disorders, most notably depressive disorders.

Depending on the site of the cerebral lesion, dementias are classified as cortical and subcortical. Subcortical dementia occurs in Huntington disease, Parkinson disease, normal pressure hydrocephalus, vascular dementia, and Wilson disease. The subcortical dementias are associated with movement

disorders, gait apraxia, psychomotor retardation, apathy, and akinetic mutism, which can be confused with catatonia. Table 25-4 lists some potentially reversible conditions that may resemble dementia. The cortical dementias occur in dementia of the Alzheimer type, Creutzfeldt–Jakob disease (CJD), and Pick disease, which frequently manifests aphasia, agnosia, and apraxia. In clinical practice, the two types of dementias overlap, and, in most cases, an accurate diagnosis can be made only by autopsy. Human prion diseases result from coding mutations in the prion protein gene (*PRNP*) and may be inherited, acquired, or sporadic. They include familial CJD, Gerstmann–Sträussler–Scheinker syndrome, and fatal familial insomnia. These are inherited as autosomal-dominant mutations. The acquired diseases include kuru and iatrogenic CJD. Kuru was an epidemic prion disease of the Fore people of Papua, New Guinea, caused by cannibalistic funeral rituals, which peaked in incidence in the 1950s. Iatrogenic disease is rare and is caused, for example, by the use of contaminated dura mater and corneal grafts and treatment with human cadaveric pituitary-derived growth hormone and gonadotropin. Sporadic CJD accounts for 85 percent of the human prion diseases and occurs worldwide, with a uniform distribution and an incidence of about 1 in 1 million per annum, with a mean age at onset of 65 years. It is exceedingly rare in individuals under 30 years of age.

Depressive Disorders

Depressive symptoms are present in about 15 percent of all older adult community residents and nursing home patients. Age itself is not a risk factor for the development of depression, but being widowed and having a chronic medical illness are associated with vulnerability to depressive disorders. High rates of recurrence characterize late-onset depression.

Table 25-4
Some Potentially Reversible Conditions that May Resemble Dementia

Substance
Anticholinergic agents
Antihypertensives

- Antipsychotics
- Corticosteroids
- Digitalis
- Narcotics
- Nonsteroidal anti-inflammatory agents
- Phenytoin
- Polypharmacotherapy
- Sedative hypnotics

Psychiatric Disorders

- Anxiety
- Depression
- Mania
- Delusional disorders

Metabolic and Endocrine Disorders

- Addison disease
- Cushing syndrome
- Hepatic failure
- Hypercarbia (chronic obstructive pulmonary disease)
- Hypernatremia
- Hyperparathyroidism
- Hyperthyroidism
- Hypoglycemia
- Hyponatremia
- Hypothyroidism
- Renal failure
- Volume depletion

Miscellaneous Conditions

- Fecal impaction
- Hospitalization
- Impaired hearing or vision

The common signs and symptoms of depressive disorders include reduced energy and concentration, sleep problems (especially early morning awakening and multiple awakenings), decreased appetite, weight loss, and

somatic complaints. The presenting symptoms may be different in older depressed patients from those seen in younger adults because of an increased emphasis on somatic complaints in older persons. Older persons are particularly vulnerable to major depressive episodes with melancholic features, characterized by depression, hypochondriasis, low self-esteem, feelings of worthlessness, and self-accusatory trends (especially about sex and sinfulness) with paranoid and suicidal ideation. A geriatric depression scale is given in Table 25-5.

Cognitive impairment in depressed geriatric patients is referred to as depression-related cognitive dysfunction (sometimes misleadingly called pseudodementia), which can be confused easily with nonreversible dementias. In common dementias such as that caused by Alzheimer disease, intellectual performance usually is global, and impairment is consistently poor; in depression-related cognitive dysfunction, deficits in attention and concentration are variable. Compared with patients who have neurodegenerative dementias, patients with depression-related cognitive dysfunction are less likely to have language impairment and to confabulate; when uncertain, they are more likely to say "I don't know"; and their memory difficulties are more limited to free recall than to recognition on cued recall tests. Depression-related cognitive dysfunction occurs in about 15 percent of depressed older patients, and 25 to 50 percent of patients with neurodegenerative dementias are depressed.

Table 25-5
Geriatric Depression Scale (Short Version)

Answers indicating depression are boldfaced. Each answer counts one point; scores greater than 5 indicate probable depression.

1. Are you basically satisfied with your life?	Yes/**No**
2. Have you dropped many of your activities and interests?	**Yes**/No
3. Do you feel that your life is empty?	**Yes**/No
4. Do you often get bored?	**Yes**/No
5. Are you in good spirits most of the time?	Yes/**No**

6. Are you afraid that something bad is going to happen to you?	**Yes**/No
7. Do you feel happy most of the time?	Yes/**No**
8. Do you often feel helpless?	**Yes**/No
9. Do you prefer to stay at home, rather than going out and doing new things?	**Yes**/No
10. Do you feel you have more problems with memory than most?	**Yes**/No
11. Do you think it is wonderful to be alive now?	Yes/**No**
12. Do you feel pretty worthless the way you are now?	**Yes**/No
13. Do you feel full of energy?	Yes/**No**
14. Do you feel that your situation is hopeless?	**Yes**/No
15. Do you think that most people are better off than you are?	**Yes**/No

Special Instructions. The scale can be used as a self-rating or observer-rated metric. It has also been used as an observer-rated scale in mildly demented subjects.

From Yesavage JA. Geriatric depression scale. *Psychopharmacol Bull*. 1988;24:709, with permission.

Schizophrenia

Schizophrenia usually begins in late adolescence or young adulthood and persists throughout life. Although the first episodes diagnosed after age 65 are rare, a late-onset type beginning after age 45 has been described. Women are more likely to have a late onset of schizophrenia than men. Another difference between early-onset and late-onset schizophrenia is the greater prevalence of paranoid schizophrenia in the late-onset type. About 20 percent of persons with schizophrenia show no active symptoms by age 65; 80

percent show varying degrees of impairment. Psychopathology becomes less marked as patient's age.

The residual type of schizophrenia occurs in about 30 percent of persons with schizophrenia. It primarily presents with negative symptoms, including emotional blunting, social withdrawal, eccentric behavior, and illogical thinking. Delusions and hallucinations are uncommon. Because most persons with residual schizophrenia cannot care for themselves, long-term hospitalization is required.

Older persons with schizophrenic symptoms respond reasonably well to antipsychotic drugs. Medication must be administered judiciously, and lower-than-usual dosages often are useful for older adults.

Delusional Disorder

The age of onset of delusional disorder usually is between ages 40 and 55, but it can occur at any time during the geriatric period. Delusions can take many forms; the most common are persecutory—patients believe that they are being spied on, followed, poisoned, or harassed in some way. Persons with delusional disorder may become violent toward their supposed persecutors. Some persons lock themselves in their rooms and live reclusive lives. Somatic delusions, in which persons believe they have a fatal illness, also can occur in older persons. In one study of persons older than 65 years of age, pervasive persecutory ideation was present in 4 percent of persons sampled.

Among those who are vulnerable, delusional disorder can occur under physical or psychological stress. The death of a spouse can precipitate it, loss of a job, retirement, social isolation, adverse financial circumstances, debilitating medical illness or surgery, visual impairment, and deafness. Delusions also can accompany other disorders—such as dementia of the Alzheimer type, alcohol use disorders, schizophrenia, depressive disorders, and bipolar I disorder—which need to be ruled out. Delusional syndromes also can result from prescribed medications or be early signs of a brain tumor. The prognosis is fair to good in most cases; the best results are achieved through a combination of psychotherapy and pharmacotherapy.

Persecutory delusions characterize a late-onset delusional disorder called *paraphrenia*. It develops over several years and is not associated with

dementia. Some workers believe that the disorder is a variant of schizophrenia that first becomes manifest after age 60. Patients with a family history of schizophrenia show an increased rate of paraphrenia.

Anxiety Disorders

Anxiety disorders usually begin in early or middle adulthood, but some appear for the first time after age 60. The initial onset of panic disorder in older persons is rare but can occur. The ECA study determined that the 1-month prevalence of anxiety disorders in persons age 65 and older is 5.5 percent. By far, the most common disorders are phobias (4 to 8 percent). The rate for panic disorder is 1 percent.

The signs and symptoms of phobia in older adults are less severe than those that occur in younger persons, but the effects are equally, if not more, debilitating for older patients. Existential theories help explain anxiety when no specifically identifiable stimulus exists for a chronically anxious feeling. Older persons must come to grips with death. The person may deal with the thought of death with a sense of despair and anxiety, rather than with equanimity and Erikson's "sense of integrity." The fragility of the autonomic nervous system in older persons may account for the development of anxiety after a significant stressor. Because of concurrent physical disability, older persons react more severely to PTSD than younger persons.

Obsessive-Compulsive Disorders

Obsessions and compulsions may appear for the first time in older adults, although older adults with obsessive-compulsive disorder (OCD) usually had demonstrated evidence of the disorder (e.g., being orderly, perfectionistic, punctual, parsimonious) when they were younger. When symptomatic, patients become excessive in their desire for orderliness, rituals, and sameness. They may become generally inflexible and rigid and have compulsions to check things again and again. OCD (in contrast to obsessive-compulsive personality disorder) is characterized by ego-dystonic rituals and obsessions and may begin late in life.

Somatic Symptom Disorders

Disorders characterized by physical symptoms resembling medical diseases

are relevant to geriatric psychiatry because somatic complaints are common among older adults. More than 80 percent of persons over 65 years of age have at least one chronic disease—usually arthritis or cardiovascular problems. After age 75, 20 percent have diabetes, and an average of four diagnosable chronic illnesses that require medical attention.

Hypochondriasis is common in persons over 60 years of age, although the peak incidence is in those 40 to 50 years of age. The disorder usually is chronic, and the prognosis guarded. Repeated physical examinations help reassure patients that they do not have a fatal illness, but invasive and high-risk diagnostic procedures should be avoided unless medically indicated.

Telling patients that their symptoms are imaginary is counterproductive and usually engenders resentment. Clinicians should acknowledge that the complaint and pain are real to the patient, and a psychological or psychopharmacological approach to the problem is indicated.

Alcohol and Other Substance Use Disorder

Older adults with alcohol dependence usually give a history of excessive drinking that began in young or middle adulthood. They usually are medically ill, primarily with liver disease, and are either divorced, widowed, or are men who never married. Many have arrest records and are numbered among homeless persons. A large number have a chronic dementing illness, such as Wernicke encephalopathy or Korsakoff syndrome. Of nursing home patients, 20 percent have alcohol dependence.

Overall, alcohol and other substance use disorders account for 10 percent of all emotional problems in older persons, and dependence on such substances as hypnotics, anxiolytics, and narcotics is more common in old age than is generally recognized. Substance-seeking behavior characterized by crime, manipulativeness, and antisocial behavior is rarer in older than in younger adults. Older patients may abuse anxiolytics to allay chronic anxiety or to try to help sleep. The maintenance of chronically ill cancer patients with narcotics prescribed by a physician produces dependence, but the need to provide pain relief takes precedence over the possibility of narcotic dependence and is justified.

The clinical presentation of older patients with alcohol and other substance use disorders varies and includes confusion, poor personal hygiene,

depression, malnutrition, and the effects of exposure and falls. The sudden onset of delirium in older persons hospitalized for medical illness is most often caused by alcohol withdrawal. Alcohol abuse also should be considered in older adults with chronic gastrointestinal (GI) problems.

Older persons may misuse over-the-counter substances, or nicotine and caffeine. Over-the-counter analgesics are used by 35 percent of older persons, and 30 percent use laxatives. Unexplained GI, psychological, and metabolic problems should alert clinicians to over-the-counter substance abuse.

Sleep Disorders

Advanced age is the single most important factor associated with the increased prevalence of sleep disorders. Sleep-related phenomena reported more frequently by older than by younger adults are sleeping problems, daytime sleepiness, daytime napping, and the use of hypnotic drugs. Clinically, older persons experience higher rates of breathing-related sleep disorder and medication-induced movement disorders than younger adults.

In addition to altered regulatory and physiologic systems, the causes of sleep disturbances in older persons include primary sleep disorders, other mental disorders, general medical disorders, and social and environmental factors. Among the primary sleep disorders, dyssomnias are the most frequent, mainly primary insomnia, nocturnal myoclonus, restless legs syndrome, and sleep apnea. Of the parasomnias, rapid eye movement (REM) sleep behavior disorder occurs almost exclusively among older men. The conditions that commonly interfere with sleep in older adults also include pain, nocturia, dyspnea, and heartburn. The lack of a daily structure and social or vocational responsibilities contributes to poor sleep.

As a result of the decreased length of their daily sleep–wake cycle, older persons without daily routines, especially patients in nursing homes, may experience an advanced sleep phase, in which they go to sleep early and awaken during the night.

Even modest amounts of alcohol can interfere with the quality of sleep and can cause sleep fragmentation and early morning awakening. Alcohol can also precipitate or aggravate obstructive sleep apnea. Many older persons use alcohol, hypnotics, and other CNS depressants to help them fall asleep, but data show that these persons experience more early morning awakening than

trouble falling asleep. When prescribing sedative-hypnotic drugs for older persons, clinicians must monitor the patients for unwanted cognitive, behavioral, and psychomotor effects, including memory impairment (anterograde amnesia), residual sedation, rebound insomnia, daytime withdrawal, and unsteady gait.

Changes in sleep structure among persons over 65 years of age involve both REM sleep and nonrapid eye movement (NREM) sleep. The REM changes include the redistribution of REM sleep throughout the night, more REM episodes, shorter REM episodes, and less total REM sleep. The NREM changes include the decreased amplitude of delta waves, a lower percentage of stages 3 and 4 sleep, and a higher percentage of stages 1 and 2 sleep. Also, older persons experience increased awakening after sleep onset.

Altered timing and consolidation of the sleep account for much of the deterioration in the quality of sleep. This is due, in part, to decreasing melatonin and alternated responses to the adenosine system with age. With advanced age, persons have a lower amplitude of circadian rhythms, a 12-hour sleep-propensity rhythm, and shorter circadian cycles.

SUICIDE RISK

Elderly persons have a higher risk of suicide than any other population. The suicide rate for white men over the age of 65 is five times higher than that of the general population. One-third of elderly persons report loneliness as the principal reason for considering suicide. Approximately 10 percent of elderly individuals with suicidal ideation report financial problems, poor medical health, or depression as reasons for suicidal thoughts. Suicide victims differ demographically from individuals who attempt suicide. About 60 percent of those who commit suicide are men; 75 percent of those who attempt suicide are women. Suicide victims, as a rule, use guns or hang themselves, whereas 70 percent of suicide attempters take a drug overdose, and 20 percent cut or slash themselves. Psychological autopsy studies suggest that most elderly persons who commit suicide have had a psychiatric disorder, most commonly depression. Psychiatric disorders of suicide victims, however, often do not receive medical or psychiatric attention. More elderly suicide victims are widowed, and fewer are single, separated, or divorced than is true of younger adults. Violent methods of suicide are more common in the elderly, and

alcohol use and psychiatric histories appear to be less frequent. The most common precipitants of suicide in older individuals are physical illness and loss, whereas problems with employment, finances, and family relationships are more frequent precipitants in younger adults. Many elderly persons who commit suicide communicate their suicidal thoughts to family or friends before the act of suicide.

Older patients with significant medical illnesses or a recent loss should be evaluated for depressive symptomatology and suicidal ideation or plans. Thoughts and fantasies about the meaning of suicide and life after death may reveal information that the patient cannot share directly. There should be no reluctance to question patients about suicide because no evidence indicates that such questions increase the likelihood of suicidal behavior.

OTHER CONDITIONS OF OLD AGE

Vertigo

Feelings of vertigo or dizziness, a common complaint of older adults, cause many older adults to become inactive because they fear falling. The causes of vertigo vary and include anemia, hypotension, cardiac arrhythmia, cerebrovascular disease, basilar artery insufficiency, middle ear disease, acoustic neuroma, benign postural vertigo, and Ménière disease. Most cases of vertigo have a vital psychological component, and clinicians should ascertain any secondary gain from the symptom. The overuse of anxiolytics can cause dizziness and daytime somnolence. Treatment with meclizine, 25 to 100 mg daily, has been successful in many patients with vertigo.

Syncope

The sudden loss of consciousness associated with syncope results from a reduction of cerebral blood flow and brain hypoxia. A thorough medical workup is required to rule out potential causes. Causes of syncope are listed in Table 25-6.

Hearing Loss

About 30 percent of persons over age 65 have significant hearing loss (presbycusis). After age 75, that figure rises to 50 percent. The causes vary.

Clinicians should be sensitive to hearing loss in patients who complain they can hear but cannot understand what is being said or who asks that questions be repeated. Most elderly persons with hearing loss can be treated with hearing aids.

Elder Abuse

An estimated 10 percent of persons above 65 years of age are abused. The American Medical Association defines elder abuse as "an act or omission which results in harm or threatened harm to the health or welfare of an elderly person." Mistreatment includes abuse and neglect—physically, psychologically, financially, and materially. Sexual abuse does occur. Acts of omission include withholding food, medicine, clothing, and other necessities.

Table 25-6
Causes of Syncope

Cardiac Disorders

  - Aortic stenosis
  - Mitral prolapse and regurgitation
  - Hypertrophic cardiomyopathy
  - Myxoma
- Electrical
  - Tachyarrhythmia
  - Bradyarrhythmia
  - Heart block
  - Sick sinus syndrome
- Functional
  - Ischemia and infarct

Situational Hypotension
- Dehydration (diarrhea, fasting)
- Orthostatic hypotension
- Postprandial hypotension
- Micturition, defecation, coughing, swallowing

Abnormal Cardiovascular Reflexes
- Carotid sinus syndrome
- Vasovagal syncope

Drugs
- Vasodilators
- Calcium channel blockers
- Diuretics
- β-Blockers

Central Nervous System Abnormalities
- Cerebrovascular insufficiency
- Seizures

Metabolic Abnormalities
- Hypoxemia
- Hypoglycemia or hyperglycemia
- Anemia

Pulmonary Disorders
- Chronic obstructive pulmonary disease
- Pneumonia
- Pulmonary embolus

Family conflicts and other problems often underlie elder abuse. The victims tend to be very old and frail. They often live with their assailants, who may be financially dependent on the victims. Both the victim and the perpetrator tend to deny or minimize the presence of abuse. Interventions include providing legal services, housing, and medical, psychiatric, and social services.

SPOUSAL BEREAVEMENT

Demographic data suggest that 51 percent of women and 14 percent of men over the age of 65 will be widowed at least once. Spousal loss is among the most stressful of all life experiences. As a group, older adults appear to have a more favorable outcome than expected following the death of a spouse. Depressive symptoms peak within the first few months after death but decline

significantly within a year. A relationship exists between spousal loss and subsequent mortality. Elderly survivors of spouses who committed suicide are especially vulnerable, as are those with psychiatric illness.

PSYCHOPHARMACOLOGICAL TREATMENT OF GERIATRIC DISORDERS

Specific guidelines should be followed regarding the use of all drugs in older adults. A pretreatment medical evaluation is essential, including an electrocardiogram (ECG). It is especially useful to have the patient or a family member bring in all currently used medications because multiple drug use could be contributing to the symptoms.

Most psychotropic drugs should be given in equally divided doses three or four times over 24 hours. Older patients may not be able to tolerate a sudden rise in drug blood levels resulting from one sizeable daily dose. Any changes in blood pressure and pulse rate and other side effects should be watched. For patients with insomnia, however, giving the significant portion of an antipsychotic or antidepressant at bedtime takes advantage of its sedating and soporific effects. Liquid preparations are useful for older patients who cannot or will not swallow tablets. Clinicians should frequently reassess all patients to determine the need for maintenance medication, changes in dosage, and development of adverse effects. If a patient is taking psychotropic drugs at the time of the evaluation, the clinician should discontinue these medications, if possible, and, after a washout period, reevaluate the patient during a drug-free baseline state.

Adults over 65 years of age use the most significant number of medications of any age group; 25 percent of all prescriptions are written for them. Adverse drug reactions caused by medications result in the hospitalization of nearly 250,000 persons in the United States each year. Psychiatric drugs are among the most commonly prescribed, along with cardiovascular and diuretic medications; 40 percent of all hypnotics dispensed in the United States each year are to those older than 75 years of age, and 70 percent of older persons use over-the-counter medications, compared with only 10 percent of young adults.

Principles

The primary goals of the pharmacologic treatment of older persons are to improve the quality of life, maintain persons in the community, and delay or avoid their placement in nursing homes. The individualization of dosage is the basic tenet of geriatric psychopharmacology.

Alterations in drug dosages are required because of the physiologic changes that occur as we age. Renal disease is associated with a decreased renal clearance of drugs; liver disease results in a decreased ability to metabolize drugs; cardiovascular disease and reduced cardiac output can affect both renal and hepatic drug clearance. GI disease and decreased gastric acid secretion also influence drug absorption. As a person ages, the ratio of lean to fat body mass also changes. With normal aging, lean body mass decreases, and body fat increases. Changes in the ratio of lean to fat body mass that accompany aging affect the distribution of drugs. Many lipid-soluble psychotropic drugs are distributed more widely in fat than in lean tissue, so a drug's action can be unexpectedly prolonged in older persons. Similarly, changes in end-organ or receptor-site sensitivity must be taken into account. In older persons, the increased risk of orthostatic hypotension from psychotropic drugs is related to reduced functioning of blood pressure–regulating mechanisms.

As a general rule, the lowest possible dose should be used to achieve the desired therapeutic response. Clinicians must know the pharmacodynamics, pharmacokinetics, and biotransformation of each drug prescribed and the effects of the interaction of the drug with other drugs that a patient is taking. An adage in geriatric medicine regarding the use of drugs is: Start low, go slow.

PSYCHOTHERAPY FOR GERIATRIC PATIENTS

The standard psychotherapeutic interventions—such as insight-oriented psychotherapy, supportive psychotherapy, cognitive therapy, group therapy, and family therapy—should be available to geriatric patients. According to Sigmund Freud, persons older than 50 years are not suited for psychoanalysis because their mental processes lack elasticity. In the view of many who followed Freud, however, psychoanalysis is possible after age 50. Advanced age certainly limits the plasticity of the personality, but as Otto Fenichel stated, "It does so in varying degrees and at very different ages so that no

general rule can be given." Insight-oriented psychotherapy may help remove a specific symptom, even in older persons. It is of most benefit when patients have possibilities for libidinal and narcissistic gratification, but it is contraindicated if it would bring only the insight that life has been a failure and that the patient has no opportunity to make up for it.

Common age-related issues in therapy involve the need to adapt to recurrent and diverse losses (e.g., the deaths of friends and loved ones), the need to assume new roles (e.g., the adjustment to retirement and the disengagement from previously defined roles), and the need to accept mortality. Psychotherapy helps older persons to deal with these issues and the emotional problems surrounding them and to understand their behavior and the effects of their behavior on others. In addition to improving interpersonal relationships, psychotherapy increases self-esteem and self-confidence, decreases feelings of helplessness and anger, and improves the quality of life.

Psychotherapy helps relieve tensions of biologic and cultural origins and helps older persons work and play within the limits of their functional status and as determined by their past training, activities, and self-concept in society. In patients with impaired cognition, psychotherapy can produce remarkable gains in both physical and mental symptoms. In one study conducted in a nursing home, 43 percent of the patients receiving psychotherapy showed less urinary incontinence, improved gait, greater mental alertness, improved memory, and better hearing than before psychotherapy.

Therapists must be more active, supportive, and flexible in conducting therapy with older than with younger adults, and they must be prepared to act decisively at the first sign of an incapacity that requires the active involvement of another physician, such as an internist or that requires consulting with, or enlisting the aid of, a family member.

Older persons usually seek therapy for a therapist's unqualified and unlimited support, reassurance, and approval. Patients often expect a therapist to be all-powerful, all-knowing, and able to effect a magical cure. Most patients eventually recognize that the therapist is human and that they are engaged in a collaborative effort. In some cases, however, the therapist may have to assume the idealized role, especially when the patient is unable or unwilling to test reality effectively. With the help of the therapist, the patient deals with problems that had been avoided previously. As the therapist offers

direct encouragement, reassurance, and advice, the patient's self-confidence increases as conflicts are resolved.

▲ 25.3 Psychiatric Emergencies

A psychiatric emergency is any disturbance in thoughts, feelings, or actions for which immediate therapeutic intervention is necessary. For a variety of reasons—such as the growing incidence of violence, the increased appreciation of the role of medical disease in altered mental status, and the epidemic of alcoholism and other substance use disorders—the number of emergency psychiatry patients is on the rise. The widening scope of emergency psychiatry goes beyond general psychiatric practice to include such specialized problems as the abuse of substances, children, and spouses; violence in the form of suicide, homicide, and rape; and such social issues as homelessness, aging, and competence. The emergency psychiatrist must be up to date on medicolegal issues and managed care. This section provides an overview of psychiatric emergencies in general and in adults in particular. Psychiatric emergencies in children is covered later in this chapter.

TREATMENT SETTINGS

Nonpsychiatrists do most emergency psychiatric evaluations in a general medical emergency room setting, but specialized psychiatric services are increasingly favored. Regardless of the type of setting, an atmosphere of safety and security must prevail. An adequate number of staff members—including psychiatrists, nurses, aides, and social workers—must be present at all times. Additional personnel to help out in times of overcrowding should be available. Specific responsibilities, such as the use of restraints, should be clearly defined and practiced by the entire emergency team. Clear communication and lines of authority are essential. The organization of the staff into multidisciplinary teams is desirable.

Children and young adolescents are best served in a pediatric setting. Unless there is a risk of behavioral problems or of their leaving the hospital against advice, they need not be sent to the adult psychiatric emergency service.

Immediate access to the medical emergency department and appropriate diagnostic services is necessary because one-third of medical conditions present with psychiatric manifestations. The full spectrum of psychopharmacological options should be available to the psychiatrist.

Violence in the emergency service cannot be condoned or tolerated. The code of conduct expected of staff members and patients must be posted and understood from the time of the patient's arrival in the emergency room. Security is best managed as a clinical issue by the clinical staff, not by law enforcement personnel. Whenever possible, agitated and threatening patients should be sequestered from the nonagitated. Seclusion and restraint rooms should be located close to the nursing station for close observation.

The entire staff must understand that patients in physical and emotional distress are fragile and that various expectations and fantasies, often unrealistic, influence their responses to treatment. For example, a man with impaired reality testing who is brought in by the police against his will may not understand that the clinician is interested in helping him. Other patients, influenced by previous unsatisfactory treatment experiences, may be hostile. Some patients believe that psychiatrists can read minds or are only interested in admitting patients to lock them away. Such people see little point in openly discussing their problems. Many people have an inaccurate understanding of their rights as patients. All clinical interventions must take those expectations and attitudes into account to minimize the possibility of misunderstanding and consequent problems.

EPIDEMIOLOGY

Psychiatric emergency rooms are used equally by men and women and more by single than by married persons. About 20 percent of these patients are suicidal, and about 10 percent are violent. The most common diagnoses are depressive disorders, manic episodes, schizophrenia, and alcohol dependence. About 40 percent of all patients seen in psychiatric emergency rooms require hospitalization. Most visits occur during the night hours, but usage difference is not based on the day of the week or the month of the year. Contrary to popular belief, studies have not found that the use of psychiatric emergency rooms increases during the full moon or the Christmas season.

EVALUATION

The primary goal of an emergency psychiatric evaluation is the timely assessment of the patient in crisis. To that end, the physician must make an initial diagnosis, identify the precipitating factors and immediate needs, and begin treatment or refer the patient to the most appropriate treatment setting. Given the unpredictable nature of emergency medicine work, with many patients presenting both physical and emotional complaints, and because of the limited space and the competition for ancillary services, a pragmatic approach to the patient is required. Sometimes, moving the patient out of the emergency department into the most appropriate diagnostic or treatment setting is best for the patient. Medical emergencies are generally better managed elsewhere in the system. Keeping the number of emergency patients in one place to a minimum reduces the chance of agitation and violence.

The standard psychiatric interview—consisting of a history, a mental status examination, and, when appropriate and depending on the rules of the emergency department, a full physical examination and ancillary tests—is the cornerstone of the emergency psychiatry evaluation. The emergency department psychiatrist, however, must be ready to introduce modifications as needed. For example, the emergency psychiatrist may have to structure the interview with a rambling manic patient, medicate or restrain an agitated patient, or forgo the usual rules of confidentiality to assess an adolescent's risk of suicide. In general, any strategy introduced in the emergency department to accomplish the goal of assessing the patient is considered consistent with good clinical practice as long as the rationale for the strategy is documented in the medical record.

What constitutes a psychiatric emergency is highly subjective. The emergency department has increasingly come to serve as an admitting area, a holding area, a detoxification center, and a private medical office. Such medical conditions as head traumas, acute intoxications, withdrawal states, and AIDS encephalopathies may present with acute psychiatric manifestations. The emergency psychiatrists must rapidly assess and distinguish the genuine emergency psychiatric patients from those who are less acutely ill and from nonpsychiatric emergencies. A triage system using psychiatrists, nurses, and psychiatric social workers is an efficient and effective way to identify emergency, urgent, and nonurgent patients, who can

then be prioritized for care (Fig. 25-1).

In one model, every patient who comes to the emergency department is assessed by a triage nurse on arrival to ascertain the patient's chief complaint, clinical condition, and vital signs. The psychiatrist then briefly meets with the patient and other significant people involved in the case—family members, emergency medical service technicians, and police—to assign the patient to one of the three categories—emergency, urgent, and nonurgent—or to refer the patient to an appropriate treatment setting, such as the medical emergency medicine service. Having a senior clinician perform that task ensures rapid identification of the most urgent and troublesome cases, an appropriate allocation of resources, and an answer to the most common question heard in the emergency department: "When am I going to see a doctor?"

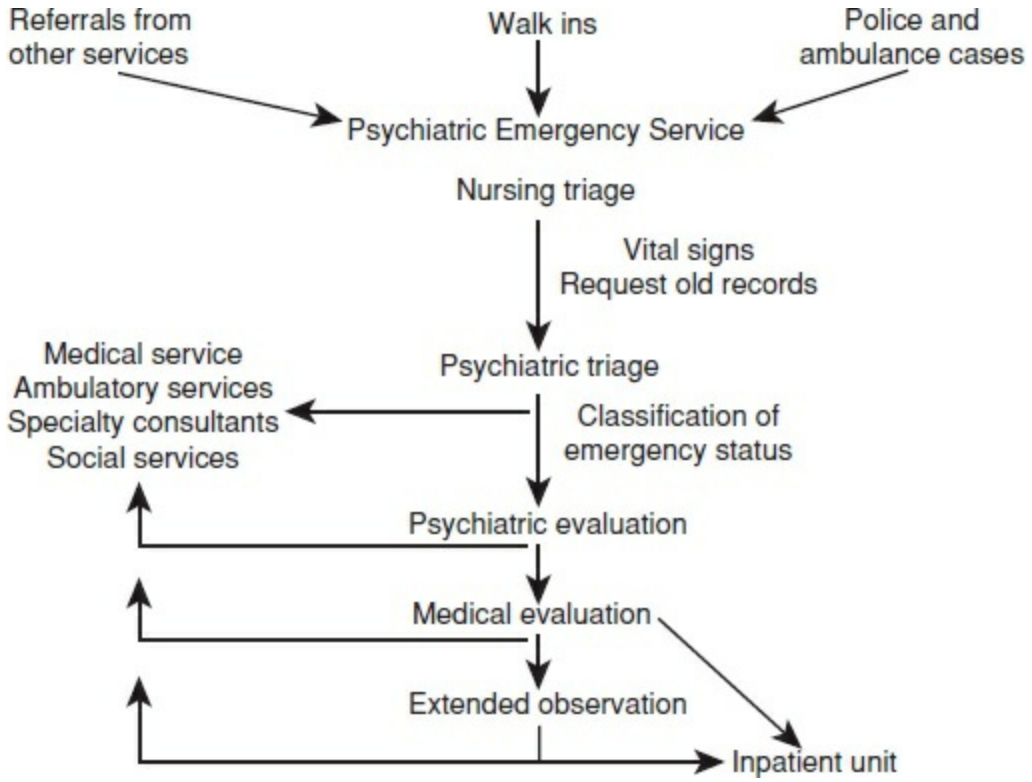

FIGURE 25-1
Evaluation and treatment of psychiatric emergencies.

The psychiatrist then assigns clinical responsibility for each patient to the appropriate personnel. As the evaluation often stretches over more than one shift, a careful procedure to transfer responsibility and to pass along information from shift to shift must be built into the system by using visual,

oral, and written communications. A request for old records should be made automatically for every patient who is evaluated in the emergency department. Each emergency should be judged on its own merits. However, information from previous records and workers in the field and family members can be of crucial importance in assessing patients, especially patients who are psychotic, frightened, or otherwise unable or unwilling to cooperate in giving a good history.

The psychiatrist should have access to multilingual staff and other translation services. The use of the patient's friends or family members as translators is not desirable because of the possibility of unconscious or deliberate denial or distortion of the clinical picture stemming from their involvement with the patient.

An initial assessment of the patient's total biopsychosocial needs is optimal, but the patient's emergency status, other patients, waiting to be seen, and the constraints of the emergency setting often make such a full assessment a moot point. At a minimum, the emergency evaluation should address the following five questions before any disposition is decided on: (1) Is it safe for the patient to be in the emergency department? (2) Is the problem physiologic, functional, or a combination? (3) Is the patient psychotic? (4) Is the patient suicidal or homicidal? (5) To what degree is the patient capable of self-care? Table 25-7 provides a general strategy for evaluating patients.

Patient Safety

Physicians should consider the question of the patient's safety before evaluating every patient. The answer must address the issues of the emergency department physical layout, staffing patterns and communication, and patient population. Psychiatrists must then take stock of themselves: Are they in the proper frame of mind to conduct an evaluation? Do any issues in the case spark countertransference reactions? The self-assessment should go on throughout the evaluation. The physical and emotional safety of the patient takes priority over all other considerations. If verbal interventions fail or are contraindicated, the use of medication or restraints must be considered and, if necessary, ordered. Careful attention to the possible outbreak of agitation or disruptive behavior beyond acceptable limits is often the best

insurance against untoward occurrences.

Table 25-7
General Strategy in Evaluating the Patient

I. Self-protection

A. Know as much as possible about the patients before meeting them.

B. Leave physical restraint procedures to those who are trained.

C. Be alert to risks of impending violence.

D. Attend to the safety of the physical surroundings (e.g., door access, room objects).

E. Have others present during the assessment if needed.

F. Have others in the vicinity.

G. Attend to developing an alliance with the patient (e.g., do not confront or threaten patients with persecutory psychoses).

II. Prevent harm

A. Prevent self-injury and suicide. Use whatever methods are necessary to prevent patients from hurting themselves during the evaluation.

B. Prevent violence toward others. During the evaluation, briefly assess the patient for the risk of violence. If the risk is deemed significant, consider the following options:

1. Inform the patient that violence is not acceptable.

2. Approach the patient in a nonthreatening manner.

3. Reassure, calm, or assist the patient’s reality testing.

4. Offer medication.

5. Inform the patient that restraint or seclusion will be used if necessary.

6. Have teams ready to restrain the patient.

7. When patients are restrained, always closely observe them, and frequently check their vital signs. Isolate restrained patients from surrounding agitating stimuli. Immediately plan a further approach—medication, reassurance, medical evaluation.

III. Rule out nonpsychiatric etiologies.

IV. Rule out impending psychosis.

Medical or Psychiatric?

The most important question for the emergency psychiatrist to address is whether the problem is medical, psychiatric, or both. Medical conditions—such as diabetes mellitus, thyroid disease, acute intoxications, withdrawal states, AIDS, and head traumas—can present with prominent mental status changes that mimic common psychiatric illnesses. Such conditions may be life-threatening if not treated promptly. Generally, the treatment of medical illness is more definitive, and the prognosis is better than for a functional psychiatric disorder. The psychiatrist must consider all casual possibilities.

Once patients are labeled psychiatric, their complaints may not be taken seriously by nonmental health professionals. However, such patients' conditions may deteriorate. Because of such factors as deinstitutionalization, homelessness, and chronic alcoholism, the mentally ill are at significant risk of tuberculosis, vitamin deficiencies, and other easily overlooked but easily treated conditions. Symptoms such as paranoia, internal preoccupation, and acute psychosis can make a routine medical diagnosis exceedingly tricky. Each patient must be assessed for the possibility that a nonpsychiatric medical illness is combined with an underlying psychiatric illness. A young man who comes to the emergency department intoxicated or in alcohol withdrawal two or three times a month may one day come with a subdural hematoma as a result of a fall. Table 25-8 lists feature that point to a medical cause of a mental disorder.

Table 25-8
Features that Point to a Medical Cause of a Mental

Disorder
Acute onset (within hours or minutes, with prevailing symptoms)
First episode
Older age
Current medical illness or injury
Significant substance abuse
Nonauditory disturbances of perception
Neurologic symptoms—loss of consciousness, seizures, head injury, change in headache pattern, change in vision
Classic mental status signs—diminished alertness, disorientation, memory impairment, impairment in concentration and attention, dyscalculia, concreteness
Other mental status signs—speech, movement, or gait disorders
Constructional apraxia—difficulties in drawing clock, cube, intersecting pentagons, Bender–Gestalt test

SPECIFIC INTERVIEW SITUATIONS

Psychosis

Whether the patient is psychotic refers less to diagnosis and more to the severity of symptoms and life disruption. The patient's degree of withdrawal from objective reality, level of affectivity, intellectual functioning, and degree of regression are other important parameters. Impairment in any of those areas may lead to difficulties in conducting an evaluation. Agitated, assaultive behavior or failure to comply with treatment recommendations may also result. A paranoid, hypervigilant patient may misperceive a staff member's offer of help as an attack and may lash out in self-defense. Command auditory hallucinations may cause a patient to deny symptoms and to throw prescriptions in the garbage immediately after leaving the emergency department. The psychiatrist should be alert to the complications that can arise with patients whose reality testing is impaired, and the psychiatrist should modify the approach accordingly.

All communication with patients must be straightforward. All clinical interventions should be briefly explained using language the patient can

understand. Psychiatrists should not assume that the patient trusts or believes them or even wants their help. Clinicians must be prepared to structure or to terminate an interview to limit the potential for agitation and regression.

Depression and Potentially Suicidal Patients

The clinician should always ask about suicidal ideas as part of every mental status examination, especially if the patient is depressed. The patient may not realize that such symptoms as waking during the night and increased somatic complaints are related to depressive disorders. The patient should be asked directly, "*Are you or have you ever been suicidal?*" "*Do you want to die?*" "*Do you feel so bad that you might hurt yourself?*" Eight of 10 persons who eventually kill themselves give warnings of their intent. If the patient admits to a plan of action, that is a particularly dangerous sign. If a patient who has been threatening suicide becomes quiet and less agitated than before, that may be an ominous sign. The clinician should be primarily concerned with the factors listed in Table 25-9.

Table 25-9
History, Signs, and Symptoms of Suicidal Risk

1. Previous attempt or fantasized suicide
2. Anxiety, depression, exhaustion
3. Availability of means of suicide
4. Concern for effect of suicide on family members
5. Verbalized suicidal ideation
6. Preparation of a will, resignation after agitated depression
7. Proximal life crisis, such as mourning or impending surgery
8. Family history of suicide
9. Pervasive pessimism or hopelessness

A suicide note, a family history of suicide, or previous suicidal behavior on the part of the patient increases the risk of suicide. Evidence of impulsivity or pervasive pessimism about the future also places the patient at risk. If the physician decides that the patient is in imminent risk for suicidal behavior, the patient must be hospitalized or otherwise protected. A difficult situation

arises when the risk does not seem to be immediate, but the potential for suicide is present as long as the patient remains depressed. If the psychiatrist decides not to hospitalize the patient immediately, the doctor should insist that the patient promise to call whenever the suicidal pressure mounts.

Violent Patients

Patients may be violent for many reasons, and the interview with a violent patient must attempt to ascertain the underlying cause of violent behavior because cause determines intervention. The differential diagnosis of violent behavior includes psychoactive substance-induced organic mental disorder, antisocial personality disorder, catatonia, medical infections, cerebral neoplasms, decompensating obsessive-compulsive personality disorder, dissociative disorders, impulse control disorders, sexual disorders, alcohol idiosyncratic intoxication, delusional disorder, paranoid personality disorder, schizophrenia, temporal lobe epilepsy, bipolar disorder, and uncontrollable violence secondary to interpersonal stress. The psychiatric interview must include questions that attempt to sort out the differential for violent behavior and questions directed toward the prediction of violence.

The best predictors of violent behavior are (1) excessive alcohol intake; (2) a history of violent acts, with arrests or criminal activity; and (3) a history of childhood abuse. Table 25-10 lists some of the most significant factors in assessing and predicting violence.

Rape and Sexual Abuse

Rape is the forceful coercion of an unwilling victim to engage in a sexual act, usually sexual intercourse, although anal intercourse and fellatio can also be acts of rape. As with other acts of violence, rape is a psychiatric emergency that requires immediate, appropriate intervention. Rape victims may suffer sequelae that persist for a lifetime. Rape is a life-threatening experience, and the victim has almost always been threatened with physical harm, often with a weapon. In addition to rape, other forms of sexual abuse include genital manipulation with foreign objects, infliction of pain, and forced sexual activity.

Most rapists are male, and most victims are female. Male rape does occur, however, often in institutions where men are detained (e.g., prisons). Women

between the ages of 16 and 24 years are in the highest risk category, but female victims as young as 15 months and as old as 82 years have been raped. More than a third of all rapes are committed by rapists known to the victim, 7 percent by close relatives. About one-quarter of rapes involve more than one rapist (gang rape).

Table 25-10
Assessing and Predicting Violent Behavior

1. Signs of impending violence
    a. Very recent acts of violence, including property violence
    b. Verbal or physical threats (menacing)
    c. Carrying weapons or other objects that may be used as weapons (e.g., forks, ashtrays)
    d. Progressive psychomotor agitation
    e. Alcohol or drug intoxication
    f. Persecutory ideation in a psychotic patient
    g. Command violent auditory hallucinations—some but not all patients are at high risk
    h. Mental disorders due to a medical condition, global or with frontal lobe findings; less commonly with temporal lobe findings (controversial)
    i. Patients with catatonic excitement
    j. Certain patients with mania
    k. Certain patients with agitated depression
    l. Personality disorder patients prone to rage, violence, or impulse dyscontrol
2. Assess the risk of violence
    a. Consider violent ideation, wish, intention, plan, availability of means, implementation of plan, wish for help.
    b. Consider demographics—sex (male), age (15–24), socioeconomic status (low), social supports (few).
    c. Consider past history: violence, nonviolent antisocial acts, impulse dyscontrol (e.g., gambling, substance abuse, suicide or self-injury, psychosis).
    d. Consider overt stressors (e.g., marital conflict, real or

symbolic loss).

Typical reactions in both rape and sexual abuse victims include shame, humiliation, anxiety, confusion, and outrage. Many victims wonder whether they are partly responsible and somehow invited the assault. Victim behavior is less critical in precipitating a rape than it is in precipitating a homicide or a robbery. Rape and sexual abuse victims are often confused after the assault. Clinicians should be reassuring, supportive, and nonjudgmental. Inform the patient about the availability of medical and legal services and about rape crisis centers that provide multidisciplinary services.

If possible, a female clinician should evaluate the patient because the victim may find it easier to talk with a woman than with a man. The evaluation should take place in private. When rape or sexual abuse has not been acknowledged openly, it is usually because many victims hesitate to discuss the assault and thus avoid the topic. If the patient appears to be anxious when questioned about sexual history and avoids the discussion, it is vital to validate the patient's avoidance. Recognize that the rape victim has undergone unanticipated, life-threatening stress. It is legally and therapeutically essential to take a detailed and complete history of the attack.

With the patient's written consent, collect evidence, such as semen and pubic hair, that may be used to identify the rapist. Take photographs of the evidence, if possible. The medical record may be used as evidence in criminal proceedings; therefore, meticulous objective documentation of all aspects of the evaluation is essential.

TREATMENT OF EMERGENCIES

Psychotherapy

In an emergency psychiatric intervention, all attempts are made to help patients' self-esteem. Empathy is critical to healing in a psychiatric emergency. The acquired knowledge of how biogenetic, situational, developmental, and existential forces converge at one point to create a psychiatric emergency is tantamount to the maturation of skill in emergency psychiatry. Adjustment disorder in all age groups may result in tantrum-like outbursts of rage. These outbursts are particularly common in marital

quarrels, and police are often summoned by neighbors distressed by the sounds of a violent altercation. Such family quarrels should be approached with caution because they may be complicated by alcohol use and the presence of dangerous weapons. The warring couple frequently turns their combined fury on an unwary outsider. Wounded self-esteem is a significant issue, and clinicians must avoid patronizing or contemptuous attitudes and try to communicate an attitude of respect and an authentic peacemaking concern.

In family violence, psychiatrists should note the unique vulnerability of selected close relatives. A wife or husband may have a curious masochistic attachment to the spouse and can provoke violence by taunting and otherwise undermining a partner's self-esteem. Such relationships often end in the murder of the provoking partner and sometimes in the suicide of the other partner—the dynamics behind most so-called suicide pacts. As with many suicidal patients, many violent patients require hospitalization and usually accept the offer of inpatient care with a sense of relief.

More than one psychotherapist or type of psychotherapy is frequently used in emergency therapy. For example, a 28-year-old man, depressed and suicidal after a colostomy for intractable colitis, whose wife was threatening to leave him because of his irritability and their constant altercations, may be referred to a psychiatrist for supportive psychotherapy and antidepressant medication, to a marital therapist with his wife to improve their marital functioning, and to a colostomy support group to learn ways of coping with a colostomy. Emergency psychiatric clinicians are pragmatic; they use every necessary mode of therapeutic intervention available to resolve the crisis and facilitate value exploration and growth, with less concern than usual about diluting a therapeutic relationship. Emergency therapy emphasizes how various psychiatric modalities act synergistically to enhance recovery.

No single approach is appropriate for all persons in similar situations. What should a doctor say to a patient and family experiencing an emergency, such as a suicide attempt or a schizophrenic break? For some, a genetic rationale helps; the information that an illness has a vital biologic component relieves some persons. For others, however, this approach underlines a lack of control and increases depression and anxiety. All feel helpless because neither the family nor the patient can alter the behavior to minimize the likelihood of recurrence. Some persons may benefit from an explanation of family or individual dynamics. Others only want someone to listen to them;

in time, they reach their understanding.

In an emergency, as in any other psychiatric situation, when a clinician does not know what to say, the best approach is to listen. Persons in crisis reveal how much they need support, denial, ventilation, and words to conceptualize the meaning of their crisis and to discover paths to resolution.

Pharmacotherapy

The primary indications for the use of psychotropic medication in an emergency room include violent or assaultive behavior, massive anxiety or panic, and extrapyramidal reactions, such as dystonia and akathisia as adverse effects of psychiatric drugs. Laryngospasm is a rare form of dystonia, and psychiatrists should be prepared to maintain an open airway with intubation if necessary.

Persons who are delusional or in a state of catatonic excitement require tranquilization. Episodic outbursts of violence may respond to antipsychotics (haloperidol, second-generation antipsychotics), benzodiazepines and antihistamines. If history suggests a seizure disorder, use clinical studies to confirm the diagnosis and evaluation to ascertain the cause. If the findings are positive, anticonvulsant therapy is initiated, or appropriate surgery is provided (e.g., in the case of a cerebral mass). Conservative measures may suffice for intoxication from drugs of abuse. Sometimes, drugs such as haloperidol (5 to 10 mg every half-hour to an hour) are needed until a patient is stabilized. Benzodiazepines may be used instead of, or in addition to, antipsychotics (to reduce the antipsychotic dosage). When a recreational drug has strong anticholinergic properties, benzodiazepines are more appropriate than antipsychotics.

Violent, struggling patients are subdued most effectively with an appropriate sedative or antipsychotic. Diazepam (5 to 10 mg) or lorazepam (2 to 4 mg) may be given slowly intravenously (IV) over 2 minutes. Clinicians must give IV medication with great care to avoid respiratory arrest. Patients who require IM medication can be sedated with haloperidol (5 to 10 mg IM). If the furor is caused by alcohol or is part of a postseizure psychomotor disturbance, the sleep produced by a relatively small amount of an IV medication may go on for hours. On awakening, patients are often entirely alert and rational and typically have complete amnesia about the violent

episode.

If the disturbance is part of an ongoing psychotic process and returns as soon as the IV medication wears off, continuous medication may be given. It is sometimes better to use small IM or oral doses at half-hour to 1-hour intervals (e.g., haloperidol, 2 to 5 mg, or diazepam, 20 mg) until the patient is controlled than to use large dosages initially, which can result in an overmedicated patient. As the disturbing behavior is brought under control, successively smaller and less frequent doses should be used. During the preliminary treatment, a patient's blood pressure and other vital signs should be monitored.

Restraints

Restraints are used when patients are so dangerous to themselves or others that they pose a severe threat that cannot be controlled in any other way. Patients may be restrained temporarily to receive medication or for long periods if we cannot use medications. Usually, patients in restraints quiet down after a time. On a psychodynamic level, such patients may even welcome the control of their impulses provided by restraints. Table 25-11 provides a summary of the use of restraints.

Disposition

In some cases, the usual option of admitting or discharging the patient is not considered optimal. Suspected toxic psychoses, brief decompensations in a patient with a personality disorder, and adjustment reactions to traumatic events, for example, may be best managed in an extended-observation setting. Allowing the patient more time in a secure environment can result in sufficient improvement or clarification of the issues to make traditional inpatient treatment unnecessary. It can also spare the patient the trauma and stigma of psychiatric admission and can free up bed space for needier patients. Crisis intervention for victims of rape and other traumas can also be done in an extended-observation setting.

When the decision is to admit the patient to the hospital, it is preferable to do so voluntarily. Allowing patients that option gives them a sense of control over their lives and of participation in the treatment decisions. Patients who meet involuntary admission criteria based on dangerousness to themselves or

others cannot leave the hospital without further review and can always be converted to involuntary status if warranted.

Table 25-11
Use of Restraints

Recommended principles for physical restraint use

- Use only after nonphysical approaches fail
- Maintain the privacy and dignity of the patient throughout the intervention
- The limitation on movement should be as nonrestrictive as safely possible
- Medical personnel should be properly trained for in how to use and monitor this intervention
- The ED should set appropriate and consistent guidelines for restraint, including
  - what treatments should be given
  - what monitoring is necessary
  - how the patient will be evaluated for ending the restraint
- The patient should be explicitly and continuously observed by the treatment team
- The use of physical restraint should be consistent with all standards and rules

Adapted from: American College of Emergency Physicians (ACEP). Use of patient restraints. Policy statement. *Ann Emerg Med*. 2014;64(5):574.

Because the initial evaluation is often inconclusive, definitive treatment is best deferred until the patient can be further assessed in the inpatient unit or the outpatient department. When the diagnosis is clear, however, and the patient's response to previous treatment is known, nothing is gained by delay. For example, a patient with chronic schizophrenia that has decompensated after discontinuing the usual regimen of antipsychotic medication is best served by a prompt resumption of treatment.

Even if patients feel comfortable coming to the emergency department in times of need, the emergency psychiatrist should always direct or redirect

them to the most appropriate treatment setting. Patients in the psychopharmacology clinic who have missed their regular appointments should be given only enough medication to sustain them until they can be seen in the clinic. Feedback to others treating them should be a matter of course.

The emergency department is often the gateway to the department of psychiatry or the general hospital. First impressions carry a great deal of weight. The kind of attention and concern showed to patients on arrival in the emergency room strongly affects how they will respond to staff members and treatment recommendations and even their treatment compliance long after they have left the emergency room.

Documentation

In the interests of good care, respect for patients' rights, cost control, and medicolegal concerns, documentation has become a central focus for the emergency physician. The medical record should convey a concise picture of the patient, highlighting all pertinent positive and negative findings. Gaps in information and their reason should be mentioned. The names and the telephone numbers of interested parties should be noted. A provisional diagnosis or differential diagnosis must be made. An initial treatment plan or recommendations should follow from the findings of the patient's history, mental status examination and other diagnostic tests, and the medical evaluation. The writing must be legible. The emergency physician has unusual latitude under the law to perform an adequate initial assessment; however, all interventions and decisions must be thought out, discussed, and documented in the patient's record.

Specific Psychiatric Emergencies

Table 25-12 outlines common psychiatric emergencies in alphabetical order. Readers are referred to the index and relevant chapters of this textbook for a thorough discussion of each disorder.

PSYCHIATRIC EMERGENCIES IN CHILDREN

Few children or adolescents seek psychiatric intervention on their own, even

during a crisis; thus, most of their emergency evaluations are initiated by parents, relatives, teachers, therapists, physicians, and child protective service workers. Some referrals are for the evaluation of life-threatening situations for the child or others, such as suicidal behavior, physical abuse, and violent or homicidal behavior. Other urgent but non–life-threatening referrals pertain to children and adolescents with exacerbations of clear-cut serious psychiatric disorders, such as mania, depression, florid psychosis, and school referral. Less diagnostically obvious situations occur when children and adolescents present with a history of a wide range of disruptive, aberrant behaviors and are accompanied by an overwhelmed, anxious, and distraught adult who perceives the child's actions as an emergency, despite the absence of life-threatening behavior of an evident psychiatric disorder. In those cases, the spectrum of contributing factors is not immediately apparent, and the emergency psychiatrist must assess the entire family or system involved with the child. Familial stressors and parental discord can contribute to the evolution of a crisis for a child. For example, immediate evaluations are sometimes legitimately indicated for a child caught in the crossfire of feuding parents or a seemingly irreconcilable conflict between a set of parents and a school, therapist, or protective service worker regarding the needs of the child (Table 25-13).

Table 25-12
Common Psychiatric Emergencies

Syndrome	Emergency Manifestations	Treatment Issues
Abuse of child or adult	Signs of physical trauma	Management of medica problems; psychiatric evaluation; report to authorities
Acquired immune deficiency syndrome (AIDS)	Changes in behavior secondary to medical causes; changes in	Management of neurologic illness; management of psychological concomitants;

	behavior secondary to fear and anxiety; suicidal behavior	reinforcement of social support
Adolescent crises	Suicidal attempts and ideation; substance abuse, truancy, trouble with law, pregnancy, running away; eating disorders; psychosis	Evaluation of suicidal potential, extent of substance abuse, family dynamics; crisis-oriented family and individual therapy; hospitalization if necessary; consultation with appropriate extrafamilial authorities
Agoraphobia	Panic; depression	Alprazolam, 0.25–2 mg antidepressant medication
Agranulocytosis (clozapine induced)	High fever, pharyngitis, oral and perianal ulcerations	Discontinue medication immediately; administer granulocyte colony-stimulating factor
Akathisia	Agitation, restlessness, muscle discomfort; dysphoria	Reduce antipsychotic dosage; propranolol (30–120 mg a day); benzodiazepines; diphenhydramine orally or IV; benztropine IM

Alcohol-Related Emergencies

Alcohol delirium	Confusion, disorientation, fluctuating consciousness and perception, autonomic hyperactivity; may be fatal	A benzodiazepine; haloperidol for psychotic symptoms may be added if necessary
Alcohol intoxication	Disinhibited behavior, sedation at high doses	With time and protectiv environment, symptoms abate
Alcohol-persisting amnestic disorder	Confusion, loss of memory even for all personal identification data	Hospitalization; hypnosis; rule out organic cause
Alcohol-persisting dementia	Confusion, agitation, impulsivity	Rule out other causes for dementia; no effective treatment; hospitalization if necessary
Alcohol psychotic disorder with hallucinations	Vivid auditory (at times visual) hallucinations with affect appropriate to content (often fearful); clear sensorium	Haloperidol for psychotic symptoms
Alcohol seizures	Grand mal seizures; rarely status epilepticus	Diazepam, phenytoin; prevent by using chlordiazepoxide during detoxification
Alcohol withdrawal	Irritability, nausea,	Fluid and electrolytes

	vomiting, insomnia, malaise, autonomic hyperactivity, shakiness	maintained; sedation with benzodiazepine restraints; monitoring of vital signs; 100 mg thiamine IM
Idiosyncratic alcohol intoxication	Marked aggressive or assaultive behavior	Generally no treatment required other than protective environment
Korsakoff syndrome	Alcohol stigmata, amnesia, confabulation	No effective treatment; institutionalization often needed
Wernicke encephalopathy	Oculomotor disturbances, cerebellar ataxia; mental confusion	Thiamine, 100 mg IV o IM, with $MgSO_4$ give before glucose loading
Amphetamine (or related substance) intoxication	Delusions, paranoia; violence; depression (from withdrawal); anxiety, delirium	Antipsychotics; restraints; hospitalization if necessary; no need for gradual withdrawal; antidepressants may be necessary
Anorexia nervosa	Loss of 25% of body weight of the norm for age and sex	Hospitalization; electrocardiogram (ECG), fluid and electrolytes; neuroendocrine evaluation
Anticholinergic	Psychotic	Discontinue drug, IV

intoxication	symptoms, dry skin and mouth, hyperpyrexia, mydriasis, tachycardia, restlessness, visual hallucinations	physostigmine, 0.5–2 mg, for severe agitation or fever, benzodiazepines; antipsychotics contraindicated
Anticonvulsant intoxication	Psychosis; delirium	Dosage of anticonvulsant is reduced
Benzodiazepine intoxication	Sedation, somnolence, and ataxia	Supportive measures; flumazenil, 7.5–45 m a day, titrated as needed, should be used only by skilled personnel with resuscitative equipment available
Bereavement	Guilt feelings, irritability; insomnia; somatic complaints	Must be differentiated from major depressiv disorder; antidepressants not indicated; benzodiazepines for sleep; encourageme of ventilation
Borderline personality disorder	Suicidal ideation and gestures; homicidal ideations and gestures; substance abuse; micropsychotic	Suicidal and homicidal evaluation (if great, hospitalization); sma dosages of antipsychotics; clear follow-up plan

	episodes; burns, cut marks on body	
Brief psychotic disorder	Emotional turmoil, extreme lability; acutely impaired reality testing after obvious psychosocial stress	Hospitalization often necessary; low dosage of antipsychotics may b necessary but often resolves spontaneously
Bromide intoxication	Delirium; mania; depression; psychosis	Serum levels obtained (>50 mg a day); bromide intake discontinued; large quantities of sodium chloride IV or orally; agitation, paraldehyd or antipsychotic is used
Caffeine intoxication	Severe anxiety, resembling panic disorder; mania; delirium; agitated depression; sleep disturbance	Cessation of caffeine-containing substances; benzodiazepines
Cannabis intoxication	Delusions; panic; dysphoria; cognitive impairment	Benzodiazepines and antipsychotics as needed; evaluation o suicidal or homicidal risk; symptoms usually abate with time and reassuranc
Catatonia	Marked	Rapid tranquilization

	psychomotor disturbance (either excitement or stupor); exhaustion; can be fatal	with benzodiazepine or antipsychotics; monitor vital signs
Cimetidine psychotic disorder	Delirium; delusions	Reduce dosage or discontinue drug
Clonidine withdrawal	Irritability; psychosis; violence; seizures	Symptoms abate with time, but antipsychotics may b necessary; gradual lowering of dosage
Cocaine intoxication and withdrawal	Paranoia and violence; severe anxiety; manic state; delirium: schizophreniform psychosis; tachycardia, hypertension, myocardial infarction, cerebrovascular disease; depression and suicidal ideation	Antipsychotics and benzodiazepines; antidepressants or electroconvulsive therapy (ECT) for withdrawal depressio if persistent; hospitalization
Delirium	Fluctuating sensorium; suicidal and homicidal risk; cognitive clouding; visual, tactile, and	Evaluate all potential contributing factors and treat each accordingly; reassurance, structure, clues to orientation;

	auditory hallucinations; paranoia	benzodiazepines and low-dosage, high-potency antipsychotics must be used with extreme care because of their potential to act paradoxically and increase agitation
Delusional disorder	Most often brought into emergency department involuntarily; threats directed toward others	Antipsychotics if patient will comply (IM if necessary); intensive family intervention; hospitalization if necessary
Dementia	Unable to care for self; violent outbursts; psychosis; depression and suicidal ideation; confusion	Small dosages of high-potency antipsychotics; clues to orientation; organic evaluation, including medication use; family intervention
Depressive disorders	Suicidal ideation and attempts; self-neglect; substance abuse	Assessment of danger to self; hospitalization if necessary, nonpsychiatric cause of depression must be evaluated
L-Dopa intoxication	Mania; depression; schizophreniform disorder, may induce rapid cycling in patients with bipolar I	Lower dosage or discontinue drug

	disorder	
Dystonia, acute	Intense involuntary spasm of muscles of neck, tongue, face, jaw, eyes, or trunk	Decrease dosage of antipsychotic; benztropine or diphenhydramine IM
Group hysteria	Groups of people exhibit extremes of grief or other disruptive behavior	Group is dispersed with help of other health care workers; ventilation, crisis-oriented therapy; if necessary, small dosages of benzodiazepines
Hallucinogen-induced psychotic disorder with hallucinations	Symptom picture is result of interaction of type of substance, dose taken, duration of action, user's premorbid personality, setting; panic; agitation; atropine psychosis	Serum and urine screens; rule out underlying medical o mental disorder; benzodiazepines (2–20 mg) orally; reassurance and orientation; rapid tranquilization; often responds spontaneously
Homicidal and assaultive behavior	Marked agitation with verbal threats	Seclusion, restraints, medication
Hypertensive crisis	Life-threatening hypertensive reaction secondary to ingestion of tyramine-	Antihypertensive medications as per emergency medicine team make sure symptoms are not secondary to

	containing foods in combination with monoamine oxidase inhibitors (MAOIs); headache, stiff neck, sweating, nausea, vomiting	hypotension (side effect of MAOIs alone)
Hyperthermia	Extreme excitement or catatonic stupor or both; extremely elevated temperature; violent hyperagitation	Hydrate and cool; may be drug reaction, so discontinue any drug rule out infection
Hyperventilation	Anxiety, terror, clouded consciousness; giddiness, faintness; blurring vision	Shift alkalosis by havin patient breathe into paper bag; patient education; antianxiet agents
Hypothermia	Confusion; lethargy; combativeness; low body temperature and shivering; paradoxical feeling of warmth	IV fluids and rewarming cardiac status must be carefully monitored; avoidanc of alcohol
Incest and sexual abuse of child	Suicidal behavior; adolescent crises; substance abuse	Corroboration of charg protection of victim; contact social services; medical an psychiatric evaluatio

		crisis intervention
Insomnia	Depression and irritability; early morning agitation; frightening dreams; fatigue	Hypnotics only in short term; treat any underlying mental disorder; rules of sleep hygiene
Intermittent explosive disorder	Brief outbursts of violence; periodic episodes of suicide attempts	Benzodiazepines or antipsychotics for short term; long-term evaluation with computed tomography (CT) scan, sleep-deprived electroencephalogra (EEG), glucose tolerance curve
Jaundice	Uncommon complication of low-potency phenothiazine use (e.g., chlorpromazine)	Change drug to low dosage of a low-potency agent in a different class
Leukopenia and agranulocytosis	Side effects within the first 2 mo of treatment with antipsychotics	Patient should call immediately for sore throat, fever, etc., an obtain immediate blood count; discontinue drug; hospitalize if necessary
Lithium toxicity	Vomiting; abdominal pain; profuse diarrhea; severe	Lavage with wide-bore tube; osmotic diuresis; medical

	tremor, ataxia; coma; seizures; confusion; dysarthria; focal neurologic signs	consultation; may require intensive car unit treatment
Major depressive episode with psychotic features	Major depressive episode symptoms with delusions; agitation, severe guilt; ideas of reference; suicide and homicide risk	Antipsychotics plus antidepressants; evaluation of suicide and homicide risk; hospitalization and ECT if necessary
Manic episode	Violent, impulsive behavior; indiscriminate sexual or spending behavior; psychosis; substance abuse	Hospitalization; restraints if necessary; rapid tranquilization with antipsychotics; restoration of lithium levels
Marital crises	Precipitant may be discovery of an extramarital affair, onset of serious illness, announcement of intent to divorce, or problems with children or work; one or both members of the couple may be in therapy or may be	Each should be questioned alone regarding extramarita affairs, consultations with lawyers regarding divorce, and willingness to work in crisis-oriente or long-term therapy to resolve the problem; sexual, financial, and psychiatric treatment

	psychiatrically ill; one spouse may be seeking hospitalization for the other	histories from both, psychiatric evaluatio at the time of presentation; may be precipitated by onset of untreated mood disorder or affective symptoms caused by medical illness or insidious-onset dementia; referral for management of the illness reduces immediate stress and enhances the healthier spouse's coping capacity; children may give insights available onl to someone intimatel involved in the social system
Migraine	Throbbing, unilateral headache	Sumatriptan 6 mg IM
Mitral valve prolapse	Associated with panic disorder; dyspnea and palpitations; fear and anxiety	Echocardiogram; alprazolam or propranolol
Neuroleptic malignant syndrome	Hyperthermia; muscle rigidity; autonomic instability; parkinsonian	Discontinue antipsychotic; IV dantrolene; bromocriptine orally; hydration and cooling

	symptoms; catatonic stupor; neurologic signs; 10% to 30% fatality; elevated creatine phosphokinase (CPK)	monitor CPK levels
Nitrous oxide toxicity	Euphoria and light-headedness	Symptoms abate without treatment within hours of use
Nutmeg intoxication	Agitation; hallucinations; severe headaches; numbness in extremities	Symptoms abate within hours of use without treatment
Opioid intoxication and withdrawal	Intoxication can lead to coma and death; withdrawal is not life-threatening	IV naloxone, narcotic antagonist; urine and serum screens; psychiatric and medical illnesses (e.g., AIDS) may complicate picture
Panic disorder	Panic, terror; acute onset	Must differentiate from other anxiety-producing disorders, both medical and psychiatric; ECG to rule out mitral valve prolapse; short-acting benzodiazepines for symptomatic management; long-

		term management may include an antidepressant
Parkinsonism	Stiffness, tremor, bradykinesia, flattened affect, shuffling gait, salivation, secondary to antipsychotic medication	Oral antiparkinsonian drug for 4 wk to 3 mo decrease dosage of the antipsychotic
Perioral (rabbit) tremor	Perioral tumor (rabbit-like facial grimacing) usually appearing after long-term therapy with antipsychotics	Decrease dosage or change to a medication in another class
Phencyclidine (or phencyclidine-like intoxication)	Psychosis; can lead to death; acute danger to self and others	Serum and urine assay benzodiazepines may interfere with excretion; antipsychotics may worsen symptoms because of anticholinergic side effects; medical monitoring and hospitalization for severe intoxication
Phenelzine-induced psychotic disorder	Psychosis and mania in predisposed people	Reduce dosage or discontinue drug

Phenylpropanolamine toxicity	Psychosis; paranoia; insomnia; restlessness; nervousness; headache	Symptoms abate with dosage reduction or discontinuation (foun in over-the-counter diet aids and oral an nasal decongestants
Phobias	Panic, anxiety; fear	Treatment same as for panic disorder
Photosensitivity	Easy sunburning secondary to use of antipsychotic medication	Patient should avoid strong sunlight and use high-level sunscreens
Pigmentary retinopathy	Reported with dosages of thioridazine of 800 mg a day or above	Remain below 800 mg day of thioridazine
Postpartum psychosis	Childbirth can precipitate schizophrenia, depression, reactive psychoses, mania, and depression; affective symptoms are most common; suicide risk is reduced during pregnancy but increased in the postpartum period	Danger to self and others (including infant) must be evaluated and prope precautions taken; medical illness presenting with behavioral aberration is included in the differential diagnosis and must be sought and treated; care must be paid to the effects on father, infant, grandparents, and other children

Posttraumatic stress disorder	Panic, terror; suicidal ideation; flashbacks	Reassurance; encouragement of return to responsibilities; avoi hospitalization if possible to prevent chronic invalidism; monitor suicidal ideation
Priapism (trazodone induced)	Persistent penile erection accompanied by severe pain	Intracorporeal epinephrine; mechanical or surgical drainage
Propranolol toxicity	Profound depression; confusional states	Reduce dosage or discontinue drug; monitor suicidality
Rape	Not all sexual violations are reported; silent rape reaction is characterized by loss of appetite, sleep disturbance, anxiety, and, sometimes, agoraphobia; long periods of silence, mounting anxiety, stuttering, blocking, and physical symptoms during the interview when the sexual	Rape is a major psychiatric emergency; victim may have enduring patterns of sexual dysfunction; crisis-oriented therapy, social support, ventilation, reinforcement of healthy traits, and encouragement to return to the previous level of functioning a rapidly as possible; legal counsel; thorough medical examination and test

		history is taken; fear of violence and death and of contracting a sexually transmitted disease or being pregnant	to identify the assailant (e.g., obtaining samples of pubic hairs with a pubic hair comb, vaginal smear to identify blood antigens in semen); i a woman, methoxyprogesteron or diethylstilbestrol orally for 5 days to prevent pregnancy; i menstruation does n commence within 1 wk of cessation of th estrogen, all alternatives to pregnancy, including abortion, should be offered; if the victim has contracted a venereal disease, appropriate antibiotics; witnesse written permission is required for the physician to examine photograph, collect specimens, and release information t the authorities; obtai consent, record the history in the patient' own words, obtain required tests, recor

		the results of the examination, save al clothing, defer diagnosis, and provide protection against disease, psychic trauma, and pregnancy; men's ar women's responses to rape affectively ar reported similarly, although men are more hesitant to talk about homosexual assault for fear they will be assumed to have consented
Reserpine intoxication	Major depressive episodes; suicidal ideation; nightmares	Evaluation of suicidal ideation; lower dosage or change drug; antidepressant of ECT may be indicated
Schizoaffective disorder	Severe depression; manic symptoms; paranoia	Evaluation of dangerousness to se or others; rapid tranquilization if necessary; treatmen of depression (antidepressants alone can enhance schizophrenic symptoms); use of antimanic agents

Schizophrenia	Extreme self-neglect; severe paranoia; suicidal ideation or assaultiveness; extreme psychotic symptoms	Evaluation of suicidal and homicidal potential; identificatio of any illness other than schizophrenia; rapid tranquilization
Schizophrenia in exacerbation	Withdrawn; agitation; suicidal and homicidal risk	Suicide and homicide evaluation; screen fo medical illness; restraints and rapid tranquilization if necessary; hospitalization if necessary; reevaluation of medication regimen
Sedative, hypnotic, or anxiolytic intoxication and withdrawal	Alterations in mood, behavior, thought —delirium; derealization and depersonalization; untreated, can be fatal; seizures	Naloxone to differentiat from opioid intoxication; slow withdrawal with benzodiazepine; hospitalization
Seizure disorder	Confusion; anxiety; derealization and depersonalization; feelings of impending doom; gustatory or olfactory hallucinations; fugue-like state	Immediate EEG; admission and sleep deprived and 24-hr EEG; rule out pseudoseizures; anticonvulsants
Substance withdrawal	Abdominal pain;	Symptoms of

	insomnia, drowsiness; delirium; seizures; symptoms of tardive dyskinesia may emerge; eruption of manic or schizophrenic symptoms	psychotropic drug withdrawal disappea with time or disappea with reinstitution of the substance; symptoms of antidepressant withdrawal can be successfully treated with anticholinergic agents, such as atropine; gradual withdrawal of psychotropic substances over 2–4 wk generally obviate development of symptoms
Sudden death associated with antipsychotic medication	Seizures; asphyxiation; cardiovascular causes; postural hypotension; laryngeal–pharyngeal dystonia; suppression of gag reflex	Specific medical treatments
Sudden death of psychogenic origin	Myocardial infarction after sudden psychic stress; voodoo and hexes; hopelessness, especially	Specific medical treatments; folk healers

	associated with serious physical illness	
Suicide	Suicidal ideation; hopelessness	Hospitalization, antidepressants
Sympathomimetic withdrawal	Paranoia; confusional states; depression	Most symptoms abate without treatment; antipsychotics; antidepressants if necessary
Tardive dyskinesia	Dyskinesia of mouth, tongue, face, neck, and trunk; choreoathetoid movements of extremities; usually but not always appearing after long-term treatment with antipsychotics, especially after a reduction in dosage; incidence highest in the elderly and brain damaged; symptoms are intensified by antiparkinsonian drugs and masked but not cured by	No effective treatment reported; may be prevented by prescribing the least amount of drug possible for as little time as is clinically feasible and using drug-free holidays fo patients who need to continue taking the drug; decrease or discontinue drug at first sign of dyskineti movements

	increased dosages of antipsychotic	
Thyrotoxicosis	Tachycardia; gastrointestinal dysfunction; hyperthermia; panic, anxiety, agitation; mania; dementia; psychosis	Thyroid function test (T_3, T_4, thyroid-stimulating hormone [TSH]); medical consultation
Toluene abuse	Anxiety; confusion; cognitive impairment	Neurologic damage is nonprogressive and reversible if toluene use in discontinued early
Vitamin B_{12} deficiency	Confusion; mood and behavior changes; ataxia	Treatment with vitamin B_{12}
Volatile nitrates	Alternations of mood and behavior; light-headedness; pulsating headache	Symptoms abate with cessation of use

An emergency setting is often the site of an initial evaluation of chronic problem behavior. For example, an identified problem—such as severe tantrums, violence, and destructive behavior in a child—may have been present for months or even years. Nevertheless, the initial contact with the mental health system in the emergency room or private office may be the first opportunity for the child or adolescent to disclose underlying stressors, such as physical or sexual abuse.

Given the integral relation of severe family dysfunction to childhood behavioral disturbance, the emergency psychiatrist must assess familial discord and psychiatric disorder in family members during an urgent evaluation. One way to make the assessment is to interview the child and the individual family members, both alone and together, and to obtain a history from informants outside the family whenever possible. Noncustodial parents, therapists, and teachers may add valuable information regarding the child's daily functioning. Many families, especially those with mental illness and severe dysfunction, may have little or no inclination to seek psychiatric help on a nonurgent basis; therefore, the emergency evaluation becomes the only way to engage them in an extensive psychiatric treatment program.

Table 25-13
Familial Risk Factors

Physical and sexual abuse
Recent family crisis: loss of a parent, divorce, loss of job, family move
Severe family dysfunction, including parental mental illness

Life-Threatening Emergencies

Suicidal Behavior

ASSESSMENT. Suicidal behavior is the most common reason for an emergency evaluation in adolescents. Despite the minimal risk for a complete suicide in a child less than 12 years of age, suicidal ideation or behavior in a child of any age must be carefully evaluated, with particular attention to the psychiatric status of the child and the ability of the family or the guardians to provide the appropriate supervision. The assessment must determine the circumstances of the suicidal ideation or behavior, its lethality, and the persistence of the suicidal intention. An evaluation of the family's sensitivity, supportiveness, and competence must be done to assess their ability to monitor the child's suicidal potential. Ultimately, during an emergency evaluation, the psychiatrist must decide whether the child may return home to

a safe environment and receive outpatient follow-up care or whether hospitalization is necessary. A psychiatric history, a mental status examination, and an assessment of family functioning help establish the general level of risk.

MANAGEMENT. When self-injurious behavior has occurred, the adolescent likely requires hospitalization in a pediatric unit for treatment of the injury or the observation of medical sequelae after toxic ingestion. If the adolescent is medically clear, the psychiatrist must decide whether the adolescent needs psychiatric admission. If the patient persists in suicidal ideation and shows signs of psychosis, severe depression (including hopelessness), or marked ambivalence about suicide, psychiatric admission is indicated. An adolescent who is taking drugs or alcohol should not be released until an assessment can be done when the patient is not intoxicated. Patients with high-risk profiles—such as late-adolescent males, especially those with substance abuse and aggressive behavior disorders, and those who have severe depression or who have made prior suicide attempts, particularly with lethal weapons—warrant hospitalization. Young children who made suicide attempts, even when the attempt had a low lethality, need psychiatric admission if the family is so chaotic, dysfunctional, and incompetent that follow-up treatment is unlikely.

Violent Behavior and Tantrums

ASSESSMENT. The first task in an emergency evaluation of a violent child or adolescent is to make sure that both the child and the staff members are physically protected so that nobody gets hurt. If the child appears to be calming down in the emergency area, the clinician may indicate to the child that it would be helpful if the child recounted what happened and may ask whether the child feels in sufficient control to do so. If the child agrees and the clinician judges the child to be in reasonable control, the clinician may approach the child with the appropriate backup close at hand. If not, the clinician may either give the child several minutes to calm down before reassessing the situation or, with an adolescent, suggest that medication may help the adolescent relax.

If the adolescent is combative, physical restraint may be necessary before anything else is attempted. Some rageful children and adolescents brought to

an emergency setting by overwhelmed families can regain control of themselves without the use of physical or pharmacologic restraint. Children and adolescents are most likely to calm down if approached calmly in a nonthreatening manner and given a chance to tell their side of the story to a nonjudgmental adult. At this time, the psychiatrist should look for any underlying psychiatric disorder that may be mediating the aggression. The psychiatrist should speak to family members and others who have been witnessing the episode to understand the context in which it occurred and the extent to which the child has been out of control.

MANAGEMENT. Prepubertal children, in the absence of major psychiatric illness, rarely require medication to keep them safe, because they are generally small enough to be physically restrained if they begin to hurt themselves or others. It is not immediately necessary to administer medication to a child or an adolescent who was in a rage but is in a calm state when examined. Adolescents and older children who are assaultive, extremely agitated, or overtly self-injurious and who may be difficult to subdue physically may require medication before a dialogue can take place.

Children who have a history of repeated, self-limited, severe tantrums may not require admission to a hospital if they can calm down during the evaluation. However, the pattern, no doubt, will reoccur unless ongoing outpatient treatment for the child and the family is arranged. For adolescents who continue to pose a danger to themselves or others during the evaluation period, admission to a hospital is necessary.

Fire Setting

ASSESSMENT. A sense of emergency and panic often surrounds the parents of a child who has set a fire. Parents or teachers often request an emergency evaluation, even for a very young child who has accidentally lit a fire. Many children, during normal development, become interested in fire, but in most cases, a school-aged child who has set a fire has done so accidentally while playing with matches and seeks help to put it out. When a child has a strong interest in playing with matches, the level of supervision by family members must be clarified so that no further accidental fires occur. The clinician must distinguish between a child who accidentally or even impulsively sets a

single fire and a child who engages in repeated fire setting with premeditation and subsequently leaves the fire without making any attempt to extinguish it. In repeated fire setting, the risk is more significant than in a single occurrence, and the psychiatrist must determine whether underlying psychopathology exists in the child or the family members. The psychiatrist should also evaluate family interactions because any factors that interfere with adequate supervision and communication—such as high levels of marital discord and harsh, punitive parenting styles—can impede appropriate intervention.

Fire setting is one of a triad of symptoms—enuresis, cruelty to animals, and fire setting—that were believed, some years ago, to be typical of children with conduct disorders; however, no evidence indicates that the three symptoms are genuinely linked, although conduct disorder is the most frequent psychiatric disorder that occurs with pathologic fire setting.

MANAGEMENT. The critical component of management and treatment for firesetters is to prevent further incidents while treating any underlying psychopathology. In general, fire setting alone is not an indication for hospitalization, unless a continued direct threat exists that the patient will set another fire. The parents of children with a pattern of fire setting must be emphatically counseled that the child must not be left alone at home and should never be left to take care of younger siblings without direct adult supervision. Children who exhibit a pattern of concurrent aggressive behaviors and other forms of destructive behavior are likely to have a poor outcome. Outpatient treatment should be arranged for children who repeatedly set fires. Behavioral techniques that involve both the child and the family help decrease the risk for further fire setting, as is positive reinforcement for alternate behaviors.

Child Abuse: Physical and Sexual

Assessment. Physical and sexual abuse occurs in girls and boys of all ages, in all ethnic groups, and at all socioeconomic levels. The abuses vary widely for severity and duration, but any form of continued abuse constitutes an emergency for a child. No single psychiatric syndrome is a sine qua non of physical or sexual abuse, but fear, guilt, anxiety, depression, and ambivalence

regarding disclosure commonly surround the child who has been abused.

Young children who are being sexually abused may exhibit precocious sexual behavior with peers and present detailed sexual knowledge that reflects exposure beyond their developmental level. Often, children who endure sexual or physical abuse display sadistic and aggressive behaviors themselves. Abused children are likely to be threatened with severe and frightening consequences by the perpetrator if they reveal the situation to anyone. Frequently, an abused child who is victimized by a family member is placed in the irreconcilable position of having to choose between enduring the abuse or risk destroying the family, not being believed or being abandoned.

In cases of suspected abuse, the child and other family members must be interviewed individually to give each member a chance to speak privately. If possible, the clinician should observe the child with each parent individually to get a sense of the spontaneity, warmth, fear, anxiety, or other prominent features of the relationships. One observation is generally not sufficient to make a final judgment about the family relationship. However, abused children almost always have mixed emotions toward abusive parents.

Physical indicators of sexual abuse in children include sexually transmitted diseases (e.g., gonorrhea); pain, irritation, and itching of the genitalia and the urinary tract; and discomfort while sitting and walking. In many instances of suspected sexual abuse, however, physical evidence is not present. Thus, a careful history is essential. The physician should speak directly about the issues without leading the child in any direction, because already frightened children may be easily influenced to endorse what they think the examiner wants to hear. Furthermore, children who have been abused often retract all or part of what has been disclosed during an interview.

The use of anatomically correct dolls in the assessment of sexual abuse can help the child identify body parts and show what has happened, but no conclusive evidence supports sexual play with dolls as a means of validating abuse.

Neglect: Failure to Thrive

Assessment. In child neglect, a child’s physical, mental, or emotional condition has been impaired because of the inability of a parent or caretaker

to provide adequate food, shelter, education, or supervision. Similar to abuse, any form of continued neglect is an emergency for the child. Parents who neglect their children range widely and may include parents who are very young and ignorant about the emotional and concrete needs of a child, parents with depression and significant passivity, substance-abusing parents, and parents with a variety of incapacitating mental illnesses.

In its extreme form, neglect can contribute to failure to thrive—that is, an infant, usually under 1 year of age, becomes malnourished in the absence of an organic cause. Failure to thrive typically occurs under circumstances in which adequate nourishment is available, but a disturbance within the relationship between the caretaker and the child results in a child who does not eat sufficiently to grow and develop. A negative pattern may exist between the mother and the child in which the child refuses feedings, and the mother feels rejected and eventually withdraws. She may then avoid offering food as frequently as the infant needs it. Observation of the mother and the child together may reveal a nonspontaneous, tense interaction, with withdrawal on both sides, resulting in a seeming apathy in the mother. Both the mother and the child may seem depressed.

A rare form of failure to thrive in children who are at least several years old and are not necessarily malnourished is the syndrome of psychosocial dwarfism. In that syndrome, marked growth retardation and delayed epiphyseal malnutrition accompany a disturbed relationship between the parent and the child, along with bizarre social and eating behaviors in the child. Those behaviors sometimes include eating from garbage cans, drinking toilet water, binging and vomiting, and diminished outward response to pain. Half of the children with the syndrome have decreased growth hormone. Once the children are removed from the troubled environment and placed in another setting, such as a psychiatric hospital with appropriate supervision and guidance regarding meals, the endocrine abnormalities normalize, and the children begin to grow at a more rapid rate.

Management. In cases of child neglect, as with physical and sexual abuse, the most crucial decision to be made during the initial evaluation is whether the child is safe in the home environment. Whenever neglect is suspected, it must be reported to the local child protective service agency. In mild cases, the decision to refer the family for outpatient services, as opposed to

hospitalizing the child, depends on the clinician's conviction that the family is cooperative and willing to be educated and to enter into treatment and that the child is not in danger. Before a neglected child is released from an emergency setting, a follow-up appointment must be made.

Education for the family must begin during the evaluation; the family must be told, in a nonthreatening manner, that failure to thrive can become life-threatening, that the entire family needs to monitor the child's progress, and that they will receive some help in overcoming the many possible obstacles interfering with the child's emotional and physical well-being.

Anorexia Nervosa

Anorexia nervosa occurs in females about 10 times as often as in males. It is characterized by the refusal to maintain body weight, leading to weight at least 15 percent below the expected weight, by a distorted body image, by a persistent fear of becoming fat, and by the absence of at least three menstrual cycles. The disorder usually begins after puberty, but it has occurred in children of 9 to 10 years of age, in whom expected weight gain does not occur, rather than a loss of 15 percent of body weight. The disorder reaches medical emergency proportions when the weight loss approaches 30 percent of body weight or when metabolic disturbances become severe. Hospitalization then becomes necessary to control the ongoing process of starvation, potential dehydration, and the medical complications of starvation, including electrolyte imbalances, cardiac arrhythmias, and hormonal changes.

Acquired Immune Deficiency Syndrome

Assessment. AIDS, which is caused by the human immunodeficiency virus (HIV), occurs in neonate through perinatal transmission from an infected mother, in children and adolescents secondary to sexual abuse by an infected person, and adolescents through intravenous drug abuse with an infected person or intravenous drug abuse with infected needles and sexual activities with infected partners. Child and adolescent hemophiliac patients may contract AIDS through tainted blood transfusions.

Children and adolescents may present for emergency evaluations at the urging of a family member of a peer; in some cases, they take the initiative

themselves when they are faced with anxiety or panic about high-risk behavior. Early screening of high-risk persons may lead to the treatment of asymptomatic infected patients with such drugs as azidothymidine (AZT) and possibly other new medications that may slow the course of the disease. During the assessment of the risks for HIV infection, the doctor can start to educate the patient and family so that an adolescent who is not infected but exhibits high-risk behavior can be counseled about that behavior and safe-sex practices.

In children, the brain is often a primary site for HIV infection; encephalitis, decreased brain development, and such neuropsychiatric symptoms as impairment in memory, concentration, and attention span may be present before the diagnosis is made. The virus can be present in the cerebrospinal fluid before it shows up in the bloodstream. Changes in cognitive function, frontal lobe disinhibition, social withdrawal, slowed information processing, and apathy constitute some common symptoms of the AIDS dementia complex. Mood disorders, personality changes, and frank psychosis can also occur in patients infected with HIV.

Munchausen Syndrome by Proxy

Assessment. Munchausen syndrome by proxy, essentially, is a form of child abuse in which a parent, usually the mother, or a caretaker repeatedly fabricates or inflicts injury or illness in a child for whom the medical intervention is then sought, often in an emergency setting. Although it is a rare scenario, mothers who inflict injury often have some prior knowledge of medicine, leading to sophisticated symptoms; the mothers sometimes engage in inappropriate camaraderie with the medical staff regarding the treatment of the child. Careful observation may reveal that the mothers often do not exhibit appropriate signs of distress on hearing the details of the child's medical symptoms. Prototypically, such mothers tend to present themselves as highly accomplished professionals in ways that seem inflated or blatantly untrue.

The illnesses appearing in the child can involve any organ system, but specific symptoms are commonly presented: bleeding from one or many sites, including the GI tract, the genitourinary system, and the respiratory system; seizures; and CNS depression. At times, the illness is simulated,

rather than inflicted.

Urgent Non–Life-Threatening Situations

School Refusal

ASSESSMENT. Refusal to go to school may occur in a young child who is first entering school or in an older child or adolescent who is making a transition into a new grade or school, or it may emerge in a vulnerable child without an apparent external stressor. In any case, school refusal requires immediate intervention, because the longer the dysfunctional pattern continues, the more difficult it is to interrupt.

School refusal is generally associated with separation anxiety, in which the child's distress is related to the consequences of being separated from the parent, so the child resists going to school. School refusal can also occur in children with school phobia, in which the school is the target of fear and distress. In either case, a severe disruption of the child's life occurs. Although mild separation anxiety is universal, particularly among very young children who are first facing the school, treatment is required when a child actually cannot attend school. Severe psychopathology, including anxiety and depressive disorders, is often present when school refusal occurs for the first time in an adolescent. Children with separation anxiety disorder typically present extreme worries that catastrophic events will befall their mothers, attachment, or themselves as a result of the separation. Children with separation anxiety disorder may also exhibit many other fears and symptoms of depression, including such somatic complaints such as headaches, stomachaches, and nausea. Severe tantrums and desperate pleas may ensue when preoccupation that a parent will be harmed during the separation is frequently verbalized; in adolescents, the stated reasons for refusing to go to school are often physical complaints.

As part of an urgent assessment, the psychiatrist must ascertain the duration of the patient's absence from school and must assess the parents' ability to participate in a treatment plan that will undoubtedly involve firm parental guidelines to ensure the child's return to school. The parents of a child with separation anxiety disorder often exhibit excessive separation anxiety or other anxiety disorders themselves, thereby compounding the

child's problem. When the parents are unable to participate in a treatment program from home, hospitalization should be considered.

MANAGEMENT. When school refusal caused by separation anxiety is identified during an emergency evaluation, the underlying disorder can be explained to the family, and an intervention can be started immediately. In severe cases, however, a multidimensional, long-term family-oriented treatment plan is necessary. Whenever possible, a separation-anxious child should be brought back to school the next school day, despite the distress, and a contact person within the school (counselor, guidance counselor, or teacher) should be involved to help the child stay in school while praising the child for tolerating the school situation.

When school refusal has been going on for months or years or when the family members are unable to cooperate, a treatment program to move the child back to school from the hospital should be considered. When the child's anxiety is not diminished by behavioral methods alone, antidepressants are helpful. Medication is generally prescribed not at the initial evaluation, but after a behavioral intervention has been tried.

Other Childhood Disturbances

Posttraumatic Stress Disorder. Children who have been subjected to a severe catastrophic or traumatic event may present for a prompt evaluation because they have extreme fears of the specific trauma occurring again or sudden discomfort with familiar places, people, or situations that previously did not evoke anxiety. Within weeks of a traumatic event, a child may recreate the event in play, in stories, and in dreams that directly replay the terrifying situation. A sense of reliving the experience may occur, including hallucinations and flashback (dissociative) experiences, and intrusive memories of the event come and go. Many traumatized children, over time, go on to reproduce parts of the event through their victimization behaviors toward others, without being aware that those behaviors reflect their own traumatic experiences.

Dissociative Disorders. Dissociative states—including the extreme form, multiple personality disorder—are believed most likely to occur in children

who have been subjected to severe and repetitive physical, sexual, or emotional abuse. Children with dissociative symptoms may be referred for evaluation because family members or teachers observe that the children sometimes seem to be spaced out or distracted or act like different persons. Dissociative states are occasionally identified during the evaluation of violent and aggressive behavior, particularly in patients who honestly do not remember chunks of their behavior.

When a child who dissociates is violent or self-destructive or endangers others, hospitalization is necessary. A variety of psychotherapy methods have been used in the complex treatment of children with dissociative disorders, including play techniques and, in some cases, hypnosis.
